THIS book was written primarily as a text for students in the Department of Geodetic Science at Ohio State University, where the author is an associate professor. It is, consequently, an extremely specialized work, and in some parts reads more like lecture-notes than a text-book; for example, it begins uncompromisingly with a 9-page list of symbols. The subjects treated fall into two main divisions: the first, of 130 pages, covers the theory of occultations and solar eclipses, and their geodetic uses, in great detail and with many worked examples; the second division, which occupies some 250 pages, is devoted to artificial satellites and their geodetic applications. The subjects covered here include close-satellite orbital theory, methods of observation, the uses of satellites as 'triangulation points' for geometrical geodesy, and dynamical investigations using satellite orbits. The book ends with a specification for geodetic satellites, and the National Aeronautics and Space Administration *Satellite Situation Report* for September 30, 1963.

The author shows a very wide knowledge of the specialized literature and uses it most judiciously. More than 700 papers are listed in his bibliographies and from these he has extracted and presented the methods he likes best. The result is an excellent introductory text-book in satellite geodesy, comprehensive, up to date and well balanced. Readers should not be deterred by the unhappy blurb on the jacket: the publishers were unwise to associate nationalistic sentiment with a subject which, above all others, is world-wide. Though the book will not appeal to the general reader, those working on the subject will welcome it gratefully as a reference book; and any university which contemplates adding some space-age investigations to its syllabus will find here a ready-made course.

Inorganic Ultramicroanalysis

(International Series of Monographs on Analytical Chemistry, Vol. 15.) By I. P. Alimarin and M. N. Petrikova. Translated by M. G. Hell. (Oxford, London, New York and Paris: Pergamon Press, 1964.) 40*s*.

ULTRAMICROANALYSIS concerns itself with quantities of materials ranging from micrograms to picograms, normal concentrations of reactant solutions being maintained by the use of small volumes of liquid media.

The present monograph collates and systematizes the information on those techniques of inorganic ultramicroanalysis which have been described in the literature since the time of the earlier publications of Benedetti-Pilcher and his colleagues. It does not embrace the radiochemical work of McMillan, Abelson and Seaborg which led to the isolation of minute quantities of the first transuranic elements, neptunium and plutonium. The only mention of radioactive techniques in the book refers to the use of silver-110 and RaE to demonstrate the decrease in the adsorption on the walls of micro-vessels which have been coated with methyltrichlorsilane.

General ultramicro apparatus of capillary type is described in great detail; the use of various microscopes and micromanipulators is illustrated; condenser rods and fibre reactions are demonstrated. Moist chambers, centrifuges, micro-heaters and coloriscopic capillary cuvettes receive comprehensive treatment.

Wilson's qualitative scheme for systematic qualitative analysis is presented in didactic fashion. Micro methods for electrolysis, extraction and ion-exchange separation are lucidly described. Quantitative ultramicroanalysis occupies half the total text of the book. Ultramicro balances of many kinds are described with much theoretical detail, and other techniques for weighing are mentioned briefly. Microtitrations, with either colorimetric or potentiometric endpoints, are described and the amperometric method developed. The volume ends with a concise description of the uses of the Holter–Malmstrom microcolorimeter and of the Beckmann ultramicroanalytical spectrophotometer.

Prof. Alimarin and Dr. Petrikova are to be congratulated on having written an excellent and comprehensive introduction to a subject which is slowly asserting its importance in the fields of research and industrial chemistry. This publication has considerable didactic value and will also be welcomed by lecturers in universities and technical colleges.

D. T. Lewis

Chromatography in Geology

By Arthur S. Ritchie. (Methods in Geochemistry and Geophysics Series.) Pp. viii+185. (Amsterdam, London and New York: Elsevier Publishing Company, 1964.) 50*s*.

THIS slight text of around 50,000 words sails under false colours. It concludes with the statement that "in theoretical geology, chromatographic processes have become recognized as being of the greatest importance"—but all that is said on this topic amounts to no more than three short pages of obscure observations on gels and colloids. A more appropriate title for the book would have been "Chromatography in Inorganic Mineral Analysis", for after introductory chapters on "The Chromatographic Process" and "Chromatographic Techniques" it is with the analysis of soils, minerals and waters that the main section "Applications of Chromatography to Geology" is wholly concerned. It is, however, remarkable that a work concerned with the use of chromatographic techniques in the mineral industry should fail to mention not only the pioneer researches of the late F. H. Burstall and his colleagues at the Chemical Research Laboratory, during the early days of the British atomic energy effort, but also the milliard-dollar uranium industry utilizing the anion exchange resins then introduced. From the point of view of the academic geochemist, the omission of any reference to the importance of chromatographic techniques in recent American studies on palæobiochemistry is equally striking. Perhaps it is understandable that no literature from the U.S.S.R. should be quoted, but to write on the role of gels in mineral genesis without even mentioning Chukrov's Russian-language monograph *Colloids in the Earth's Crust* seems strangely inadequate. The 30-page index which helps to swell the book is for the most part unnecessary.

C. F. Davidson

Annual Rings in Big Sagebrush, *Artemisia tridentata*

By Charles Wesley Ferguson. (Papers of the Laboratory of Tree-Ring Research, No. 1.) Pp. viii + 95. (Tucson: University of Arizona Press, 1964.) n.p.

IT is well known that after felling a woody plant with annual growth rings, it is possible to determine its length of life by counting the growth increments on a transversely cut surface. Experts in dendrochronology can go a stage further, however, for by examining the growth ring pattern in a specimen that has long been dead, they can assess the probable date when it was formerly alive. Furthermore, with proper precautions, the width of successive annual rings can be used to draw conclusions concerning change in climate and ecological conditions as well as about the dates of archæological sites. With these aims in view, the author of this booklet has made an intensive investigation of the annual rings in big sagebrush (*Artemisia tridentata* Nutt.) of the family Compositae, collected from selected areas in the western United States. *A. tridentata* is of special interest because of its capacity to 'invade' areas that are capable of growing, or which have grown, a grass cover. The structure of the plant is of interest to anatomists because of its ability to produce successive rings of interxylary cork in the wood.

C. R. Metcalfe

A COMPARISON BETWEEN THE OLDUVAI HOMININES AND THOSE OF JAVA AND SOME IMPLICATIONS FOR HOMINID PHYLOGENY*

By Prof. P. V. TOBIAS
Department of Anatomy, University of the Witwatersrand, Johannesburg
AND
Prof. G. H. R. VON KOENIGSWALD
Department of Palæontology, Rijksuniversiteit, Utrecht

DURING June 11–13, 1964, we enjoyed the unique opportunity of comparing directly a large selection of Javanese fossil jaws and teeth, as well as a small number of Chinese fossils, with the hominid material discovered by the Leakeys at Olduvai and Natron, Tanganyika. One of us (P. V. T.) had been working at Cambridge for some time on the original African fossils, through the courtesy of Dr. L. S. B. Leakey; the other (G. H. R. v. K.) visited Cambridge from Holland in company with a good number of the Asian fossil originals. Full and free discussion, comparison and measurement took place for three days.

Materials Compared

African: The mandible, parietals, upper molar and sundry additional cranial fragments of the type specimen of *Homo habilis*.

The mandibular fragment, left lower molar, premolar and another dental fragment, from site *BK*I, the lowest living floor in the Olduvai sequence to yield remains of *H. habilis*.

Three unworn, perfectly preserved, isolated teeth of *H. habilis*, and other cranial fragments, found on the same living floor as yielded *Australopithecus* (*Zinjanthropus*) *boisei* (*FLK NI*).

The remains from the lower part of Bed II, namely, the well-preserved mandible with complete lower dentition, as well as parts of left and right maxillæ with 8 upper premolars and molars, and calvaria, of the advanced hominine from *MNK*II.

The teeth of Olduvai 15 and 16, the former of which was reported in paragraph *D* of Leakey and Leakey[1] but not allocated to any taxonomic category, while the latter was provisionally allocated to *Homo habilis*[2]; both of which dentitions one of us (P. V. T.) has since concluded are, in fact, within the range of australopithecine teeth and should therefore not be included with the *Homo habilis* remains.

The mandible of a large-toothed australopithecine from Lake Natron in northern Tanganyika[1].

Casts of a number of South African australopithecine fossils, as well as of the mandible of the Swartkrans hominine ('*Telanthropus*' I).

Asian: The mandibular fragment of *Meganthropus palaeojavanicus* I; a second, unpublished mandibular fragment with two molars, referred to briefly by von Koenigswald[3] and attributed to *M. palaeojavanicus* (*Meganthropus* II).

The Sangiran *B* mandible, classified by Weidenreich[4] as *Pithecanthropus robustus* and by von Koenigswald[3] as *P. modjokertensis*, but included in more recent classifications under *Homo erectus erectus*[5].

The maxilla of '*Pithecanthropus*' IV (claimed by von Koenigswald[3] as a Djetis Beds pithecanthropine).

The 1939 mandible designated by von Koenigswald *P. dubius*[6].

Two groups of teeth assigned by von Koenigswald to *Sinanthropus officinalis*[7] and to *Hemanthropus peii*[8], respectively.

Numbers of other isolated teeth from China and Java, including some thought to have belonged to Peking man.

Observations

(1) *The Lower Bed II Hominine of Olduvai.* The most striking fact to emerge from the comparisons is that the jaws and teeth of the lower Bed II hominine, which had been included as a late paratype of *Homo habilis*[2], are extremely close in morphology to those of *Pithecanthropus* IV and Sangiran *B* (Figs. 1 and 2).

Fig. 1. Right maxilla of Olduvai hominid 13, from the lower part of Bed II, compared with the '*Pithecanthropus*' IV maxilla from Java

Fig. 2. Mandible of Olduvai hominid 13, from the lower part of Bed II, compared with the Sangiran *B* mandible from Java

* Since the two authors do not follow the same classification, we have wherever possible used vernacular names (for example, habiline, pithecanthropine), or names based on type localities (for example, Olduvai Bed II), etc., to designate specimens, or we have stated the synonyms (for example, *Pithecanthropus modjokertensis* (von Koenigswald) 1936, *Pithecanthropus robustus* Weidenreich 1945).

In mesiodistal lengths, the upper and lower teeth of the two forms are almost identical, as Table 1 indicates. However, the Javanese teeth are somewhat broader, in buccolingual diameter.

Table 1

		Olduvai Bed II hominine (Olduvai 13)	Swartkrans hominine ('*Telanthropus*' I)	Javanese hominine (*Pithecanthropus* IV maxillæ and Sangiran *B* mandible)
Maxillary teeth				
P^3	*M–D*	8·3		8·4
	B–L	11·4		12·3
P^4	*M–D*	8·7		8·2
	B–L	11·5		12·0
M^1	*M–D*	12·5		12·1
	B–L	12·6		13·6
M^2	*M–D*	12·8		13·5
	B–L	13·8		15·5
M^3	*M–D*	12·0		10·7
	B–L	13·1		13·8

P_4	*M–D*	8·9		9·0
	B–L	9·8		10·9
M_1	*M–D*	12·7	11·8*–11·9*	12·8
	B–L	11·6	11·5–11·9	13·0
M_2	*M–D*	13·8	13·3–13·6	13·5
	B–L	12·2	12·3–13·1	13·4
M_3	*M–D*	14·6	14·1, 14·1	14·6
	B–L	12·5	12·4, 12·4	12·5

* Shortened by approximal attrition.

Both sets of tooth measurements were made by the same observer (P. V. T.), using the same technique with the same special instrument, on the same occasion. The total mandibular molar length of Olduvai 13 is 41·1 mm, that of Sangiran *B* 40·9; the total mandibular premolar–molar length ($P_4 - M_3$) is 50·0 for Olduvai 13, and 49·9 for Sangiran *B*. Similarly, for the maxillary teeth, the total molar length is 37·3 (Olduvai 13) and 36·3 (*Pithecanthropus* IV), while the total premolar–molar length (P^3–M^3) is 54·3 (Olduvai 13) and 52·9 (*Pithecanthropus* IV).

The dental dimensions for '*Telanthropus*' I are extremely close to those for M_2 and M_3, but M_1 is shortened by approximal attrition. The values for the left and right '*Telanthropus*' I teeth are given in that order in the third column of Table 1.

The Sangiran, Olduvai 13 and '*Telanthropus*' I specimens agree in having M_3 longer than M_2 and M_1, as in the Montmaurin mandible, but in contrast with the dentitions of Choukoutien, Heidelberg and Ternifine. The large talonid, which is so marked a feature of the mandibular premolars of *Homo habilis*, is encountered as well in the Sangiran *B* mandible; on the right P_4 the absolute talonid length is 2·6 mm in Sangiran *B* and 2·8 in Olduvai 13 and the relative talonid length (talonid index) is 2·27 and 2·04 respectively, indicating a relatively bigger talonid in the Olduvai specimen.

Among the differences between the two forms are the greater depth of the Sangiran mandible (34·3 mm at M_1 as against 26·3 in Olduvai 13), the presence in the Asian form of 4 mental foramina but in the African form of only 1, as well as the aforementioned greater breadth of the Asian teeth.

So far as the cranial capacity is concerned, an estimate of the capacity in the Bed II hominine has not yet been obtained; at the same time, we both feel that the capacity of the various pithecanthropine crania should be re-determined, since reconstruction of missing parts of the calvariæ can now be based on better samples of related crania. For the moment, the resemblance between the two specimens rests on dental and gnathic traits.

It has been pointed out elsewhere[9,10] that the Bed II hominine exhibits the same morphological departures from the australopithecine pattern of teeth and jaws, as do the Bed I habilines, but to a more marked degree. In fact, the reduction of tooth size, both of crowns and roots, would seem to have carried the Bed II specimen, Olduvai 13, to a dental size slightly smaller than the corresponding teeth in the pithecanthropine specimens. This applies as well to the body of the mandible and the size and general morphology of the maxillæ. In these respects, the Bed I habilines are less advanced in a hominizing direction than that of Bed II and are definitely more primitive than any pithecanthropine from Java. In the light of the foregoing, we think it wisest to keep the Bed II hominines separate from the Bed I habilines.

Our general conclusion about the Bed II hominine, Olduvai 13, is that, dentally and gnathically, it would seem to represent an African counterpart of the *modjokertensis* or *robustus* grade of hominid organization which occurs in Java. On the basis of the '*Telanthropus*' I mandible, the only '*Telanthropus*' specimen of which a cast has been available to us, it would seem that '*Telanthropus*' fits into the same group: to this extent we would support Simonetta's[11] attribution of '*Telanthropus*' to *Pithecanthropus* and Robinson's[12] attribution of it to *Homo erectus*.

(2) *The Bed I Hominine of Olduvai.* As regards the Bed I *H. habilis*, we are agreed that this represents a distinct taxon, showing an advance over the australopithecine grade of organization, but not yet on the pithecanthropine (*H. erectus*) grade. Morphologically, the Bed. I *H. habilis* appears to be on the hominid line from *Australopithecus africanus* and possibly leading to a pithecanthropine grade of organization.

The Bed I *H. habilis* is certainly more primitive than any of the pithecanthropine fossils from Java. Dentally, there is a resemblance between it and *Meganthropus palaeojavanicus* (Fig. 3). The *Meganthropus* type specimen is somewhat bigger-toothed than the Bed I *H. habilis*. We had before us a further unpublished mandible from Java, attributed to *Meganthropus*, but unfortunately no casts of Marks's[13] specimen nor the recently published pithecanthropine mandible of Sartono[14], both of which were discovered in the Djetis Beds at Sangiran. The tooth measurements given in Table 2 were made by one of us (P. V. T.) on the same occasion, on the type specimen of *Meganthropus palaeojavanicus* (*Meganthropus* I), on the unpublished mandibular fragment (*Meganthropus* II) with 2nd and 3rd molars, and on the type specimen of *Homo habilis*.

Table 2

		Bed I *H. habilis* (range)	Bed I *H. habilis* (type)	*Meganthropus* I (type)	*Meganthropus* II (unpublished)
P_3	*M–D*	9·5–9·9 ($n=3$)	9·6, 9·9	10·1	—
	B–L	9·5–10·3 ($n=3$)	10·3, 10·1	11·7	—
P_4	*M–D*	10·3–11·1 ($n=3$)	10·3, 11·1	9·8	—
	B–L	10·7–11·3 ($n=3$)	10·7, 10·7	11·9	—
M_1	*M–D*	14·3 ($n=2$)	14·3, 14·3	14·8	
	B–L	12·2–12·4 ($n=2$)	12·2, 12·4	13·6	—
M_2	*M–D*	15·6 ($n=1$)	15·6, —	—	14·4
	B–L	13·5 ($n=1$)	13·5, —	—	13·8

For the type specimens of *H. habilis* and *M. palaeojavanicus*, the premolar-molar length (P_3–M_1) is: *H. habilis* 34·2 (left), 35·3 (right); *Meganthropus* I: 34·7 (right), that is, the *Meganthropus* I value is midway between the values for the left and right sides of the *H. habilis* type jaw.

The P_3 in both African and Asian forms has a high crest connecting the buccal and lingual cusps; but the lingual cusp of *H. habilis* is higher than in *Meganthropus*. Both have a well-developed anterior fovea and in both the talonid is well developed. The talonid length in *H. habilis* is 2·6 and in *Meganthropus* 3·2 mm long, giving talonid indices of 2·15 and 1·91 respectively; in other words, the talonid is both absolutely and relatively somewhat longer in *Meganthropus* than in *H. habilis*. The shape

Fig. 3. Mandible of the type specimen of *Homo habilis* from site *FLKNNI*, Bed I, Olduvai Gorge, compared with the type specimen of *Meganthropus palaeojavanicus* from Java

indices (L/B per cent) are 93·2 (left) and 98·0 (right) in *H. habilis* and 86·3 in *Meganthropus*.

In both forms, P_4 has very similar cusps. Both have a long talonid, measuring in mesiodistal extent 3·8 in *H. habilis* and 3·5 in *Meganthropus*, giving very similar indices of 1·63 and 1·71 respectively. The talonid of *H. habilis* is more distally situated, that of *Meganthropus* is slewed around to a more distolingual position. The shape indices are 96·3 (left) and 103·7 (right) in *H. habilis* and 82·4 in *Meganthropus*.

The first molars are very similar in cusp pattern and both have an anterior fovea, but the M_1 of *H. habilis* is appreciably narrower in buccolingual diameter than its homologue in *Meganthropus* (L/B index in *H. habilis* is 117·2 on the left and 115·3 on the right; in *Meganthropus* 108·8).

The shape indices show that the teeth of *H. habilis* are more markedly elongated and narrowed than those of *Meganthropus*; in fact, the *H. habilis* indices for all three teeth fall completely outside the range of indices for 21 australopithecine P_3's, 20 australopithecine P_4's and 31 australopithecine M_1's, save for one Sterkfontein tooth (*Sts* 24), which has a higher index than the right M_1 of *H. habilis* but not as high as the left M_1.

Robinson[15,16] has suggested that *Meganthropus* is simply an australopithecine. While we agree with him in respect of the African (Garusi, Tanganyika) specimen assigned to *Meganthropus africanus*, we feel that *Meganthropus* of Java shows certain advances over the australopithecine grade of hominid organization. Most striking is the posterior surface of the symphyseal region which is well preserved in the type specimen of *Meganthropus*: the structure is plane with small genial tubercles. There is no deep pit nor massive inferior transverse torus as in the Natron jaw and the large *A. robustus crassidens* (*Paranthropus*) jaws. In this respect, the surface of the post-symphyseal region in *M. palaeojavanicus* strongly resembles that in the pithecanthropines (*Homo erectus*) of Asia and Africa. The somewhat reduced tooth roots are reflected in the relatively high position of the mental foramen, which is just nearer the top edge than the lower edge of the corpus mandibulæ; whereas in *A. robustus* and *A. boisei* it is nearer the lower edge. For example, if we express the projection height of the foramen from the upper edge of the mandibular body as a percentage of the total projection height, we obtain a value of 54·3 per cent in the Natron (australopithecine) jaw; whereas in *Meganthropus* I the value is 49·5 and in an obviously more hominized specimen, namely, that of the Bed II Olduvai 13, the value is 45·9. A further expression of the smaller tooth-roots in *Meganthropus* I is the lesser robusticity of the alveolar portion[7] of the mandible: the most robust part is the lower margin (torus marginalis), whereas in the Natron jaw as well as the large *A. robustus* jaws from Swartkrans, the alveolar portion is far more robust, whereas the lower margin is much less massive, giving a characteristic tapering section from the alveolar girth above to the marginal girth below.

Our feeling about *Meganthropus palaeojavanicus* is that, while it has some strong australopithecine resemblances, it shows several features in which it is somewhat advanced beyond the australopithecine grade of organization. In this sense, it stands in relation to *Australopithecus* as does *Homo habilis*, except that *Homo habilis* has departed further in some respects, such as dental reduction and elongation.

(3) A further parallel between the Asian and African fossils is provided by the more advanced pithecanthropines of the Trinil Beds and of Choukoutien, on one hand, and those of north-west Africa (*Atlanthropus*) and of the upper part of Bed II, Olduvai ('Chellean Man') on the other.

Conclusions

It would seem to us that four grades of hominization can be recognized in the African and Asian sequence of the Lower and early Middle Pleistocene:

1st Grade: *Australopithecus* in South and East Africa; ? in Asia.

2nd Grade: *Homo habilis* in Africa; ? *Meganthropus* in Asia.

3rd Grade: Olduvai 13 and the Swartkrans hominine ('*Telanthropus*') in Africa; the Sangiran *B* mandible and *Pithecanthropus* IV in Asia.

4th Grade: 'Chellean Man' and *Atlanthropus* in Africa; the Trinil Beds hominid (*P. erectus* or *Homo erectus erectus*) and the Choukoutien hominid (*P. pekinensis* or *Homo erectus pekinensis*) in Asia.

There is as yet no general agreement as to the taxonomic status which should be accorded these grades. The 2nd grade is best represented by the Bed I *H. habilis* material, since no cranium or maxilla of *Meganthropus* is known for sure. One of us (G. H. R. v. K.) thinks that this grade should be accorded separate generic or subgeneric status; Leakey, Tobias and Napier[2] have proposed separate specific status within the genus *Homo*; while yet others have proposed either in discussion or in writing (D. R. Hughes, *The Times* of London, June 10, 1964) that sub-specific status within the species *Homo erectus* should be accorded the *H. habilis* remains, that is, that they become *Homo erectus habilis*.

As for the 3rd grade, some have given the hominid represented by *Pithecanthropus* IV and Sangiran *B* separate specific ranking within the genus *Pithecanthropus* (*P. robustus* or *P. modjokertensis*). On the other hand, in one of the most recent classifications[5], it has been lumped into the same sub-species as the Trinil Beds hominid, that is, *Homo erectus erectus*.

We do not propose here to enter into a discussion of the taxonomy of the 4th grade of hominization.

Thus, from the 2nd grade onwards, there are remarkable parallels between the Asian and African sequences. However, we remain unconvinced that there is as yet any unequivocal evidence pointing to the presence in Asia of a frankly australopithecine grade of organization. Simons[17] has suggested that the teeth designated *Hemanthropus peii*[8] are australopithecine. It is not impossible, too, that they may represent the 2nd (habiline or meganthropine) grade of post-australopithecine differentiation; we should feel much happier to have such teeth in a mandible or cranium before accepting either proposition.

This work was supported by the Wenner-Gren Foundation for Anthropological Research, the South African

Council for Scientific and Industrial Research and by the Boise Fund.

METEOROLOGICAL FACTORS IN RADIOCOMMUNICATIONS AT VERY SHORT WAVE-LENGTHS*

By Dr. R. L. SMITH-ROSE, C.B.E.

Past President, International Scientific Radio Union; Secretary General, Inter-Union Commission on Frequency Allocations for Radio Astronomy and Space Science

THE history of the development of radiocommunications shows that there has been a constant interchange between the mathematician or theoretical physicist and the engineer keen on achieving rapid practical results. It is also of interest to note the manner in which the various portions of the electromagnetic wave spectrum have been exploited for communication and other practical aims. The classical laboratory work of Heinrich Hertz on the physical properties of electric waves was carried out at frequencies of a few hundred megacycles per second. In 1896 Marconi demonstrated the transmission of waves of 1,000 Mc/s (corresponding to a wave-length of 30 cm) over distances of a few kilometres. However, the practical use of such short waves did not at the time appear very promising; and in the endeavour to increase the range of transmission, more power had to be supplied to an antenna system of greater height and length, resulting in the generation of waves of lower frequency. The successful achievement of communication over thousands of kilometres greatly surprised those theoretical workers who had assumed that diffraction was the only mechanism by which such waves could overcome the curved surface of the Earth. For the next quarter of a century, the world's radiocommunications were developed at wave-lengths corresponding to the medium- and high-frequency portion of the spectrum (300 kc/s–30 Mc/s). As has long been well known, the propagation of such waves over all but the shortest distances—up to, say, 100 or 200 km—is determined by reflexion from the ionized regions of the Earth's surface.

About 1916, the practical possibilities of transmitting and receiving waves at frequencies of about 50–100 Mc/s were being explored. Again, it was considered that since waves of such frequencies were unlikely to be efficiently reflected from the regions of the ionosphere, the range of transmission would be limited approximately to the optical horizon distance. But once more it was found by practical experiment that the range of transmission could exceed such a distance. and, furthermore, that the amount of this excess varied with atmospheric conditions which themselves depended on season, time and portion of the world in which the experiments were conducted. These effects were encountered to a more marked extent as investigations carried the frequencies used from hundreds to thousands of megacycles per second. Since it was now clear that the ionization of the atmosphere could have little effect in determining the path of waves of such very high frequencies, it was necessary to examine more closely the normal physical properties of the troposphere—temperature, pressure and especially the humidity —in order to explain the phenomena which accompany the propagation of such waves over various distances beyond the normal horizon.

In this way began that portion of the science of radiometeorology, which is concerned with the influence of meteorological conditions on the propagation of radio waves, and particularly on practical radiocommunications. By about 1930 there was experimental evidence sufficient to indicate that radio waves of frequencies in excess of 50 Mc/s could be received at distances well beyond the optical horizon of the sending antenna. When the transmission was over a land path, it was affected by diffraction over hills as well as by refraction in the atmosphere. For cases in which the transmission was over a sea path, the changing atmospheric conditions could result in variable refraction effects with accompanying variations in received signal strength. In particular, it was found that for transmission over sea in warm climatic conditions, such as prevail in the Mediterranean area or the Indian Ocean, the bending of the waves could approach, and even exceed, the curvature of the Earth; and result in what became known as 'abnormal propagation' conditions. Such phenomena of super-refraction have been the subject of extensive research in many parts of the world, but they form part only of the general influence of meteorological conditions on the propagation of waves of very- and ultra-high frequencies and above, and their application to radiocommunication problems.

Propagation of Radio Waves by Tropospheric Refraction

In 1893, Lord Rayleigh considered the problem of the refraction in the Earth's atmosphere of incoming rays of light from stars and other celestial bodies. It has thus been known throughout the history of radio development that the atmosphere can act as a refracting medium for electromagnetic waves passing through it; but this phenomenon was not of any great significance in the use of frequencies below 30 Mc/s. As already mentioned, experimental evidence of such refraction became available in about the 1930's when several radiocommunication links were established in various parts of the world on frequencies of about 40 Mc/s and above, and over distances that were well beyond the limits of the geometrical horizon. In the following decade, the exploitation of frequencies up to several thousand megacycles per second, for both radar and communications, provided ample evidence of similar long-distance transmission around the curved surface of the Earth.

(*a*) *Standard tropospheric wave propagation.* For the past decade or more the propagation of radio waves of

* Substance of a lecture given at the NATO Summer School on Radiometeorology at Lagonissi, Greece, on September 10.

frequencies between 30 and 30,000 Mc/s has been investigated by scientists and engineers in various parts of the world; and the resulting experience has been co-ordinated by the appropriate international radio organizations—URSI (the International Scientific Radio Union) and CCIR (the International Radio Consultative Committee)—in collaboration, as appropriate, with WMO (the World Meteorological Organization). As a result, there has been a large measure of international agreement on the description of the Earth's atmosphere, under what is conveniently termed standard and non-standard conditions (see ref. 8).

The refracting properties of the Earth's atmosphere may be expressed by the parameter 'N' in the following expression:

$$N = (n - 1)\,10^6 = \frac{77{\cdot}6}{T}\left(p + 4810\frac{e}{T}\right) \qquad (1)$$

where n = refractive index of the air, T = absolute temperature (° K), e = water vapour pressure (mbar), p = atmosphere pressure (mbar).

Under all conditions normally encountered in the lower atmosphere, the value of n is a few hundred parts in a million greater than unity. While this absolute value of the refractive index is not of great importance in radio wave propagation, it is now well established that small variations in its value, even of one or two parts in a million, may be a determining factor in the phenomena associated with the transmission of waves through the troposphere. Hence the use of the symbol N as a unit, in terms of which the variations of atmospheric conditions are conveniently expressed.

When considering the path of radio waves transmitted between any two points, it is necessary to realize that the refraction occurs relative to a curved Earth. Hence it had become the practice among scientists and engineers working in this field to make use of a 'modified refractive index', defined as the sum of the refractive index for a given height above sea-level and the ratio of this height to the radius of the Earth. It is convenient to make use of this modified index in terms of a refractive modulus, M, the unit of which is one million times the amount by which the modified refractive index exceeds unity. Thus:

$$M = \left\{(n - 1) + \frac{h}{a}\right\} \times 10^6 \qquad (2)$$

For international research in this field of tropospheric wave propagation, it is furthermore convenient to define for reference purposes a standard radio atmosphere as one in which the refractive modulus, M, varies uniformly with height above the Earth's surface. The gradient of this modulus, which is considered as normal for a well-mixed atmosphere, has a value of 0·12 M units/m (equal to 3·6 M units/100 ft.). In the past, it has been found convenient to associate normal refraction conditions with a standard atmosphere having this gradient of modulus of refractive index; and it has been customary to simplify the calculations by using an effective radius of curvature of the Earth of 4/3 times the actual radius.

More recent research, however, has led to the definition of a 'basic reference atmosphere' in the following form:

$$n(h) = 1 + \{289 \times 10^{-6} \exp(-0{\cdot}136h)\} \qquad (3)$$

where h is the height above sea-level (km). It is to be noted that the refractive index in the first kilometre of such a basic reference atmosphere is very nearly equal to that in an atmosphere corresponding to an Earth of effective radius of 4/3 the actual or geometrical radius. The use of the exponential relationship (3) is more appropriate for the calculation of field strengths under practical conditions, and it has the added advantage of being more accurate when the height of either sending or receiving stations is greater than 1 km.

In later research, it has been observed that the variations of the mean values of the refractive index of the atmosphere may often be approximately represented by the general exponential formula:

$$n(h) = 1 + N_s \exp(-bh) \times 10^{-6} \qquad (4)$$

in which, as before, $N = (n - 1) \times 10^6$ and the subscript s refers to the values at the surface of the Earth, h is the height above the Earth in kilometres, and b is determined by the relation:

$$\exp(-b) = 1 + \Delta N/N_s \qquad (5)$$

where ΔN (a negative quantity) is the difference between the values of N at the surface of the Earth and 1 km above it.

Some investigations have shown that ΔN is in general correlated with the surface value N_s, and typical values according to climate have been deduced as follows:

$\Delta N = -7{\cdot}3 \exp(0{\cdot}0056\,N_s)$ in the United States.
$-9{\cdot}3 \exp(0{\cdot}0046\,N_s)$ in the Federal Republic of Germany.
$-3{\cdot}9 \exp(0{\cdot}0072\,N_s)$ in the United Kingdom.

These formulæ are useful for estimating values of ΔN in cases where only surface meteorological data are available.

(*b*) *Non-standard wave propagation.* It has been assumed here that the Earth's atmosphere is a well-mixed medium, which results in a steady and uniform refraction of radio waves transmitted through it. Many years of practical experience have shown that radio waves are often transmitted to distances well beyond the range to be expected from the assumption of a standard atmosphere. Sometimes in such cases reception is fairly steady; but in other cases the strength of the received signals varies between wide limits. Experience with radio sounding balloons has shown that there are times when sudden changes in atmospheric conditions can result in the formation of a reflecting layer, so that in extreme cases the radio waves are in effect trapped in a wave-guide formed by the layer and the Earth's surface. The existence of such a stable and super-refracting layer at an appropriate height in the atmosphere can thus give rise to a marked increase in signal strength and range of reception. Conversely, on other occasions the atmosphere may be below standard in its refracting properties, and the range of reception is then reduced to that determined by rectilinear propagation. In many cases, the waves arrive at the receiver by more than one path with the accompaniment of interference effects and variation of the resulting signals.

Extensive investigations have been conducted in various parts of the world on the phenomena referred to here as 'super-refraction'. For the condition of partial or total reflexion, it is necessary to have a well-defined and widespread layer with marked changes in refractive index at its boundaries. The coefficient of reflexion increases, first, with the difference in the vertical gradient of refractive index inside and outside the layer; and secondly, with the thickness of the layer in relation to the wavelength of the radiation passing through it. For true reflexion conditions to prevail, there must be marked changes in atmospheric conditions within a height range that is not too large compared with the wave-length. Such considerations have been used to explain the transmission of radio waves in the metre and decimetre wavelength range (30–3,000 Mc/s), and the accompanying reception of unusually strong signals at exceptional distances. This extended range of reception is usually confined to the existence of stable anticyclonic meteorological conditions over the whole of the radio path, and is not acceptable for reliable radiocommunication. While these effects have on occasions in the past been useful in extending the range of detection of some radar systems, in more recent years they have been the cause of interference between television broadcasting systems. Stations which share the same frequency channel, and are separated

by a distance well outside their joint service areas, are occasionally subject to mutual interference due to abnormal propagation conditions over the path between them.

Propagation by Diffusion in a Stratified Atmosphere

For some years past the amount of experimental work on the propagation of radio waves in the metre and centimetre wave-bands has been rapidly accumulating; and in spite of attempts made by both the experimental and theoretical workers to explain their results, it became clear that neither of the simplified conceptions described here was entirely satisfactory. In particular, the rapid and variable fading of the received fields was not easily reconcilable with transmission through either a turbulent and well-mixed atmosphere, or one in which there was an extensive and stable 'wave-guide' formation. Furthermore, it is only in some parts of the world and at certain seasons of the year that the conditions in the lower atmosphere associated with anticyclones can be found to prevail sufficiently to explain the observed results of the radio transmission experiments.

A more detailed examination of the structure of the troposphere, aided to a considerable extent by the knowledge contributed by radio-soundings, shows that it is in general characterized by stratification accompanied by changes in refractive index of several N units. In typical cases, the horizontal dimensions of such layers may be about 1–3 km, with a thickness of 10–20 m, in which the changes in refractive index may have a mean value of 10 units. The thickness of such a layer may change by several metres along its length, with a corresponding change in N of 1 or 2 units in the layer. By examining the thermodynamics of the atmosphere, it seems reasonable to conclude that in place of the simple conditions of turbulence or no-turbulence, the atmosphere comprises both stable stratification and unstable layers. In certain cases, a systematic turbulence can result from thermal convection—perhaps resulting in the existence of several layers. In other cases, the motions of the air result in the formation of eddies or whirlpools within the stratified air. These conditions may, in general, exist simultaneously, so that one may obtain efficient transmission by refraction at the various layers accompanied by fading due to interference effects between waves arriving by different paths, or as the result of transmission through a turbulent atmosphere. Among the difficulties of the experimenter in this field is that of separating the variations in field strength with time from the spatial variations of the diffused signal, which is generally the integral of a number of component fields arriving by different paths and thus with varying differences in phase. Some scientists have attempted an experimental analysis by using a concentrated beam of radiation, which can scan the refractive medium through which the waves are transmitted. For a full exploitation of this technique, scanning in both vertical and horizontal directions would appear to be desirable, and the results displayed on suitable time bases at the receiver. When one considers that such investigations should be accompanied by the simultaneous use of the radio-sonde technique, the complexity of the whole problem is realized.

Propagation Curves for Frequencies between 40 and 1,000 Mc/s

In the preceding sections, reference has been made to the attempt to define the characteristics of the Earth's atmosphere in such a manner as to elucidate the mechanism determining the propagation of radio waves through this atmosphere. Concurrently with this research, extensive investigations have been made in various parts of the world of the experimental facts concerning the field strength of radio waves arriving from sending stations both within and beyond the horizon distance. There is a considerable amount of scientific and technical literature describing the results of such investigations (see refs. 1–10). In view of the need, however, to give practical guidance to the radio engineer concerned with the planning of communication systems including the sound and television broadcasting services, the appropriate international organization—the CCIR, to which reference has been made earlier—has co-ordinated the available material and issued its conclusions and recommendations[8].

These take the form of a series of curves showing on a statistical basis the field strength to be expected under a variety of conditions over distances up to 1,000 km from a sender radiating 1-kW effective power from a half-wave dipole. In the main recommendation (No. 370/1963), the curves were prepared from data obtained mainly in the United States and in Western Europe; and since many more measurements were made for distances up to about 500 km than above, the curves have their greatest reliability within this range. The recommendation already referred to should be read in conjunction with the contemporary *CCIR Report* (No. 239/1963), which describes the details of the construction of the curves, and the manner in which their interpretation depends on distances within or beyond the horizon, the influence of irregularities in the terrain, and the effect of transmission over a mixed land and sea path. The following *Report* (No. 240/1963) contains separate sets of curves, which have been drawn up on the basis of the somewhat limited data relating to the very varied conditions which prevail in the African continent, an area of rapid future development of radio and broadcasting services. For convenience, Africa has been divided into six regions, each corresponding to a fairly well-defined type of climate, ranging from temperate, sub-tropical (continental and maritime) to desert.

In all cases (Recommendation 370, and *Reports* 239 and 240) the sets of curves recommended for provisional use relate to two bands of frequencies, namely: (*a*) 40–250 Mc/s, and (*b*) 450–1,000 Mc/s. The individual curves apply to reception on a dipole antenna at a standard height of 10 m above ground, from transmitting antennæ at heights ranging from 37·5 to 1,200 m above the average level of the ground at distances between 3 and 15 km from the transmitter. Since the effect of irregularities of the terrain over which the waves are propagated is of greater importance at the higher frequencies, some guidance is given in the Recommendation (No. 370) on the estimation of the effect of such irregularities.

The curves are presented on a statistical basis, and show the field strengths to be expected at 50 per cent of the receiving locations, and for 50, 10 and 1 per cent of the time, respectively. In the case of transmission over land paths, the curves apply to temperate climatic conditions as encountered in parts of Europe and North America. As already mentioned, separate sets of curves are presented for the extreme conditions encountered in the African continent (*Report* 240). For propagation over sea, the relevant curves are applicable mainly to the North Sea area. In parts of the world, such as the Mediterranean and Gulf of Mexico, the received field strengths may exceed the value given in the curves, by amounts up to 20 dB at the lower frequencies, and by lesser amounts for shorter periods at higher frequencies.

While these curves represent the considered conclusions of experienced representatives from many countries interested in radiocommunications, it must be emphasized that the recommendations concerning their use should be considered as tentative pending a fuller understanding of the effect of meteorological conditions on the propagation of radio waves through the very varied atmospheric conditions encountered over both land and sea areas throughout the world. At successive assemblies of the experts at the international meetings of both URSI and CCIR, every attempt is made to co-ordinate the results

of further research, and to carry out the corresponding amendments to the recommendations on the application of the most recent knowledge to communication problems.

Influence of Atmosphere on Wave Propagation Curves

The preceding section summarizes the work done by the radio engineer in co-ordinating the results of field strength measurements on an international scale. Similar action was clearly necessary on the part of the meteorologists in presenting their conclusions on the relevant parameters of the atmosphere which may be used to adjust the estimates of field strength to any prevailing conditions throughout the world. In another *Report* (No. 233/1963), the CCIR has presented the results of an investigation of the correlation between propagation beyond the horizon and radio-meteorological parameters. For many years past, numerous measurements in temperate countries have taken into account the variation of refractive index with height above the Earth's surface. These have led to a steadily improving understanding of the bending of radio waves transmitted through the troposphere and of the resulting effect on the field strength obtained at a receiver from a distant transmitter beyond the normal optical range. While it is always desirable to have as complete knowledge as possible of the vertical gradient of refractive index of the atmosphere, experience suggests that for radiation at low angles of elevation above the horizon (less than 3°) the surface value of the refractive index may be a more useful parameter to apply than the vertical gradient of this index. Such a conclusion is, however, to be accepted tentatively pending the results of further research on a world-wide scale on the whole problem of the dependence of radio transmission on meteorological conditions in the troposphere. As an interim measure, therefore, the *CCIR Report* 233 already referred to contains a series of world-wide charts both for the index at the surface and for its vertical gradient, drawn up on the best information available for different times of the day, at each season of the year.

(*a*) *Refractive index at sea-level* N_0. The parameter N has been defined in equation (1) as a convenient unit representing the refractive index of the atmosphere in terms of its temperature, pressure and water vapour content. It is well known that the value of N decreases systematically with altitude; and therefore to avoid confusion between variations of N due to the altitude of an observatory and those due to climatology, it is desirable to reduce the value of N measured at the surface of the ground to the corresponding value N_0 at sea-level. This can be done on the assumption that the exponential relationship described by equation (4) is sufficiently representative of conditions over the range of heights required. Using a limited amount of meteorological information from more than three hundred stations in various parts of the world, values of N_0 were calculated from the formula:

$$N_0 = N_s \exp(0{\cdot}106h) \qquad (6)$$

From this relationship two world-wide contour charts have been prepared showing the mean values of N_0 for the representative months of February and August, and a third chart shows the contours of the yearly minimum monthly mean value of N_0. Owing to the limited number of locations for which measurements were available, the overall accuracy of these charts is of the order of several N units. In some areas, such as the United States, where most accurate and detailed observations have been made, the probable accuracy is correspondingly greater.

(*b*) *Charts of* ΔN. During the general investigation of the influence of radiometeorological phenomena on wave propagation through the troposphere, numerous measurements in temperate countries have taken into account the variation of the refractive index with height. To simplify the problem, the atmosphere has been represented by the difference $\Delta N \times 10^{-6}$ between the refractive index at a height of 1 km and the index at the ground. In a number of instances, theory and experiments agree in showing the existence of a correlation between the variations of the radio field strength observed and the quantity ΔN. While such a correlation has been demonstrated in temperate countries only, and on the basis of weekly or monthly median values, it has been considered worth while to prepare a series of 32 charts for certain areas in both the northern and southern hemispheres and for representative months and times of day (ref. 8). The main purpose of such charts is to indicate the wide variations of radioclimatology likely to be encountered throughout the world; at the same time, they do provide values of ΔN with an accuracy of the order of 5 N units. The general considerations embodied in these charts of values of N and ΔN may be applied to the field strength curves drawn up for the various parts of the African continent referred to in an earlier section.

Future Research in Radiometeorological Relationships

The previous sections have explained the manner in which the meteorologist's description of the lower atmosphere has proved useful to the radio engineer concerned with communications involving the propagation of waves through the troposphere. In so far as statistical results are useful to the engineer, and it must be said that they are most suitable for the planning of international communication services, then a detailed knowledge of the surface values of refractive index, in the form of the parameter N_s, meets the engineer's first requirements. If this information can be supplemented by a knowledge of the gradient of the index, ΔN, between arbitrarily chosen heights of the order of 1 km, over the path in which he is interested, then the communication engineer is grateful. He would be glad to encourage those who are adding to our knowledge of the value of ΔN under a variety of conditions by radiosonde measurements and radar soundings.

But it is to be noted that the radiometeorologists are not entirely agreed concerning the nature of the gradient of the refractive index of the air in the first kilometre or so of the atmosphere. An alternative equivalent gradient has been proposed and defined as that linear decrease of the index with height which would produce the same amount of ray bending as the actual inhomogeneous atmosphere existing over a given radio transmission path. Altogether it is well for the engineer to understand that the meteorologists may have some misgivings if a too-wide application of apparently good correlations between surface index and radio field strengths are accepted for general use. But the radio engineer has a wealth of practical experience of his own past achievements to guide him; and the main assistance he is seeking from the meteorologist is in the extension of this experience into the future and particularly into other areas of the world, where no radio experience is available, and where only limited surface meteorological measurements have so far been possible. To some extent the matter is complicated by the meteorologist's description of the atmosphere as a combination of stable layers and turbulent conditions; the proportions and extent of these clearly vary to a major degree with time and portion of the Earth under consideration. It is therefore to be hoped that the meteorologist will persist in his endeavour to understand more clearly the vagaries of our atmosphere, and will periodically produce improved guidance for the radio engineer in his endeavour to improve the world's communications services to the utmost extent required by our constantly expanding civilization. This is clearly a matter not only for collaboration between research workers in different faculties, but also for the closest

possible international collaboration among the scientists acquiring steadily advancing knowledge and the engineers who have the responsibility of applying this knowledge to useful ends.

SEALS

IN view of the considerable amount and variety of research carried out on seal biology during recent years a symposium was held in the Zoology Department, University of Cambridge, on September 9, under the auspices of the Grey Seals Consultative Committee, a body set up jointly by the Nature Conservancy and the Development Commission. The symposium was divided into two halves, the morning being devoted to those species of seal which are the object of a 'fishery' and the afternoon to the population structure, reproduction and behaviour of the grey seal, *Halichoerus grypus*.

The morning session was opened by Dr. E. B. Worthington, scientific director of the Nature Conservancy and chairman of the Grey Seals Consultative Committee. Following this, Dr. L. Harrison Matthews and Dr. R. M. Laws gave brief but compendious accounts of seals in relation to mankind in many parts of the world. Dr. Harrison Matthews discussed the various species which are subject to commercial exploitation; they are now those which gather in herds during the breeding season so that large numbers can be killed economically for oil, fur and leather; only in primitive communities is the flesh utilized. In many species, notably the Antarctic fur seals, exploitation has been controlled merely by economics; it was unregulated until the seals became so scarce that there was no longer any profit in hunting them. Then the fishery ceased and the numbers fortunately recovered. Yet, as he pointed out, most species are admirably adapted for economic exploitation combined with conservation of stocks. They are polygamous, so that there is an excess of bulls which can be cropped without reducing the breeding stock and a management policy on this basis has been strikingly successful in the Aleutians. Dr. Laws followed with a paper on the future prospects of seals as a natural resource, their interaction with fisheries and the possibilities of conservation. He thought all the various species would continue to be cropped, partly because they are valuable to man in various ways and partly also because in some areas and in some circumstances they are competitors with man for fish. Although he thought it likely that the value of fur and of oil would diminish he foresaw that the human population explosion would stimulate the cropping of seals for meat and would also be unfavourable to animals competing with man for fish. Accordingly, he saw no hope for a simple policy of protection and made a strong plea for a management policy of rational exploitation based on reliable information about seal populations. He contrasted the success of this policy in the case of the northern fur seal with the dangers of unregulated cropping as already demonstrated in several species of seal and, of course, scandalously apparent in whaling.

Six papers then followed on different species of seal. Three of them, one from New Zealand and two from the United States, were tape recordings and, although this was no real substitute for the presence of the authors in person, they did extend the interest and scope of the meeting. Mr. M. R. Smith of the University of Canterbury, New Zealand, gave an account of work on the population of Weddell seals in the McMurdo Sound in Antarctica; it was a progress report, but this work is clearly basic and fundamental, for this is a species which has not been and may never be exploited. Mr. F. O'Gorman gave an account of the numbers and distribution of the southern fur seal in South America, and was followed by a recorded talk by Drs. F. Wilke and V. B. Scheffer of the U.S. Fish and Wildlife Service on research under the Fur Seal Treaty. They told a remarkable and hopeful story, for although the Japanese denounced the 1911 Convention (which saved the Pacific fur seal from extinction and enabled stocks to recover) in 1941, because they feared the effect of the seals on their fisheries, and the nations concerned could not agree on a new treaty, they did in 1957 sign an interim convention which provides, among other things, for co-operative research. The speakers showed how fruitful this research is in providing a basis for management and were able to record that the seal population is growing steadily although an annual crop is taken. Mr. W. N. Bonner discussed the utilization of elephant seals in South Georgia. A crop of 6,000 adult bulls is taken annually and it seems that the stock can stand this rate, but only the skin and blubber are utilized. Mr. Bonner gave an account of the various attempts made to utilize the whole carcass and the difficulties that have been encountered. This paper was followed by another recorded talk, by Dr. D. E. Sergeant on Canadian research on harp seals in the north-west Atlantic. His investigation of the population dynamics of this species has shown that it is being over-exploited and has indicated the level at which the annual crop should be set.

The final paper of the morning was by Dr. A. W. Mansfield on the influence of pinnipeds on the fisheries of eastern Canada. This was a long paper discussing the status of four species of seal in the Gulf of St. Lawrence, the harp, hood, harbour or common, and grey. All species incur the enmity of fishermen as competitors for fish, but the first two are the basis of the sealing industry and have been over-exploited. A bounty is paid for the destruction of the harbour seal, but the population of grey seals is not great and the bounty is restricted to those caught in the Miramichi—the great salmon river of New Brunswick. He gave details of the diet of various species, but it is clear that many more are needed before the true effect on fisheries of seal populations can be assessed. He dealt at length with the problem of 'cod worm', a nematode found in the flesh of cod and other gadoids, the adults of which are found in the stomachs of various species of seal. This is also a growing problem in the north-east Atlantic.

The afternoon session was limited to studies of the grey seal, *Halichoerus grypus*, the species which has been the subject of so much controversy in recent years.

Prof. H. R. Hewer and Dr. K. M. Backhouse discussed the exceptional breeding-cycle. In Great Britain the young are born in the autumn and mating occurs shortly afterwards, but the implantation of the embryo is delayed and does not occur until the spring. In Canada and the Baltic the young are born in the spring and the relation between breeding season and gonad development is interesting but obscure. Prof. Hewer went on to discuss the life table which he has recently published[1], and showed that more material now available made little difference to it. This is clearly of great importance for a conservation policy. Dr. J. C. Coulson outlined the social breeding of the grey seal as exemplified on the Farne Islands and other breeding grounds around the coast of the British Isles. He showed that some degree of overcrowding (to our way of thinking) appears to be 'voluntary', and of the various hypotheses advanced to explain this phenomenon he strongly favoured Prof. V. C. Wynne-Edwards's view that this is a mechanism for population control. This is exciting ecology, and many of us were glad to be able to study it further in his joint paper with Mrs. G. Hickling[2]. A paper by Dr. J. Morton Boyd on the mortality of pups on North Rona gave some support to this theory, for it looks as if crowding is a potent factor in causing infantile mortality, and the audience clearly shared Dr. Boyd's hopes for a more intensive study of seal behaviour on this remote islet. Mr. E. A. Smith's observations on the effect of human interference on grey seal colonies added a good deal to our knowledge of the seal problem, particularly by showing that the mother–young relation is not so exclusive as had been postulated. Cows will suckle pups other than their own and pups will suck from females other than their mothers. Human interference, whether it be by hunting or merely by observing, of course also has its effect on colonies, but the impression left on one hearer at least was that seals soon get used to man as part of their environment, as indeed do most other animals. Mr. Oliver Hook gave an account of his explorations in the Baltic Sea in search of grey seals, and it was interesting to hear that there they breed on the ice in spring as they do in Canada and not on shore in the autumn as they do around Britain. It was also interesting to hear that in both Finland and Sweden in the interests of fisheries a bounty is paid for killing seals, and while the value of this to fisheries is uncertain it has enabled a certain amount of biological data to be obtained. Finally, Mr. H. G. Hurrell gave a fascinating account of the mental abilities of his tame grey seal 'Atlanta'. She is clearly an animal of great intelligence, and his account showed how much can be learned by establishing friendly relations with an animal and studying its behaviour as a companion and a pet. As in all good symposia, there was too little time for formal discussion, though Dr. Fraser Darling and Dr. Laws made some valuable points, especially that true conservation seldom implies complete protection. Fortunately the arrangements permitted informal talk, in some cases until the early hours of the morning, and there is no doubt that every one present benefited greatly. The seal problem was put into perspective. Over most of the world, commercial exploitation of stocks is taken as a matter of course, and if left to be governed by economic forces it will in the end be disastrous. But conservation is quite consistent with exploitation, and further research into the biology and ecology of these large mammals will clearly enable us to reconcile these two aspects with increasing efficiency.

NEWS and VIEWS

The Grassland Research Institute: Dr. W. Davies, C.B.E.

Dr. W. Davies, director of the Grassland Research Institute at Hurley, near Maidenhead, since its inception in 1949, retired in September 1964. Dr. Davies, who was born in London in 1899 of North Cardiganshire farming stock, was educated at Sloane School and at the University College of Wales, Aberystwyth, where he gained B.Sc., M.Sc., and D.Sc. degrees. In 1923 he was appointed grassland agronomist at the Welsh Plant Breeding Station, Aberystwyth, under Sir George Stapledon, a collaboration that by 1939 had established the Station as a grassland centre of international repute. This owed much to the extensive travels which Dr. Davies made to many countries, visits which gave him his unrivalled knowledge of world grasslands, and at the same time made workers in these countries aware of the unexploited potential in their own grasslands. In 1940 Dr. Davies moved with Stapledon to Stratford on Avon, where the Grassland Improvement Station was set up to investigate how best the mainly derelict grasslands of Britain could contribute to wartime food production. This work was consolidated in 1949, when the Ministry of Agriculture and Fisheries (as it was then called), in association with the Agricultural Research Council, established the Grassland Research Institute at Hurley with Dr. Davies as its first director. Here he was able to develop his thesis that grass is a crop being grown to feed animals and must, therefore, be studied as a soil/plant/animal complex; the impact of this thesis on world grassland thought became clear from the papers presented at the eighth International Grassland Congress held at Reading in 1960. His eminence in the sphere of international co-operation in grassland science and practice was recognized by the award of an honorary doctorate of science by the University of New Zealand, and by his election as an honorary life-member of the Royal Agricultural Society of New Zealand, as life president of the European Grassland Federation, as an Honorary Fellow of the Royal Agricultural Society of England, and as honorary councillor of the Spanish High Council for Scientific Research. Dr. Davies was appointed a Commander of the British Empire in 1964.

Dr. E. K. Woodford, O.B.E.

Dr. E. K. Woodford, who has been appointed director of the Grassland Research Institute, Hurley, Berkshire, in succession to Dr. W. Davies, has, for many years, played a leading part in the new science of chemical weed control. After war service in the Indian Army, he resumed his interrupted career as a research agronomist at the Indian Tea Association Research Institute at Tocklai. He returned to the United Kingdom in 1948 to join the Agricultural Research Council research team at Oxford under Prof. G. E. Blackman, which during the war years had undertaken the research work required for the successful introduction into British agriculture of the then new synthetic herbicides based on dinitrophenols and the substituted phenoxyacetic acids. In 1950 the team was reconstituted as the Agricultural Research Council Unit of Experimental Agronomy with Dr. Woodford as assistant director. In the early 1950's practical use of the new herbicides quickly outstripped knowledge of their action and there were many problems requiring research. Dr. Woodford realized the need for collaboration between all concerned and concentrated on building up liaison between the principal interests. It was largely as a result of his initiative that the Weed Control Joint Committee

was formed in 1952, later to become the British Weed Control Council. Dr. Woodford has been intimately concerned with the affairs of the Council and has played a special part in the organization of the biennial conferences also, as chairman of the Recommendations Committee and editor of the *Weed Control Handbook*. Dr. Woodford did much to encourage the formation of the European Weed Research Council, set up in 1960, and was its first president. Research, dissemination of information and liaison formed the principal activities of the Unit at Oxford, and soon after its formation it became clear that a permanent centre was needed for the location of staff and to provide the necessary facilities. In 1960 the Agricultural Research Council established the present Weed Research Organization at Begbroke, near Oxford, with Dr. Woodford as director. The existence and success of the Organization must be credited to a very large extent to Dr. Woodford. With typical foresight he recognized the need for, and was determined to bring into existence, a single organization to co-ordinate research and information in this rapidly moving and highly technical branch of agricultural science. Dr. Woodford's appointment to Hurley is consistent with the pioneering outlook which took him as a boy to Canada in 1930 to learn to farm and where he later obtained an M.Sc. in the University of Alberta in plant physiology. In Canada he had the opportunity of observing the development of scientific organizations unhampered by tradition, an experience which has had a marked effect on his thought and actions during his fifteen years' pioneer work in the field of weed control. Dr. Woodford's outlook and experience, together with his interest in farming and his research work in plant physiology in Canada and later at the Royal College of Science in London, will stand him in good stead in his new appointment.

Physiology in the Queen's University of Belfast: Prof. I. C. Roddie

Dr. Ian C. Roddie, reader in physiology in the Queen's University of Belfast, and consultant in physiology to the Northern Ireland Hospitals Authority, has been appointed at the age of thirty-five to the Dunville chair of physiology in the University in which he graduated in both science and medicine after a distinguished undergraduate career. The investigation into the nervous control of the blood vessels of the human limbs which he began in 1954 did much to clarify and define the independence of the nervous controls of the muscular and cutaneous circulations and disclosed the important role of low-pressure baroreceptors in the reflex control of the muscular circulation. In 1957 he was awarded a Beit Memorial fellowship, but resigned this on appointment to a lectureship. Dr. Roddie spent 1960–61 as a Harkness Fellow of the Commonwealth Fund in the University of Washington and started his present work in which the activity of vascular smooth muscle is assessed by the recording of intracellular electrical potentials. This work promises to provide a more direct answer than has hitherto been available to questions of vascular control. Dr. Roddie was Arris and Gale lecturer to the Royal College of Surgeons in 1962, and Ontario Heart Foundation lecturer this year. He has been awarded the degrees of M.D. with gold medal and D.Sc. for his research work. The Dunville chair of physiology was previously occupied by Prof. A. D. M. Greenfield, who was appointed to the chair of physiology at St. Mary's Hospital Medical School, London, as announced earlier this year (*Nature*, 201, 978; 1964).

Education in France

Under the title *The State and Education in France* the Press and Information Section of the French Embassy in London has issued a pamphlet summarizing the ruling ideas of the new Education Act of 1959, which came into force in October 1960 (Pp. 15. London: Ambassade de France, Service de Presse et d'Information, 1964). It has been somewhat modified since August 1963 and some applications are still at the experimental stage. The first effect of the Act is to raise the school-leaving age for all children from 14 to 16, and this will take effect as from 1967. The new structure provides for comparatively unified instruction for children of 11–15 during the four years of the observation cycle, only the 5–6 per cent maladjusted children requiring special education being excluded. The others are distributed between three types of education: a long general course, a short general course, and an intermediate course of two years, followed by two further years of a terminal course. Twenty comprehensive institutions known as colleges of secondary education are this year being started in an experiment in combining these three types of courses in one building and under the same headship. Technical education begins at the close of the first cycle of secondary education, and the long technical course at present given in the technical *lycées* is being removed, but they will continue to give instruction in technology providing the theoretical basis for more advanced technical training. Private education is for the most part associated with religious institutions, and its 1·7 million pupils in 13,000 institutions and taught by 78,000 teachers (40,000 secular) compares with just more than 9 million in State institutions. Besides agricultural education, depending partly on the Ministry of Agriculture, special institutions are being developed for the mentally retarded, for the maladjusted and spastics, for those with defects of sight, speech and hearing, and for young delinquents. There are also 'social formation' courses organized by the State, and the work of the schools is supported by school medical services and by school and recreational guidance services.

The Science Council of Japan

The annual report of the Science Council of Japan for 1961–62 gives a brief account of the history and functions of the Council, which was formally established in 1949, and reports on its activities during the year (Pp. 95. Tokyo: Science Council of Japan). It is expected that legislation of critical importance to scientific research will be enacted very soon, and the Council believes that it should guide research policy in Japan. The main interest of the report lies in the account of this law, intended to formulate the policies which the Government should follow for the sound development of science. The purpose and social function of scientific research are first emphasized; a second article formulates the basic prerequisites, stressing first the freedom and independence of scientific research workers, and secondly, the importance of making the results freely available. A third article insists that Government administration of research must provide the essential conditions in accordance with the particular field of science and the stage it has reached. Next, the organization for scientific research is outlined in seven articles, covering universities, colleges, research institutions and academic societies, and stressing the importance of free interchange and co-operation and the functions of the Science Council of Japan. Next comes an article stressing the flexibility of budgeting and the importance of varied sources of support. One dealing with the working conditions and treatment of scientific research workers follows, and then four further articles deal with international scientific co-operation and the exchange of scientists and scientific information. The remaining two sections of the law deal with the training of scientific research workers and with the functions of the Science Council of Japan, which will make a statement concerning the responsibilities of science when the new law is enacted. The proposed statement stresses the awareness of each scientist of the aim and social responsibilities of scientific research, and insists that scientists should have the responsibility to protest against any threat to freedom of scientific research, to point out any harmful results pro-

duced by neglect or abuse of scientific research, and to protect the welfare of the people and mankind in general. Generally, the proposed law embodies the common opinion in the Western world regarding the conditions of scientific work and the responsibilities now recognized by scientists themselves.

Solway Barrage

THE proposals for the regional project for the development of the Solway Firth Area have now been issued in a report which stresses the strategic location and character of the Solway region in the British Isles. Dr. R. L. Drew argues that any international crossroads linking Scotland, Ireland and England is bound to pivot on a Solway barrage linking Annan in Dumfriesshire and Bowness in Cumberland. The region is rich in water and the potentials this confers for the location of population and industry based on science, at the increasing levels of energy conservation and utilization demanded by a society using large amounts of energy. The communications aspect, including sea-borne trade and air travel as well as motor ways and roads, is also stressed. Dr. Drew reviews the regional activities which could be based on the project, including space and district heating, market gardening, forestry, agriculture, fishing, food processing and production, and finally its bearing on water supply generally, the conservation of energy, as well as land reclamation and water and power supply. It is estimated that perhaps £250,000 over several years would be required to delineate the full plans. The report is available from Dr. R. L. Drew, Annan, Dumfriesshire.

Planning Economic Policy

UNDER the title *Towards a Common Economic Policy for EEC*, Political and Economic Planning has issued Broadsheet No. 481 (London: July 27, 1964. 5*s*.), containing copies, usually translations, of the basic documents relating to the formation of a common economic policy for the European Community. It is preceded by an introduction by M. Forsyth, and seeks to show the extent to which the Community has progressed in this direction, and to assist the discussion of economic policy in Britain. There are several problems of economic policy which the Community and the United Kingdom share, not least the problem of the extent to which economic planning is now necessary and the form it should take.

Care, Handling and Disposal of Dangerous Chemicals

CHEMISTS spend the major part of their working lives in close proximity to potentially dangerous or toxic substances. Familiarity with the properties of the chemicals they use and an appreciation of the consequences of careless experimentation have ensured that a 'safety code', born of experience and operating almost at subliminal level, protects the mature scientific worker from disastrous accident. The booklet recently published by the Institute of Science Technology, Aberdeen, will provide the inexperienced chemist with a most valuable survey of the more dangerous chemicals and of their interactions with other reagents (*The Care, Handling and Disposal of Dangerous Chemicals*. By P. J. Gaston. Pp. 103. Aberdeen: Institute of Science Technology. Obtainable from Northern Publishers (Aberdeen), Ltd., 11 Albyn Terrace, 1964. 7*s*. 6*d*.). It will also provide a useful 'refresher course' for the more expert laboratory chemist and will guide those officers whose task it is to advise on safety matters. The handling and disposal of hazardous materials or toxic substances, the British Standards Institute marking of gas cylinders, the coding of gas-mask canisters, fire fighting, first-aid, etc., are some of the topics ably and succinctly dealt with in this booklet. There are a few errors. 'Phosphorus' is mis-spelled on p. 49, and on p. 30 diazonium salts are stated to be made by the action of 'sodium nitrate' on a primary amine. On p. 9, it is pointed out that white phosphorus and potassium chlorate form the 'basis' of a powerful explosive. It is very dubious whether these two substances could be mixed without exploding spontaneously! There are some omissions. Some mention could have been made of the disastrous consequences of adding the alkali metals to chlorinated hydrocarbons, or of the interaction of finely powdered zinc, aluminium, etc., with these halogenated organic substances. Particle size has a powerful influence in determining phase interactions. The disposal of azides (p. 28) is always a hazardous business, but they can be destroyed in cooled ammonium acetate, sodium nitrite solution by cautious addition of dilute acetic acid. Similarly the fulminate of mercury is destroyed by sodium thiosulphate to form the tetrathionate. The present publication is, however, a most valuable and useful work and it is hoped that it will be extensively read and studied by the chemical staff of all industrial and university laboratories. Its small cost covers a mammoth insurance for safety.

Polychaetes from Scotland

SEVENTEEN species of polychaete worm hitherto unknown from the Firth of Clyde and the west coast of Scotland, together with a number of others, have been described by Dr. R. B. Clark and P. G. Dawson of the Department of Zoology, University of Bristol (*Annals and Magazine of Natural History*, 6, No. 71; 13th Series, 1963). Three of these have not previously been recorded in British waters: *Harmothoe joubini*, Fauvel, *Clymenella cincta* Saint-Joseph, and an undetermined capitellid probably belonging to the genus *Mediomastus*. Both *Harmothoe joubini* and *Clymenella cincta* have been rediscovered for the first time since their original description. Only two species of *Mediomastus* are known, both from the Pacific coast of the United States. The Clyde specimen does not appear to belong to either, but its damaged condition makes precise determination impossible, and the possibility that it is an abnormal *Heteromastus*, though unlikely, is not excluded. *Pholoe synophthalmica* Claparède is another species new to British waters, but the Clyde specimens are in some respects intermediate between this species and *P. minuta* (Fabricius). In view of the known variability of the latter, it is probably preferable to regard *P. synophthalmica* as a variant of *P. minuta*. Similarly, specimens intermediate between *Aonides oxyceohala* (Sars) and *A. paucibranchiata* Southern have been found, which cast doubt on the validity of the latter species. *Praxillura longissima*, previously known only from a generic record of a single fragment collected in the Clyde, has now been positively identified. It has not been reported elsewhere in British waters.

Distinguishing the Sexes in some Scarabaeid Larvæ

AN excess of females among adults of *Costelytra zealandica* emerging from pastures that had been treated with DDT suggested that susceptibility to the insecticide might differ in the sexes, and made it desirable to have a means of recognizing them in the larval stage. The development of the sexual organs in the pre-adult stages was examined by R. Elliott (*N.Z. Science*, 7, No. 2, June 1964). An apparatus, part glandular and part chitinous, is visible through the integument of sternite 9 in living male larvæ of all three instars. The chitinous part was found to vary in shape and size, with some indication of local differences in the occurrence of different types. A similar apparatus was found in *Pyronota* sp., *Heteronychus sanctaehelenae*, *Pericoptus* sp., and *Aphodius tasmaniae*, differing in detail, the glandular element being poorly developed in the last three. Although female larvæ of *C. zealandica* are usually heavier than the corresponding males, there is no evidence from either laboratory or field observations to suggest that susceptibility to insecticides is directly governed by sex at this stage.

Training Programme in Oral Science at the Massachusetts Institute of Technology

Applications are invited for admission as candidates for a Ph.D. course in oral science at the Massachusetts Institute of Technology commencing September 1965. The course is aimed at preparing the candidates for careers in dental education and dental research, and the curriculum will stress basic sciences and advanced biosciences. The course will take three to four years; all tuition fees will be paid, and candidates will receive a generous stipend. Application is open only to citizens of the United States, or to others who have taken out first papers. Further information can be obtained from Prof. Robert S. Harris, director of Training Program in Oral Science, Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge 39, Massachusetts.

British Scientific Exchanges with East European Countries and the U.S.S.R.

A revised summary of the provisions now in force for visits under the Governmental exchange programmes with Bulgaria, Czechoslovakia, Hungary, Rumania and the U.S.S.R. in the fields of science, engineering, technology and agriculture, has been recently prepared by the British Council. Anyone interested in receiving further information on the facilities available is invited to apply to the Director, Science Department, the British Council, 59 New Oxford Street, London, W.C.1.

University Entrance Requirements in Britain

A *Compendium of University Entrance Requirements for First Degree Courses in the United Kingdom* has been issued by the Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom (Pp. 161. London: Association of Commonwealth Universities, 1964. 8*s*. 6*d*.) in accordance with recommendations of a sub-committee reporting in 1962. It is more comprehensive than the previous edition, in that it contains details of the entrance requirements of the Universities of Scotland, the Queen's University of Belfast, and the new universities of Kent, Lancaster and Warwick. It does not include the entrance requirements of the colleges of advanced technology, but these are expected to appear in a future edition, after the colleges have received their charters as universities. The course requirements are expressed in terms of the General Certificate of Education examination in 66 tables which afford easy comparison of the different university requirements, and those courses not included in the tables are listed separately. Appendixes cover the distinctive requirements of Oxford and Cambridge, and the Scottish universities, and of the courses or requirements in those of the new universities which do not fall into the usual pattern. The compendium is designed to assemble and present the details of university entrance requirements for the benefit of schools, where sixth form curricula have to be planned and sixth form boys and girls advised on their choice of subject. It should enable the schools readily to discover the extent to which the requirements of universities are common for any particular course of study.

University News:

Keele

The following appointments to lectureships have been announced: V. H. Dundas-Grant (education); L. W. F. Page (geography); Dr. D. O. Hughes (chemistry).

Leeds

In the Proctor Department of Food and Leather Science, Dr. H. G. Muller has been appointed lecturer with special concern for cereal chemistry, and Mr. T. W. Houston has been appointed to a senior research post to initiate meat research. Mr. Houston's post has been made possible through a grant from the Pig Industry Development Authority.

London

Dr. D. C. Bradley, senior professor of chemistry in the University of Western Ontario, has been appointed to the chair of inorganic chemistry tenable at Queen Mary College. Dr. G. V. Groves, lecturer at University College, has been appointed to a readership in physics tenable at that College. The title of reader in insect ecology has been conferred on Dr. T. R. E. Southwood in respect of his post at the Imperial College of Science and Technology.

Southampton

Mr. G. R. Fisher, at present lecturer in the Department of Econometrics and Social Statistics, University of Birmingham, has been appointed to the newly-created Leverhulme chair of econometrics at the University of Southampton, with effect from January 1, 1965.

Announcements

Dr. Gerhard Herzberg, director of the Pure Physics Division, National Research Council of Canada, has been awarded the Frederic Ives Medal for 1964, "in recognition of his extraordinary contributions to research, teaching, and scientific administration". The Frederic Ives Medal is awarded every two years by the Optical Society of America for distinguished work in optics.

A meeting of the Nutrition Society will be held at the Royal Veterinary College, London, on December 5. Further information can be obtained from Dr. I. Macdonald, Physiology Department, Guy's Hospital Medical School, London, S.E.1.

A symposium on "Membrane Problems" will be held in the State University of New York at Buffalo during December 8–11. Further information can be obtained from Mrs. Muniak, c/o Theoretical Biology Unit, 210 Winspear Avenue, Buffalo, New York.

A symposium on "The Scientific Basis of Maximum Permissible Levels of Radiation Exposure", arranged by the British Institute of Radiology, will be held in London on December 8. Further information can be obtained from the Secretary, British Institute of Radiology, 32 Welbeck Street, London, W.1.

A special session of the Scientific Meeting of the Palæobotanical Society will be held at the Birbal Sahni Institute of Palæobotany, Lucknow, during December 7–12. During the session a symposium will be held on "Floristics and Stratigraphy of Gondwanaland". Further information can be obtained from R. S. Sharma, Birbal Sahni Institute of Palæobotany, 53 University Road, Lucknow 7.

Addendum. The following list of references has been supplied by Prof. C. Lindegren for his joint communication with Miss Yong Nyu Bang entitled "Origin from Mitochondria of the Double-walled Viral Membrane in *Saccharomyces*" (*Nature*, 203, 431; 1964):

[1] Lindegren, C. C., and Bang, Y. N., *Antonie van Leeuwenhoek*, 27, 1 (1961).
[2] Lindegren, C. C., Bang, Y. N., and Hirano, T., *Proc. N.Y. Acad. Sci.*, 24, 540 (1962).
[3] Hirano, T., Lindegren, C. C., and Bang, Y. N., *J. Bacteriol.*, 83, 1363 (1962).

Erratum. In the article "*Para-O*-Methylation of Dopamine in Schizophrenic and Normal Individuals", by Frederick A. Kuehl, jun., Martin Hichens, Robert E. Ormond, Dr. M. A. P. Meisinger, Paul H. Gale, Vincent J. Cirillo and Dr. Norman G. Brink, which appeared on p. 154 in the July 11 issue of *Nature*, lines 8 and 9 of the right-hand column of p. 155 should read "ratio of 4-hydroxy-3-methoxy to 3-hydroxy-4-methoxyphenethylamine was found to be 4 : 1".

NEW ZEALAND DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

THE following staff changes have been announced by the New Zealand Department of Scientific and Industrial Research.

Mr. W. A. Joiner

MR. W. A. JOINER retired recently as deputy director-general of the New Zealand Department of Scientific and Industrial Research. Mr. Joiner, who was born in Scotland in 1902 and moved to New Zealand when he was nine, was educated at Wellington College and Victoria University of Wellington, where he was awarded a senior scholarship in chemistry, a Joe Jacob Joseph scholarship and a National Research scholarship, and gained his M.Sc. with honours in chemistry. Appointed as assistant analyst in the Dominion Laboratory in 1923, he specialized in fuel research, and his work on the carbonization of Waikato coals led to the establishment of a briquetting plant at Huntly in 1930. In 1934 he took a postgraduate course in chemical engineering at University College, London, and also investigated problems of coal hydrogenation at the Fuel Research Station and the Imperial Chemical Industries Works at Billingham. In 1935 he was awarded a diploma of chemical engineering by University College, London. On his return to New Zealand, he initiated a survey of the country's coal resources. In 1937 he was appointed chemical engineer in the Dominion Laboratory, and in 1941 assistant director. One of his major projects was the development of a special grass-seed dryer to overcome the problem of the poor germination of such seed when exported in a moist condition. He also played a leading part during the Second World War in the developing of mobile gas producers and in the dehydration of fruit and vegetables. In 1946 he succeeded Mr. Andrew as director of the Dominion Laboratory, and in the following year was appointed assistant secretary of the Department of Scientific and Industrial Research, in charge of the branches dealing with chemistry and geology. He became deputy secretary in 1950.

Dr. E. I. Robertson

DR. E. I. ROBERTSON, director of the Geophysics Division, has been appointed assistant director-general of the Department of Scientific and Industrial Research. Dr. Robertson was educated at Hutt Valley High School and Victoria University College, from which he graduated M.Sc. He was awarded a Shortcliffe fellowship, but because of the Second World War, during which he served in the Navy for four years, he delayed going to the University of London until 1945. There he gained his Ph.D. in geophysics. Returning to New Zealand in 1948, he took up a position as a geophysicist in the Department of Scientific and Industrial Research. In 1951 he was appointed director of the Geophysics Division of the Department, in which capacity he was responsible for scientific programmes in Samoa, Rarotonga and at Wairakei. During the International Geophysical Year, 1957–58, he played a leading part in New Zealand's contribution to the work, being chairman of the Inter-departmental Committee. Dr. Robertson has been the scientific adviser to the New Zealand Navy for several years, is chairman of the Ross Dependency Research Committee, and is a Government representative on the Council of the Royal Society of New Zealand.

Dr. F. F. Evison

DR. F. F. EVISON, superintendent of the Seismological Observatory, has been appointed director of the Geophysics Division. Dr. Evison was born in Christchurch and educated at the Victoria University of Wellington, where he gained his M.A. and B.Sc. degrees. In 1949 he went to the Imperial College of Science and Technology, London, and was awarded a Ph.D. for his work in geophysics and a diploma of the Imperial College in 1950. On returning to New Zealand he joined the staff of the Geophysical Survey Section of the Geophysics Division, and in 1960 was appointed superintendent of the Division's Seismological Observatory. In 1956 Dr. Evison was awarded a Nuffield fellowship at the University of Cambridge. He has made a special study of the Earth's crust in Antarctica and New Zealand, using earthquake waves, and has investigated the cause of earthquakes. In 1963 Dr. Evison was visiting professor in geophysics at the University of Minnesota.

Dr. R. D. Adams

DR. R. D. ADAMS has been appointed superintendent of the Seismological Observatory. Dr. Adams was born in Wellington and educated at the Victoria University of Wellington, where he gained both his M.A. and M.Sc. degrees with honours. Appointed to the New Zealand Defence Science Corps, he went to the University of Cambridge, where he was awarded a Ph.D. for his thesis on seismology. Following his return to New Zealand, Dr. Adams worked for two years at the Naval Research Laboratory, Auckland, before joining the staff of the Seismological Observatory in 1960, as a scientific officer. Dr. Adams has carried out a magnetic survey of the region between New Zealand and McMurdo Sound, Antarctica. He has undertaken research on problems of earthquake mechanism, and investigated the use of dispersive earthquake waves to examine the Earth's crustal structure in the New Zealand region.

Dr. L. Corkill

DR. L. CORKILL, director of the Crop Research Division of the New Zealand Department of Scientific and Industrial Research, has been appointed director of the Department's Grasslands Division, in succession to the late Dr. P. D. Sears. Dr. Corkill was educated at Auckland and Massey Universities, where he gained both B.Sc. and M.Agr.Sc. degrees. Appointed as a plant breeder in the Grasslands Division, he worked under the general direction of Sir Bruce Levy and was responsible for the development of many new and improved strains of pasture plants. He was associated particularly with short-rotation ryegrass and with long-rotation ryegrass, which has just been released to farmers. In 1957 Dr. Corkill was awarded a D.Sc. by the University of New Zealand for his researches on plant breeding. Later that year he was appointed director of the Crop Research Division. In 1958, together with Dr. Sears, Dr. Corkill visited Japan under the auspices of the Food and Agriculture Organization to advise the Japanese Government on pasture establishment on new land previously under scrub and on a breeding programme for plants best suited to this environment.

Dr. H. C. Smith

Dr. H. C. Smith, senior principal scientific officer in the Plant Diseases Division, has been appointed director of the Department's Crop Research Division. Dr. Smith was educated at Massey Agricultural College, where he gained an M.Agr.Sc. degree, specializing in plant pathology. In 1951 he was awarded a National research scholarship at the University of Cambridge. There he undertook research work for his Ph.D. on *Phytophthora*. On completing his Ph.D. degree in 1953, he returned to New Zealand and was appointed mycologist at the Plant Diseases Division sub-station at Lincoln. In 1960 Dr. Smith was awarded a Canadian National research fellowship, which he held at the Canadian National Research Council's Plant Research Institute at Ottawa, where he studied virus diseases of grasses and cereals, and in particular barley yellow dwarf virus which he had already been investigating in New Zealand. His work on this disease has led to the development of effective control measures of great economic significance to barley and wheat growers in New Zealand.

Dr. J. M. Hoy

Dr. J. M. Hoy has been appointed director of the Entomology Division, Nelson, in succession to the late Dr. W. Cottier. Dr. Hoy was educated at Otago Boys' and King's High Schools, Dunedin, and at Lincoln College, where he gained B.Agr.Sc. in 1942. In 1943 he became entomologist in charge of malarial control for the Royal New Zealand Air Force in the south-west Pacific area. In this capacity he spent a year in the forward Pacific war area. On his return from overseas in 1945 he joined the Entomology Division of the Department of Scientific and Industrial Research as assistant entomologist, Nelson, where he was concerned with the systematic investigation of the larvæ of grass grubs and the possible utilization of nematodes to control pasture insects. In 1953 Dr. Hoy was appointed officer-in-charge of Entomology Division's sub-station at Palmerston North. This unit made an intensive investigation of manuka blight, and Dr. Hoy was responsible for the discovery that the causal insect, *Eriococcus*, was Australian in origin. For his work on scale insects he was awarded a D.Sc. by Lincoln College early in 1964. In March 1963 Dr. Hoy joined the headquarters staff of Entomology Division at Nelson to lead the research team concerned with present work on the control of grass grub and subterranean grass caterpillar. Dr. Hoy is immediate past-president of the New Zealand Entomological Society and is vice-president of the Nelson Branch of the Royal Society of New Zealand.

ORGANIZATION AND ADMINISTRATION OF INDIAN SCIENCE

In successive annual reports on the Commonwealth Scholarship and Fellowship Plan the Commonwealth Education Liaison Committee has expressed concern at the reluctance of some scholars to return home on completion of their tenure. This was discussed at some length in the third report, and the difficulty appears to have become more acute during the past year. It is appreciated that the temptation to remain in Britain, for example, may be considerable when the scholar can see no immediate prospect of obtaining employment in his home country at the level he regards as suitable to his qualifications, or when opportunities for further research are severely limited at home.

Some light is thrown on this reluctance to return home, so far as India is concerned, by a memorandum on Indian Scientific Policy submitted by the Institute of Political and Social Studies to the Review Committee of the Council of Scientific and Industrial Research on National Research Laboratories, and published in *Minerva* (11, 519; Summer, 1964). It is also illuminated by the comments which Dr. K. A. C. Mendelssohn made in a broadcast talk "Science in India" discussing his visit to India in 1963, which was published in *The Listener* for September 24 (72, 457; 1964).

The main submission of the Institute of Political and Social Studies is that the Review Committee, to which its memorandum is addressed, should concentrate on creating a suitable climate for serious scientific research in the national research laboratories. It is considered in the memorandum that the previous Minister for Scientific Research and Cultural Affairs was at least partly aware of the problem, and it quotes his references, when addressing a recent conference of scientists and educationalists, to the lack of an atmosphere of activity sustained by critical appreciation and the existence of a bureaucracy in the scientific field, tending to a false sense of prestige due to status and office. These criticisms fully confirm Dr. Mendelssohn's observations. In general, the authors of the memorandum believe that the organization of research has proliferated too widely and rapidly, with excessive attention to buildings and equipment, etc., compared with training and expanding the initial nucleus of research staff. There are now 27 national laboratories and other allied research institutions, housed and substantially equipped and with further facilities in prospect; in spite of this, the memorandum asks the fundamental questions whether a suitable research leadership has emerged in each of these institutions, and whether a climate has developed which spurs the research worker to do his job well. The whole implication of the memorandum is that neither question can be answered in the affirmative without hesitation or reservations.

The Institute of Political and Social Studies, however, goes further and directs attention to specific points. It questions whether the laboratories are recruiting scientific workers, particularly in the senior grades, who combine aptitude for research with basic competence in the particular field. Enquiry here could go far to explain the reluctance of Indian scholars and Fellows to return from abroad. The mere fact that the memorandum suggests that it would be worth while to consider setting up a high-level selection body for recruiting scientists on the pattern of the Union Public Service Commission indicates that all is not well with present methods of recruitment. It also directs attention to the vital importance of ensuring that the research worker can rely on obtaining guidance and on critical appreciation of his efforts. It asks key questions about direction of the laboratory, both as regards the formulation and study of problems and the publication of results.

The questions about relations with industry, about the establishment of regional research laboratories, about duplication at the national level, are both searching and constructive. The memorandum gives firm support to the younger workers; like Dr. Mendelssohn, the Institute has evidently formed the opinion that the younger men do not always receive a fair chance and that conditions are not conducive to serious research by many competent scientists. The core of its criticism is, in fact, that the direction of many of the laboratories is often defective, if not incompetent, and that this position is at least partly due to the form of organization under the Council of Scientific and Industrial Research.

Perhaps the most encouraging feature of the memorandum is the evidence it provides that the Institute of Political and Social Studies has clear ideas as to what is needed, in respect of the conditions on which effective research depends, of the organization of research, and of the qualities required in its direction. Dr. Mendelssohn's broadcast talk supplies evidence that there are other Indian sources also competent to give the Review Committee all the guidance it should need as to the organization of the National Research Laboratories. At the outset, however, he makes it only too apparent that the causes run deep and that there is widespread frustration and discontent in universities as well as in Government research laboratories, largely but not wholly due to the effect of the 20 per cent cut in their budgets imposed as an emergency measure in 1963. Since the director could not dismiss his staff and their salaries had to be paid, this involved a reduction of 60–70 per cent in running expenses.

Dr. Mendelssohn picks out the quality of scientific publication, and the reluctance of Indian scientists to return to India after training in the West, as evidence that all is not well with science and technology in India. His observations satisfied him that there was justification in some of the reasons given for this reluctance—in the lack of appreciation, insufficient means for research, difficulties in obtaining equipment, pettiness and jealousy among colleagues. It seems only too clear that Dr. Dedijer's plea for a clearer understanding of science and its implications and for the formulation of scientific policy, addressed more particularly to the emerging nations, applies no less to India. Too many of her politicians, as Dr. Mendelssohn recognizes, are not science-minded, and the trouble starts in the universities, modelled on Western institutions of the pre-scientific era.

While it is true that the whole purpose of the Commonwealth Scholarship and Fellowship Plan will be defeated if many of the Scholars and Fellows do not return to their own country when tenure of their scholarship and fellowship expires, it must not be forgotten that this is largely a matter for the country which sends the scholars and Fellows. Fortunately, as Dr. Mendelssohn shows, there are hopeful signs. India, he recognizes, has scientists who are second to none. He is impressed by her reserve of capable brains and by the younger generation of scientists whose love for their subject is matched by their capacity for hard work, and often by their competence. Moreover, there are, here and there, as at the Tata Institute in Bombay and the Atomic Energy Research Laboratories at Trombay, those who have the strength of character to oppose the Government, and he does not despair of the real impetus coming, as it must, from India itself.

What is needed is to create the conditions in which the young generation of Indian scientists can develop their talents and work for their country, and what Indian professors and directors of research need is the art of talking to their own Government. These are the two key conditions which will determine the readiness of Indian scholars abroad to return to their country. This should be remembered both in discussing the future of the Commonwealth Scholarship and Fellowship Plan, and in assessing the extent and character of the technical assistance given to India. With sympathy and insight much could be done indirectly, rather than by direct action, to help Indian politicians to understand the situation and to appreciate the nature of the action required, if not merely India's science but her general economic and social development are to proceed on the scale and at the rate which has been planned.

MARINE RESEARCH AT ZANZIBAR

AN important aspect of the International Indian Ocean Expedition has been the part played by the various marine research stations in the area. Not only have they offered facilities for research vessels and made their own individual contributions to the Expedition, but, perhaps more important, their previous research activities have provided much valuable information on which the assault on the Indian Ocean could be planned. The research station at Zanzibar, although hampered during much of 1963 by the absence of its research vessel, R.V. *Manihine* (for refit and survey), nevertheless continued some promising lines of research and initiated some new ones*. Three new biologists were recruited during 1963, bringing the scientific complement up to four research officers in addition to the director.

In the absence of the R.V. *Manihine*, the deep long-line investigation, work on demersal fishes, and hydrological work had to be abandoned. On the other hand, a new vessel, the 58-ft. *Jodari*, built by and for the use of the Government-sponsored Zanzibar Fisheries Development Co., Ltd., and the purchase of a 450 × 45 fm. purse-seine net, enabled investigations to be made of day-time fishing for scombroid fishes. Of the latter, five types of shoal have been distinguished on their species composition, the majority of shoals containing bonito and frigate mackerel in the proportions of 50 : 50 to 97 : 3. The food of the tuna examined consisted chiefly of small fishes (*Stolephorus* and *Atherina*) with occasional small crustaceans and cephalopods.

Two further boats were operated by the Zanzibar Fisheries Development Co. (39 ft. and 55 ft.), both used in night purse-seining for sardine-like fishes. As elsewhere, night fishing with lights was limited to about twenty days between full moons. Initial difficulties were encountered in finding areas free from coral. Of the clupeid species, *Sardinella jussieu* (Lacépède), *S. perforata* (Cantor) and *S. sirm* (Walbaum) (the latter an offshore species) were the most abundant, but several small carangids were commonly caught (for example, *Decapterus dayi* Wakiya). The purse-seines also took significant numbers of tuna-like fishes. Highest landings were recorded during the periods May–July and November–December.

Prawns collected during three cruises off the Tanganyika coast, supplemented by specimens from elsewhere in the Indo-Pacific Ocean, were reported on at the meeting of carcinologists at Zanzibar, organized by the Scientific Council of the Commission for Technical Co-operation in Africa South of the Sahara in April. Three useful papers on plankton were published during 1963, resulting from collections made in the Zanzibar area during 1960–61; one strongly denies the popular conception of the 'impoverishment of tropical seas'.

Interest in the work of the Zanzibar station is evidenced by the amount of financial assistance received from outside sources: Unesco for library material; the Rockefeller Foundation for hydrological equipment; the Food and Agriculture Organization for deep long-line gear; the Freedom from Hunger Campaign for purse-seine net; the Munitalp Foundation for hydrographic winch, etc. It is to be hoped that the valuable contributions made by Zanzibar to knowledge of the Indian Ocean and its fisheries will continue to be recognized.

CO-ORDINATION CHEMISTRY

THE eighth international conference on "Co-ordination Chemistry" brought together some 750 research workers in Vienna during September 7–16 and gave rise to two cognate symposia, one in Czechoslovakia and the other in Hungary.

The symposium in Hungary, held at Tihany, Lake Balaton, during September 14–17, under the auspices of the Hungarian Chemical Society, with Prof. G. Schay as president and Dr. M. T. Beck as secretary, was attended by about 60 Hungarian chemists and some 100 visitors from countries as distant as the United States and Japan. The papers were preprinted in full in two octavo volumes totalling 886 pages, and authors were allowed 15 min to introduce their papers followed by 10 min discussion. The papers were drawn equally from countries east and west of the 'Iron Curtain', and the conference afforded an excellent opportunity for Western chemists to meet their counterparts from the East. The two volumes make very interesting reading, containing many authoritative reviews with new work from well-known authors. They will be published together with the discussion in the near future, and are warmly recommended to those who did not have the good fortune to attend the conference.

Tihany is a beautifully situated holiday resort on Lake Balaton and, appropriately to this wine-producing area, the lectures and discussions took place in the 'Bar' of the Tihany Motel. Participants from abroad were accommodated at the Tihany Hotel, about 100 yards away. Forty papers were presented and raised much interesting discussion, so that in many cases the discussion time was much too short. Briefly, the papers touched on the following points, and only the authors who presented papers are mentioned.

Outer sphere association of complex cations and simple anions has been examined by charge transfer spectra (C. K. Jørgensen, Switzerland) and optical rotatory dispersion (S. Kirschner, United States). Perhaps the most remarkable fact is the high degree of association which can occur. R. Larsson (Sweden) reported successive stability constants for up to four thiosulphate ions with d-$[Coen_3]^{3+}$ forming a super anion of charge 5– and requiring, for the later stages of its formation, the association of negative ions in aqueous solution of ionic strength 2.

The four papers on homogeneous hydrogenation (J. Halpern, United States; V. A. Tuloupov, U.S.S.R.; J. C. Bailar, jun., United States; and L. Simándi, Hungary) contained much new material leading to a lively discussion and firmly pointing the way to selective and specific catalysts. This was followed by papers on ligand interaction with 5f orbitals (B. Jezowska-Trzebiatowska, Poland) and some acetylacetone complexes of the uranyl ion (J. Szőke, Hungary).

A major part of the programme concerned the chemistry of aqueous solutions of complex ions. L. G. Sillén (Sweden) made an earnest plea for care in interpreting stability constant measurements and emphasized the value of a computer for checking data and calculating constants. This was followed by papers concerned with the quantitative aspects of the formation of polynuclear complexes in aqueous solution. P. Szarvas (Hungary) discussed the equilibria between isopolytungstic acids and tungstate-carboxylic acid complexes, A. E. Martell (United States) the formation and possible structures of polynuclear species derived from polyfunctional organic ligands and tri- and tetra-positive ions, and A. Gergely (Hungary) the equilibria between neodymium(III) ion and d-glycosaminic acid.

J. Bjerrum (Denmark) reviewed and correlated the great variety of different complex formation curves obtained from ligands with Cu(I), Ag(I), Au(I) and Hg(II), including new data on organic phosphines and arsines as ligands. This was followed by a paper on the formation of azido complexes in non-aqueous solvents by V. Gutmann (Austria), and a comprehensive account of the formation of mixed dimethylglyoxime (DMG) complexes of general type $M(DMG)_2X_n$ (M = Mn(II), Fe(II), Co(II), Co(III), Cu(II) and Pd(II); X = halide ion, OH, and other ligands; n = 1 or 2) (K. Burger, Hungary). Only nickel failed to form such complexes, and this was advanced as the main reason for relative insolubility of $Ni(DMG)_2$ in water.

Solvent extraction of metal ions through complex-formation with organic ligands and the enormous enhancement of the extraction by some ligand mixtures were described in papers by H. Irving (England), D. Dyrssen (Sweden), and L. Bakos (Hungary). W. K. Wilmarth (United States) discussed the base catalysed reduction of μ-peroxo bridged complexes of cobalt, and D. Konrad (Czechoslovakia) the extraction of halogen from halogenated hydrocarbons by complexes of transition metals in low valent states. The retardation of hydroformylation and hydrogenation of olefines on a cobalt catalyst was attributed by L. Markó (Hungary) to the formation of cobalt sulphide by means of cobalt carbonyl derivations such as $Co_3(CO)_9(S)$ and $Co_3(CO)_9(S)(SR)$, the sulphide being stable under carbonylation conditions.

Polymeric and polynuclear complexes formed the subject of a number of papers. The formation of oxygen bridged complex fluorides by the thermal condensation of hydroxofluoro complexes of arsenic and antimony was discussed by L. Kolditz (East Germany), and thermal degradation of the infinitely bridged complexes of methylpiperazines with cobalt halides to the binuclear $[diamine_2Co_2X_4]$ by E. Körös (Hungary). The structures and thermal decomposition of polymeric alkoxide bridged complexes were the subject of papers by D. C. Bradley (Canada), F. Majdik (Hungary) and Gy. Pfeifer (Hungary). Gy. Bor (Hungary) gave a detailed account of the application of infra-red spectroscopy to determining the structure of polynuclear metal carbonyls, and showed that the "method of local symmetry" is invalid. Infra-red and Raman spectral investigations were also carried out to determine the type of bonding in mixed halide–cyanide complexes of gold(III), for example $[AuCl_2(CN)_2]^-$ (L. H. Jones, United States).

Polynuclear complexes containing metal–metal bonds were reviewed and classified by R. S. Nyholm (England), who also described a number of new compounds in which a covalent metal–metal bond was an essential link, for example $[CH_3C(CH_2AsMe_2)_3Cu.Mn(CO)_5]$.

E. Thilo (East Germany) attributed the catalytic effect of metal ions on the hydrolysis of polyphosphates and pyrosulphate to the chelation of the cations by the polyanion. A very thorough tracer investigation of the alkaline hydrolysis of pentamminecobalt(III) carboxylates by H. Taube (United States) showed that it proceeded by two paths, at low temperatures and high $[OH^-]$ by C–O bond breaking and at high temperatures (90°) and low $[OH^-]$ (0·01 M) by breaking of the Co–O bond. The rate-determining step in strong acid hydrolysis of *cis*-$[Cr(C_2O_4)_2(H_2O)_2]^-$ involved the protonation of the complex with splitting away of $HC_2O_4^-$ (H. L. Schläfer, West Germany).

Equilibrium studies of the stabilities of mixed complexes in aqueous solution were given by I. Leden (Sweden) and by E. J. Marcus (Israel). It is often found that the mixed complexes are more stable than would be expected on the basis of the stabilities of the corresponding binary complexes, for example, HgClI exists in greater concentration than would be expected statistically from the

stability constants of $HgCl_2$ and HgI_2. Marcus generalized that the more unlike the ligands the more stabilized the mixed complex provided the two ligands form complexes of the same bonding type, and calculated the stabilization in terms of a polarized ion model.

The remaining six papers were concerned mainly with the effect of ligands on electron transfer reactions and the redox properties of complexes (C. H. Brubaker, jun., United States; G. M. Nord-Waind, Denmark; W. Langenbeck, East Germany; and L. Kiss, Hungary), concluding with a systematic review of the mechanism of catalysed redox reactions including catalysis by so-called 'inert' complexes (M. T. Beck, Hungary).

J. CHATT

A SIMPLE MASS SPECTROMETER FOR THE ANALYSIS OF ARGON AT ULTRA-HIGH VACUUM

By E. FARRAR, R. M. MACINTYRE, PROF. DEREK YORK and W. J. KENYON

Geophysics Laboratory, Department of Physics, University of Toronto

THE most modern methods of determining the ages of rock formations are based on radioactivity[1,2], perhaps the most widely used technique so far being that utilizing the decay of potassium-40 to argon-40. Potassium-40 is a long-lived rare isotope of potassium (0·0119 per cent atomic) and by virtue of a branching decay produces both argon-40 and calcium-40. A potassium–argon age measurement on a mineral involves two steps: (*a*) determination of the potassium concentration by acid digestion of the mineral followed by flame-photometry; (*b*) evaluation of the argon concentration by fusion of the mineral in vacuum followed by mass spectrometric, isotope dilution measurements on the evolved argon. While many laboratories have the facilities for potassium analysis, equally many are deterred from setting up methods of argon analysis because of the considerable expense usually thought to be involved in the acquisition of a suitable mass spectrometer. However, we have recently been experimenting with a simple, inexpensive mass spectrometer, the *MS*10, bought from Associated Electrical Industries, Ltd., and wish to report here its successful application to potassium–argon dating.

The instrument uses a 2-in. radius of curvature with 180° deflexion. A magnetic field of 1,830 gauss is produced by the small permanent magnet, and electrostatic scanning of the various ion beams is brought about by a motor-driven potentiometer in the source controls which causes the appropriate variations in accelerating voltage. When argon-40 is focused on to the collector slit the accelerating voltage is about 100 V. Ions are generated by the usual electron impact method of ionization[3], the ionizing electrons being emitted from a heated rhenium filament prior to being accelerated by falling through a potential difference of 70 V. Stable ion beams are produced with the trap current regulated at 50 μamp and these are detected with a d.c. amplifier having a 10^{11} Ω input resistor. The output is fed to a Honeywell–Brown potentiometric pen recorder, where the noise-level is less than an equivalent ion current of 2×10^{-15} amp.

Use of the static method[4] of analysis in mass spectrometry produces a great increase in sensitivity over the more usual dynamic mode. In the former technique a small fraction of gas from the inlet system is admitted to the tube, where it is then completely isolated and analysed. This requires that before such an analysis may be carried out the vacuum inside the mass spectrometer must be sufficient to ensure that isolation of the tube from the pumping system during a static analysis does not cause a significant rise in pressure. To satisfy such a requirement we have set up the *MS*10 so that it may be baked out inside an oven while being pumped out. The instrument is designed for regular baking at temperatures up to 400° C, but we have not found it necessary to exceed 200° C. With overnight baking little difficulty has been experienced in producing pressures of about 5×10^{-10} mm mercury, and these have been maintained, without further baking, over periods of several months. The pumping system uses a silicone oil, Dow Corning '705', in a metal diffusion pump—the latter being separated from the mass spectrometer tube by a liquid air trap, and being backed by a simple rotary pump. No difficulty has been experienced in reducing the background at the critical mass 36 to zero. At pressures of the order 5×10^{-10} mm mercury, the only significant peak occurs at mass 28 and is presumed to be due to nitrogen and carbon monoxide.

A very simple inlet system has been used and may be seen in Fig. 1. It is a simple matter to evacuate the inlet side so that any background contributions in the inlet at masses 36 and 38 are not detectable by the mass spectrometer and any at mass 40 is only just seen on the most sensitive range. Samples left overnight in the inlet system show no variation in 36/38 and 40/38 ratios with time.

It has frequently been reported by mass spectrometry workers that in static analysis the gases being analysed during a particular measurement are contaminated by a previous sample. Reynolds[4] has suggested that during an analysis ions are driven into the walls of the mass spectrometer tube. The composition of the embedded gases

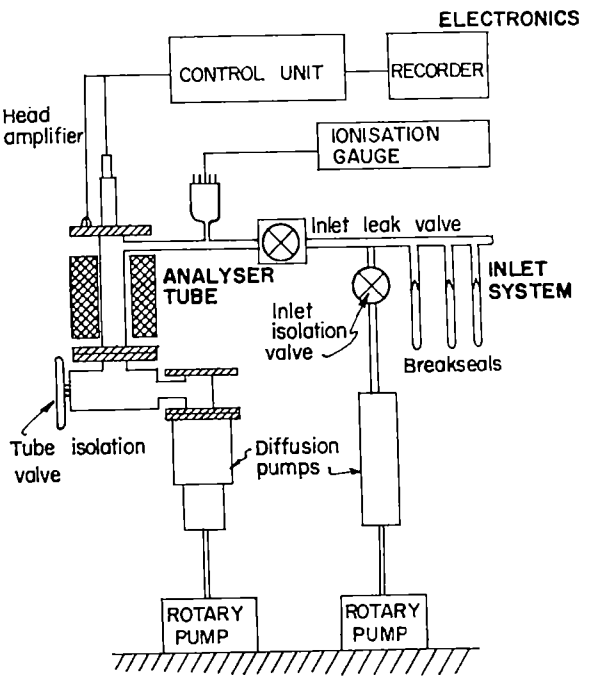

Fig. 1. Schematic diagram of experimental arrangement for static analysis of small volumes of argon on *MS*10 mass spectrometer

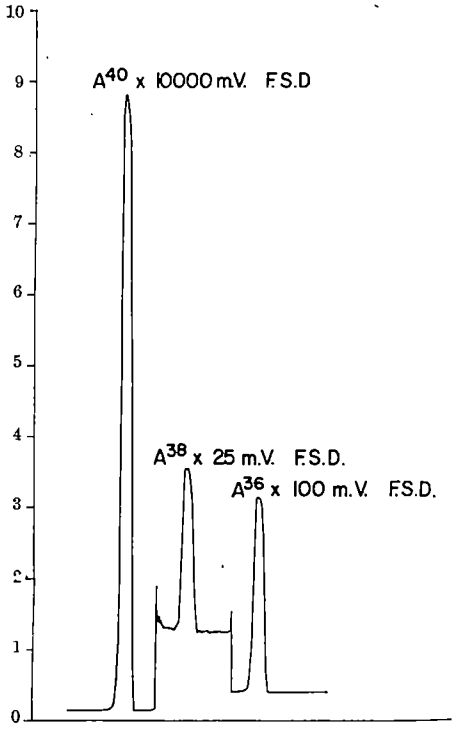

Fig. 2. Recording of atmospheric argon showing the resolution in the mass 36–40 range

would then be representative of that sample. During a subsequent analysis it appears that ion bombardment of the walls causes the embedded gases to be re-emitted into the sealed-off chamber, thus contaminating the new analysis and causing changes of the measured ratios with time. This 'memory' effect has long been troublesome and apparently is not removed completely by baking. In the *MS*10, for argon analysis, we find no trace at all of a memory effect. Measurements of the isotope ratios of an argon sample trapped in the tube for several hours show no variation with time. Peak heights barely change. This is an extreme advantage possessed by the instrument. We attribute this effect to the low accelerating voltages (100 V) used when examining the argon isotopes. That is, in this instrument, the positive ions bombard the walls of the mass spectrometer with a much lower energy than is usual. In most mass spectrometers several thousand volts are used for ion acceleration.

The isotope ratios obtained with the *MS*10 are critically dependent on the ion repeller voltage in the source. Ratios of $(^{40}Ar/^{36}Ar)_{at}$ varying from about 300 to 220 may be reproducibly produced by systematic settings of the repeller plate voltage. However, the measured ratio remains fixed for a given gas with a given repeller voltage setting. Thus, as there is no call to adjust the repeller voltage the discrimination is constant and easily found from analyses of atmospheric argon samples. The results of static analyses give good agreement with dynamic runs when the former are submitted to a root-mass correction to allow for fractionation through the inlet leak valve.

For argon analyses of this nature it is merely necessary to be able to resolve completely the peaks at masses 40, 38 and 36. This is not a severe requirement, and the *MS*10 is able to meet it. The resolving power is about 50. A typical recording of the mass spectrum of atmospheric argon is shown in Fig. 2. The argon-40 and argon-38 beams contribute no significant amount to each other. A more important feature to consider is the possible existence of 'tailing' of the argon-38 beam at the mass 36 position. As can be seen from Fig. 2, this is a negligible effect—the contribution two mass numbers away due to a beam at mass 38 is approximately 10^{-4} times of the size of the argon-38 beam.

Table 1. Table including Comparison of Analyses carried out in Toronto with others made in Various Laboratories on Same Mineral Sample

Sample	K (%)	Atm. (%)	^{40}Ar (p.p.m.)	Lab.	Age (m.y.)

$\lambda_\beta = 4{\cdot}72\ 10^{-10}$ yr.$^{-1}$. $\lambda_e = 0{\cdot}584\ 10^{-10}$ yr.$^{-1}$.

The older a mineral, the greater its argon content, the easier the mass spectrometric analysis. We have carried out fifty accurate argon analyses on mineral samples in the course of four months' work. The youngest sample we have analysed so far is a 50 m.yr.-old biotite. One g of this sample produced approximately $1{\cdot}4 \times 10^{-5}$ c.c. at N.T.P. for analysis by isotope dilution with argon-38 as the diluent. This represented far more gas than was actually needed for analysis. The manufacturers claim the sensitivity to be 5×10^{-5} amp/mm mercury, and our work indicates a figure similar to this. In Table 1 some of our results are shown, and comparisons with those obtained on the same samples by other laboratories using standard mass spectrometers are made. The close agreement in age between biotite XXIII and hornblende XXIII is noteworthy. These co-genetic minerals differ in potassium content and hence in argon content by a factor of thirty, suffered totally different atmospheric argon contaminations and still produced identical ages.

Our experience leads us to conclude that it is straightforward to use the *MS*10 mass analyser for isotopic dilution determination of the minute amounts of argon-40 generated in rocks by the radioactive decay of potassium-40. Isotope ratios can be measured with an accuracy of $\pm 0{\cdot}5$ per cent after calibration of the amplifier and recorder system. It is clear from our experiments that 1 g of a biotite 1 m.yr. in age would yield definitely sufficient argon to be measured by the *MS*10. This demonstration could have useful consequences. Laboratories at present unable to afford the more elaborate mass spectrometers could doubtless now consider

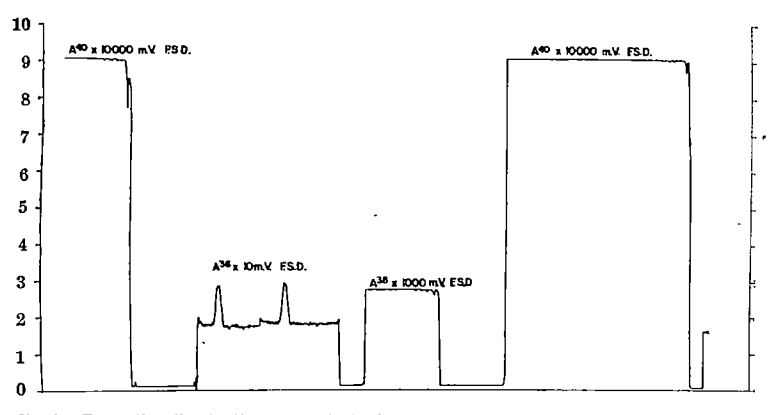

Fig. 3. Recording illustrating argon isotopic ratios in a typical analysis of a Grenville biotite

the variety of simple background analysers available of which one at least has been shown to be entirely suitable.

We thank Profs. R. M. Farquhar, J. T. Wilson, G. D. Scott and H. L. Welsh and Dr. J. A. Miller for their advice and help. This work was supported by grants from the National Research Council of Canada and the Geological Survey of Canada.

ACTIVE TRANSPORT OF ALKALINE EARTH IONS AS PHYSIOLOGICAL BASE OF THE ACCUMULATION OF SOME RADIONUCLIDES IN FRESHWATER MOLLUSCS

By O. VAN DER BORGHT and S. VAN PUYMBROECK

Radiobiology Department, Centre d'Etude de l'Energie Nucléaire, Mol, Belgium

TRANSPORT of calcium ions against an electrochemical potential gradient has been described in a variety of biological objects such as the proximal tubuli[1], the giant axon[2], the small intestine[3], the endoplasmic reticulum and other sub-cellular fractions[4,5]. In freshwater molluscs it was also suggested, but is not yet proved, that such an active transport may exist[6–8]. This aspect of calcium metabolism is of interest because molluscs are one of the most important groups of calcium-binding organisms, and because freshwater molluscs can serve as indicators for the radiocontamination of their habitat, for example, for strontium-90 (ref. 9) and radium-226 (ref. 10).

Active transport[11] of a substance implies essentially the intervention of metabolic energy. The necessity of this intervention will be established when an ionic substance such as Ca^{++} moves from a compartment having low chemical activity to one with high activity, and when this movement is not induced by electrical field or solvent drag[16].

In order to verify the existence of active uptake, we have to investigate: (1) whether a difference in concentration of calcium exists, and whether this calcium is diffusible[12] between internal and external *milieu*; (2) whether a potential difference between these two media could account for the calcium-fluxes observed[8].

Lymnaea stagnalis (L.) from a laboratory culture was used in most experiments.

The concentrations of calcium and strontium are measured by flame-spectrophotometry (Unicam *SP* 900), the radioactivity of strontium-85 and barium-133 with a single channel pulse-height analyser in a sodium iodide well crystal and the radioactivity of calcium-45 by liquid scintillation with a Packard 'Tri-Carb'. The potential differences were measured with a mV-meter (10^{11} ohm internal resistance, radiometer *pHM* 22). The movable electrodes were made from glass capillaries extended at their larger end with polyethylene tubing and filled with 3 M potassium chloride agar. These electrodes were in turn connected to the mV-meter over calomel–potassium chloride bridges.

The dialysing membrane used was a cellulose membrane supplied by Fisher Scientific Co. (Cat. No. 8–667–1), with an average pore diameter of 25 Å. Before use, it was saturated with an aqueous 5 per cent calcium chloride solution and rinsed with demineralized water until the washing water contained less than 0·01 mg/l. calcium. This membrane did not show an adsorption of calcium-45 from the blood of animals loaded with calcium-45. The statistical errors of the mean values given are the fiducial limits[15] at 95 per cent ($= \bar{x} \pm t.s_{\bar{x}}$).

(*a*) *Concentration of calcium in the blood.* The total concentration of calcium in the blood averages 150–200 mg/l., but a net uptake of calcium is possible if only 5 mg/l. calcium are present in the water. Such a concentration gradient could only exist on the basis of diffusion if the epithelium of *L. stagnalis* were permeable to calcium ions and if calcium in the blood were present in a bound form so that the diffusible blood calcium remained below 5 mg/l. The concentration of diffusible calcium in the blood can be determined by compensation-diffusion[13] of blood against solutions of calcium, without the risk that some calcium-binding components could dissociate[14]. Blood is collected in ice-cooled tubes, and 5 ml. (Ca = 166 ± 5 mg/l.) was dialysed in a basket against 5 ml. calcium chloride solution of 166 or 114 mg/ml. (at 2° C) in hermotically closed polyethylene bottles of 15 ml. capacity. Equilibrium is fully established after 24 h. In four experiments the solutions of 166 mg/l. calcium were still at the end of dialysis at 166 ± 8 mg/l., thus not changing their concentration significantly.

The solution of 114 mg/l. calcium changed to 137 ± 3 mg/l. during dialysis. If all the blood calcium is diffusible one can calculate that the final concentration should be 140 mg/l.; 94–100 per cent calcium in the blood must therefore be in a diffusible form, and diffusion alone could never result in a net movement of calcium from the water to the blood of the animals.

(*b*) *Concentration of strontium in the blood.* Four groups of 10 *L. stagnalis* were placed in 200 ml. water containing originally 40 mg/l. calcium and 5 mg/l. (Sr + ^{85}Sr). The blood contained no measurable strontium before the experiment.

The radioactivity of the blood in these animals, corresponding to 14 mg/l. (Sr + ^{85}Sr), was four times higher than that of the surrounding water after 48 h. This concentration gradient of strontium indicates an active uptake since in five experiments on compensation diffusion of 3-ml. blood dialysed against 5-ml. of a solution of 170 mg/l. calcium + 14 mg/l. strontium, a homogeneous distribution of strontium-85 is obtained. The results of these experiments were for the radioactivity outside the dialysing basket 831 ± 5 c.p.m./ml., and for the radioactivity inside this basket 848 ± 7 c.p.m./ml. Not more than 3 per cent of the strontium in the blood could thus be non-diffusible. Hence it appears that the concentration gradient for strontium as well as for calcium cannot be obtained nor even maintained by diffusion alone. If we consider the animal as having a constant volume, solvent drag alone[16] could not cause the observed accumulation. Indeed, it would be necessary to remove the solvent from the animal to maintain this constant volume. An active uptake of ions would have to occur in conjunction with the efflux of solvent in order to preserve the high internal concentration of Ca^{++} and Sr^{++} and to permit a net uptake of these ions from the external medium.

(*c*) *The potential difference between the animal and the water.* Histological preparations showed multiple blood-spaces directly under the epithelium, for example, in the

mantle of the snails. A small wound on the top of the shell produces extrusion of a little drop of blood. Since this blood is highly conducting (1,200 mg/l. Na^+) an electrode can be placed in this drop and a reference-electrode in the water. The shell is maintained dry (for example, by silicone grease) and kept outside the water, whereas the soft parts of the snail are left in the water. Thus the potential difference (*PD*) between the two sides of the epithelium that separates blood from water can then be determined. The *PD* disappears at once when the reference electrode is brought through the epithelium. This indicates that no other electrical barrier between the inner side of the epithelium and the drop of blood exists. Between two wounds on the shell, the *PD* was also zero. The *PD*'s measured varied from -5 to -30 mV (inside negative) with an average of about -15 mV.

If one applies the equation of Ussing[16]:

$$\frac{\text{outflux}}{\text{influx}} = \frac{\text{internal concentration}}{\text{external concentration}} \times e^{\text{exponent } \frac{Z.F.\ (V \text{ int.} - V \text{ ext.})}{R.T.}}$$

where e, napierian base; F, faraday (96,500 coulombs/g. equiv); R, 8,3144 joules; T, 293° K; V, PD (V); Z, charge of the ion (+ 2 for Ca); concentration considered as = activity; and assumes stationary conditions where outflux equals influx, at an external concentration of 10 mg/l. calcium and a PD of $-$ 15 mV, one finds that such a PD could maintain an internal concentration of about 31 mg/l. Since the internal concentration is as high as 150 mg/l., this PD cannot be responsible for the accumulation of calcium in the animal.

Other freshwater molluscs such as *Planorbis corneus* (L.) and *Lymnaea auricularia* (L.) can also concentrate calcium-45 and strontium-85 in their blood to levels similar to those attained by *Lymnaea stagnalis*.

(*d*) *Experiments with barium*-133. Investigations with barium-133 were carried out at low concentration in the water (0·01 mM) to avoid lethal toxic effects. Ba seems also to be taken up under these conditions, but the blood-level in *L. stagnalis* did not exceed that of the surrounding water after 76 h, although the whole animal was about 10 times more radioactive than the same volume of water.

In conclusion, the concentrating ability of these freshwater snails for some radionuclides seems to be due to an active absorption of some alkaline earth ions from dilute solutions.

We thank R. Kirchmann and Dr. G. Gerber for their advice and help.

SIMULTANEOUS MEASUREMENTS AND SPECTRAL ANALYSIS OF MICROPULSATION ACTIVITY

By R. L. KOMACK and A. S. ORANGE
U.S. Air Force Cambridge Research Laboratories
F. X. BOSTICK
University of Texas
AND
Dr. T. CANTWELL
Geoscience, Inc., Cambridge, Mass.

A PREVIOUS article[1] described a series of simultaneous measurements of telluric micropulsation activity involving recordings made in Austin, Texas, Puerto Rico and Trinidad. Initial results were reported concerning power spectra and coherency of the signals in the frequency-range of 0·01–0·25 c/s. Further processing and analysis of the data have led to additional interesting observations and the correction of some of the initial results.

The investigation consisted of an experimental programme during October 1962. Micropulsations of the Earth's electric field were recorded simultaneously at three stations: Austin, Texas (30° 18′ N., 97° 47′ W.), Camp Tortuguero, Puerto Rico (18° 29′ N., 66° 25′ W.), and the U.S. Naval Air Station, Trinidad, West Indies (10° 42′ N., 61° 38′ W.). The stations at Austin and Puerto Rico were operated by the Electrical Engineering Research Laboratory of the University of Texas. The Trinidad station was operated by the Communications Sciences Laboratory, U.S. Air Force Cambridge Research Laboratories. Approximate distances between stations were: Trinidad–Puerto Rico, 600 statute miles; Puerto Rico–Austin, 2,100 miles; and Trinidad–Austin, 2,700 miles.

At all three locations electrodes were placed in the ground approximately 0·5 km apart along magnetic north–south and east–west lines and connected to a low pass filter used for rejecting 60 c/s interference. After broadband pre-amplification the signal passed through an active band-pass filter. The half-power points of the filter were 0·01 and 1·5 c/s with attenuation rates of 6 dB per octave below the passband and 12 dB per octave above. After final amplification the signals were recorded on paper charts at a recording speed of 60 mm/min. Accurate timing was supplied by a stable-frequency standard, synchronized with *WWV*.

Recordings were made continuously through the month of October 1962. Twelve data samples approximately 1 h each in length were selected for analysis, hand digitized and put on to punched cards for computation. The data were sampled at 2-sec intervals. Great care was taken in the digitization process to ensure that all channels were sampled simultaneously.

The analysis of the signals included the computation of the resultant electric field vector, power spectra, coherencies and coherency phase angles. The analysis was

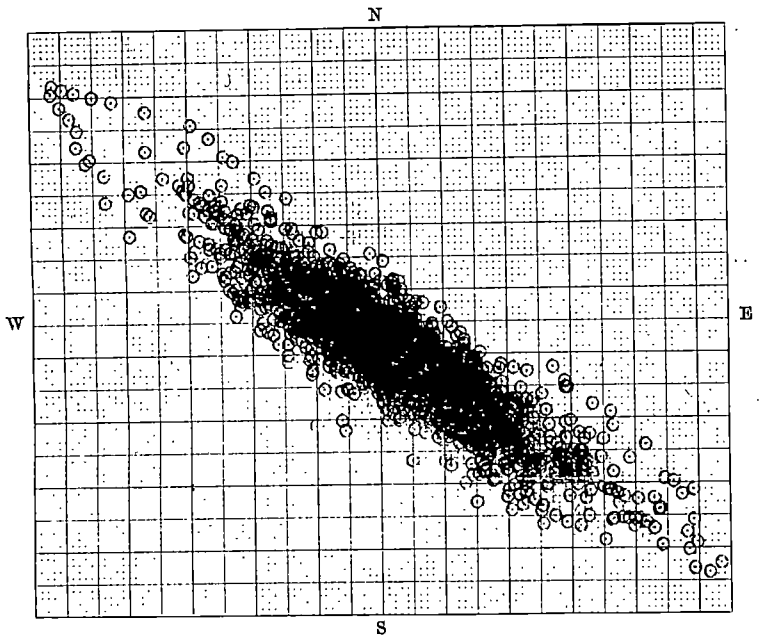

Fig. 1. *X–Y* plot of electric field data—Trinidad, October 28, 1962, 1200–1300 G.M.T.

done on an IBM 7090 using programmes developed by Simpson and utilizing the Daniell method of spectral resolution.

In order to determine the direction of the resultant electric field vector the digitized data were displayed on an *X–Y* plotter. For each sampling point the north–south voltage was plotted as the ordinate and the east–west voltage as the abscissa. All the data points for each hour-long sample were plotted together. Fig. 1 is an illustration of the result for the signal recorded on October 28, 1962, at Trinidad. Note the strongly elliptical polarization, an effect common to almost all the samples examined. For each sample the average value of the *E* vector was estimated by passing the best-fitting straight line through the data points. Table 1 is a compilation of the results for the 12 data samples which were digitized. Blanks represent plots for which it was difficult to determine the major axis of the ellipse, due primarily to low signal-to-noise ratio. Remarkably little variation in the vector direction is noted even though the data samples cover a period of 17 days and the hours 0700–2230 G.M.T. Fig. 2 is a map of the recording station locations showing the 12 sample average electric field direction. The limits of the vector over the samples are also shown.

The little variation noted in the direction of the electric field and the orientation of the resultant fields as shown in Fig. 2 indicate the strong influence of local topography and geology on telluric currents. For the case of Trinidad, an island situated about 50 km from Venezuela, the vector clearly parallels the dominant physical feature, the coast of South America, the boundary between conductive sea-water and more resistive continental mass. The *E* field at Austin, situated about 200 km inland from the Gulf of Mexico, is oriented roughly normal to the coast-line. On the island of Puerto Rico the orientation is roughly parallel with the West Indies chain. Although these islands are themselves quite a small topographical feature they are the visible portion of a large ridge of volcanic origin which is mostly submerged.

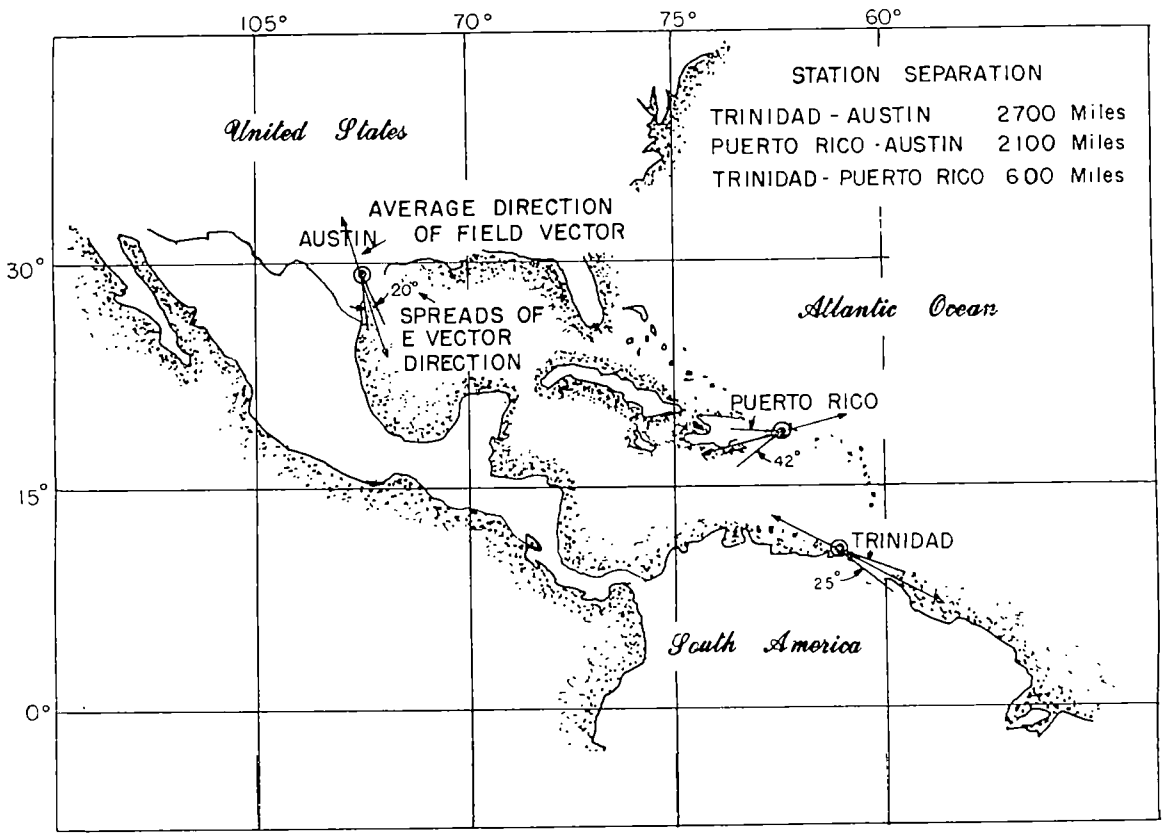

Fig. 2. Orientation of electric field vectors at Austin, Puerto Rico and Trinidad

Table 1

Sample	Date	G.M.T.	Average E vector direction, degrees west of magnetic north: Trinidad	Puerto Rico	Austin
A	13/10/62	1030–1115	67	131	32
B	15/10/62	0930–1040	55	—	30
C	16/10/62	1030–1145	53	97	—
D	17/10/62	0800–0915	40	95	24
E	20/10/62	1210–1355	54	85	15
F	24/10/62	1025–1155	52	98	35
G	24/10/62	1500–1600	62	100	26
H	28/10/62	1200–1300	54	93	27
I	30/10/62	0700–0815	55	92	29
J	30/10/62	1245–1400	55	—	—
K	30/10/62	1615–1715	53	93	19
L	30/10/62	2130–2230	55	94	—
	Averages		55° +12 −15	98° +30 −13	26° +10

The foregoing results may be partially explained by considering the idealized case shown in Fig. 3*a*. Two regions, land with conductivity σ_L and sea-water with a conductivity σ_S, are separated by a sharp boundary. In the vicinity of the boundary the tangential component of the electric fields and the normal components of the induced currents will be continuous, that is:

$$E_{T_L} = E_{T_S} = E_T \qquad (1a)$$

$$J_{N_L} = J_{T_S} = J_T \qquad (1b)$$

E and J are related through the familiar expression:

$$E = \frac{J}{\sigma} \qquad (2)$$

where σ = conductivity of the medium in mhos/m. In practice the conductivity of the sea (approximately 5 mho/m) is considerably larger than that of the land mass (approximately 1–10 m mhos/m).

Consider now Fig. 3*b*. As measured on the land, the electric field $\bar{E}$ will have components normal and tangential to the boundary. From the continuity relationships the

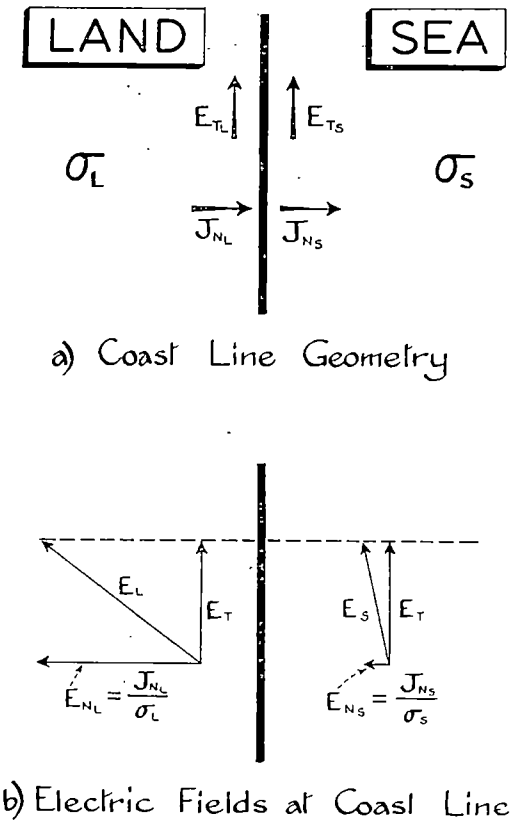

Fig. 3. Idealization of the 'coast-line' effect

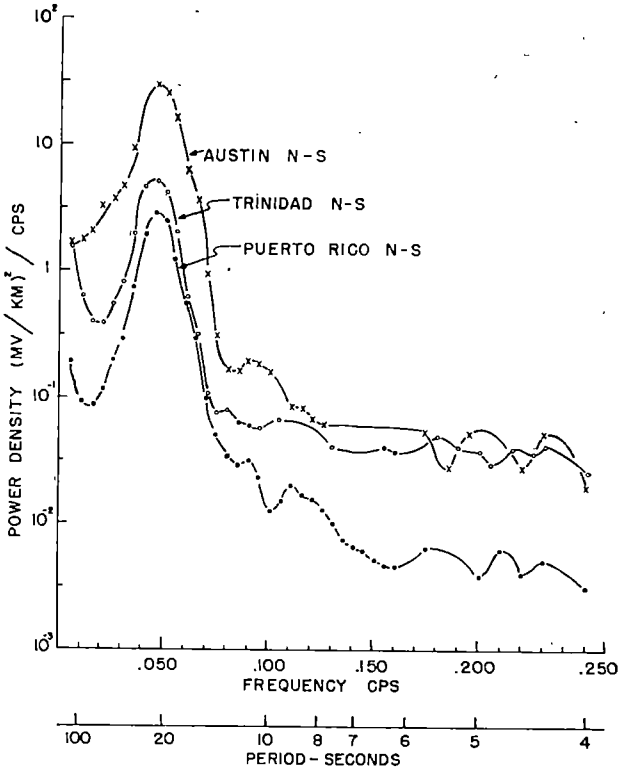

Fig. 4. Telluric current power spectra for simultaneous data, October 13, 1962, 1030–115 G.M.T.

tangential electric field measured in the sea will be the same as that for the land. Since the normal induced current must also be continuous and applying expression (2), the normal electric field as compared with that on land will vary inversely with the conductivity ratio. Since the sea-water conductivity is much larger than that on land the normal component will be much smaller. If σ_L is 0·1 per cent of σ_S, as would not be uncommon, then E_{N_S} will be 0·1 per cent of E_{N_L}. The result is that in any case except where E_L is directly normal to the boundary the resultant field as measured in the sea will be predominantly tangential to the boundary. This 'coast-line effect' is well illustrated at Trinidad. At Austin, although the site is about 200 miles from the coast the data probably reflect the influence of the sea and the propensity for the currents to flow towards the good conductor. The Austin situation is further complicated by the presence of 1/2–1 ohm-m sediments in the Gulf Coast region, resulting in an unclear land–sea boundary.

Additional power spectra and coherency computations have shown that those previously reported (ref. 1, Figs. 3–5) were in error. Corrected power spectra and coherency curves are shown in Figs. 4–6. Fig. 4, power spectra for data recorded simultaneously on October 14, 1962, displays distinct peaks at the pc frequency at all three recording locations. Note the identical peak frequency and the near-identical shape of the curves representing data recorded as much as 2,700 miles apart. Fig. 5 shows power spectra of data recorded at Austin on three separate days. The energy peak at the pc frequency is seen to vary by a factor of 3. Figs. 4 and 5 indicate that theories attempting to describe pc-type oscillations must satisfy the requirement of little latitude dependence while explaining the vast day-to-day variation in peak frequency.

Fig. 6, plots of the coherency between micropulsation data recorded on October 24, 1962, further demonstrates the simultaneity of events observed at different locations. High coherency is noted over a broad range of frequencies and even in the Trinidad–Austin case displays peaks in excess of 0·8. The fine structure observed appears on many

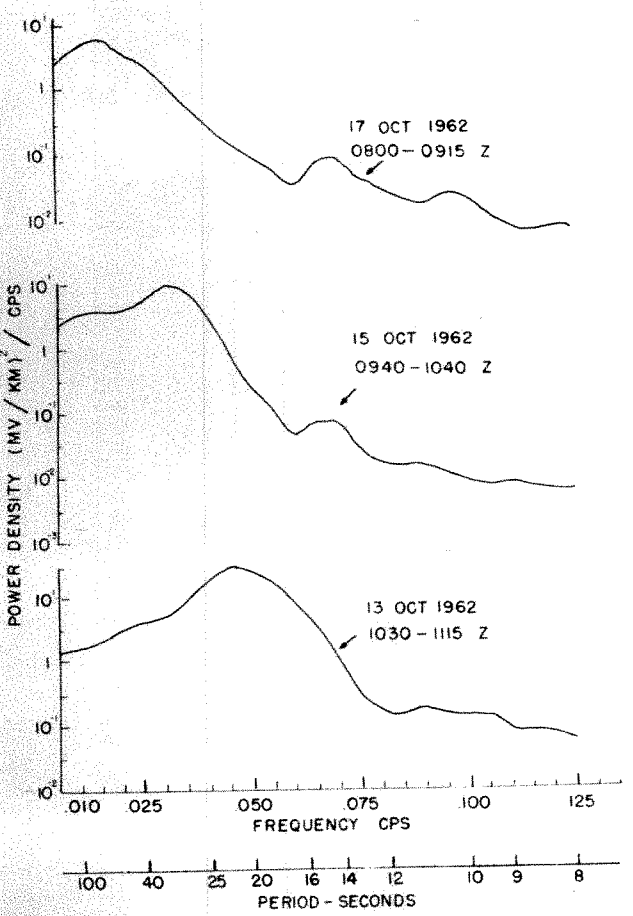

Fig. 5. Telluric current power spectra: Austin north–south recordings

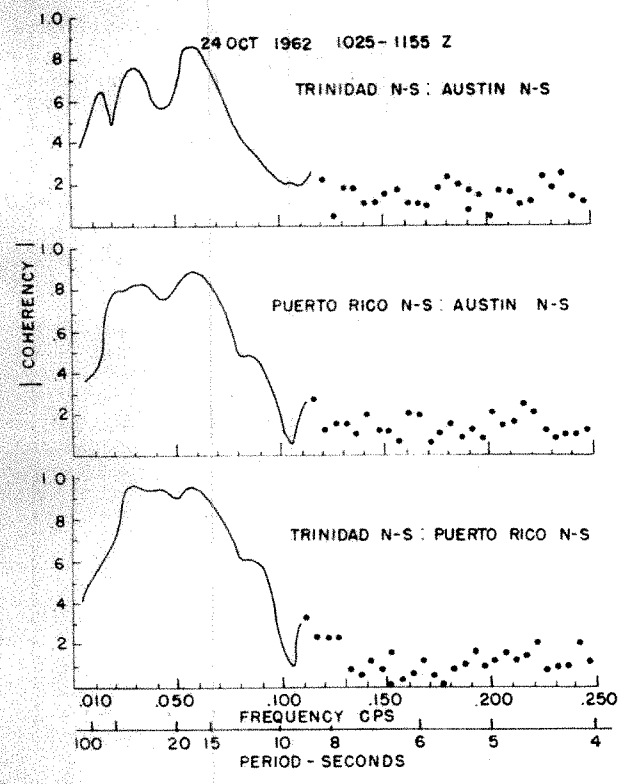

Fig. 6. Coherency analysis of Trinidad–Puerto Rico–Austin data

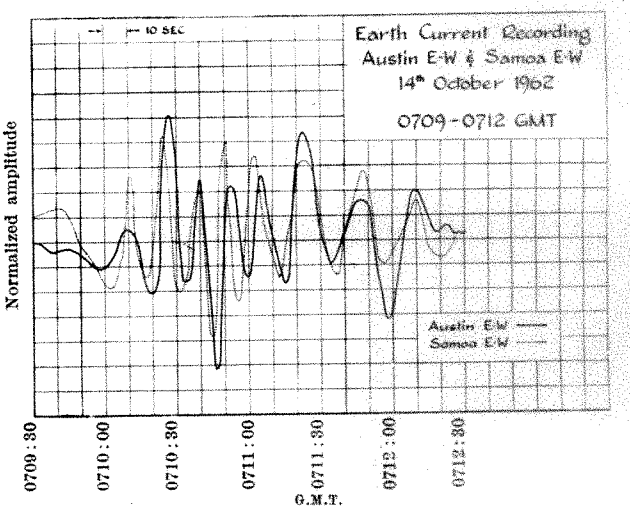

Fig. 7. Simultaneous micropulsation data, Austin east–Samoa east

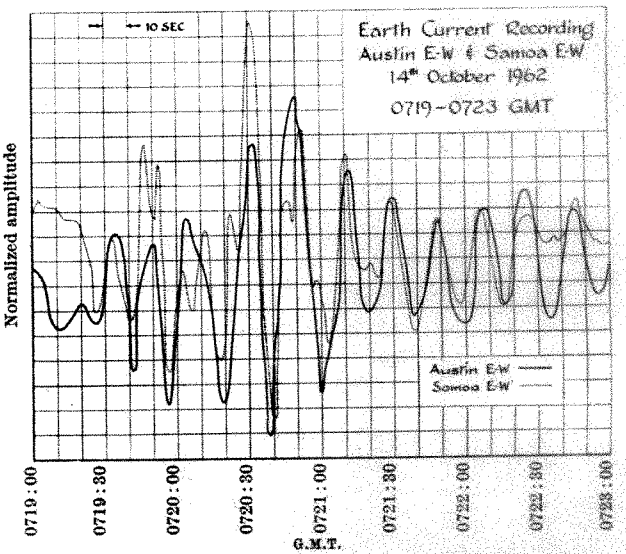

Fig. 8. Simultaneous micropulsation data, Austin east–Samoa east

of the computed coherency curves, but it is felt that insufficient data have been processed to allow meaningful comment concerning this phenomenon.

Telluric current micropulsations were also recorded during October 1962 on the island of Samoa in the South Central Pacific Ocean by an NRA, Inc. (New York, N.Y.), group. Comparison of data obtained at Samoa with those obtained at the University of Texas-*AFCRL* stations has yielded information concerning the widespread occurrence of some effects. Figs. 7 and 8 are plots of pt-type events that were simultaneously recorded at Samoa and Austin, Texas. For each case the Samoa east–west and Austin east–west data are plotted together normalized so that the peak amplitudes are roughly similar. The cycle-for-cycle similarity is striking considering that the records were obtained at stations separated by approximately 73° in longitude and 45° in latitude. At times in these figures the two signals appear perfectly synchronized. At others, such as 0709 : 50 (Fig. 7) and 0722 : 10 (Fig. 8), the Samoa signal appears to lead Austin. As yet there is no satisfactory explanation of this 'wandering' phase shift; more observations are required to evaluate the effect.

We thank Dr. S. Goldblatt of NRA, Inc., for permission to use the results obtained at Samoa.

EXPERIMENTAL POST-TRAUMATIC DYSTROPHY IN THE RABBIT

By Dr. P. KREDIET

Institute of Veterinary Anatomy,
State University of Utrecht

As a result of affections of the brain, of the spinal cord, the heart or the lungs, and especially of traumata, dystrophic phenomena for man frequently occur in the arm. If a trauma is the cause, then it is called post-traumatic dystrophy.

Hackethal[1] has shown that bruising or constriction of the n. ischiadicus in the rabbit leads to almost identical phenomena in the hind leg. His theory is that with the trauma bruising of the nerve takes place which gives rise to an ascending neuritis, which again leads to propulsive pressure on the nerve in the foramen intervertebrale.

Post-traumatic dystrophy phenomena, however, lead one to suspect a neurovegetative disregulation in the affected area. Cerebro-spinal nerves also contain vegetative fibres. To test this experimentally it is necessary in the first place to produce a lesion in the vegetative nervous system, and, if possible, with complete avoidance of any injury to the cerebro-spinal nerve fibres. Following Coujard's method[2], phenol was used as the damaging agent. The lesion of the ganglion stellatum and the plexus pelvicus caused post-traumatic dystrophy to appear in the hind legs of the rabbit along with irritation of the ganglion stellatum.

For the sake of simplicity the rabbits were treated only with phenol mixed in paraffin with a low melting-point—the injection being near the mouth of the bladder. Following this, diffusion to the plexus pelvicus occurred.

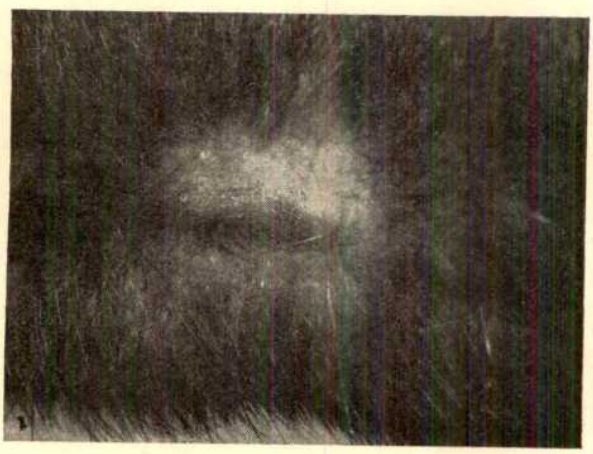

Fig. 1. Post-traumatic dystrophy in the rabbit starts with falling fur on the dorso-lateral side of the hind-leg

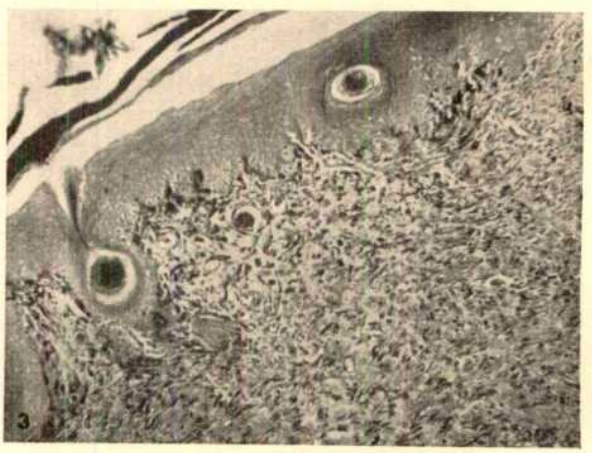

Fig. 3. The skin of the dorso-lateral side of the hind-leg in a dystrophic animal. Wide capillaries in the subcutis. Champy–Coujard technique

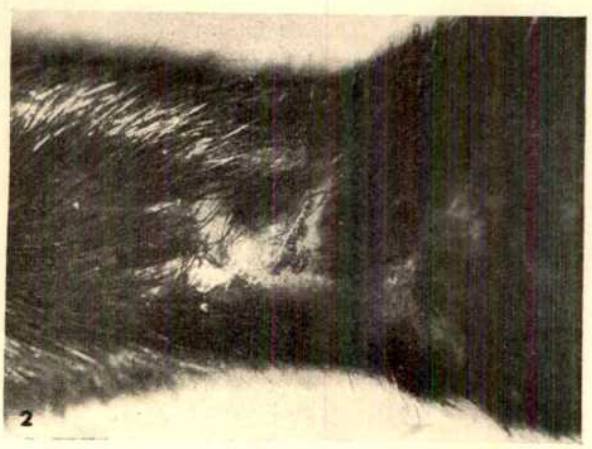

Fig. 2. Later skin lesions occur

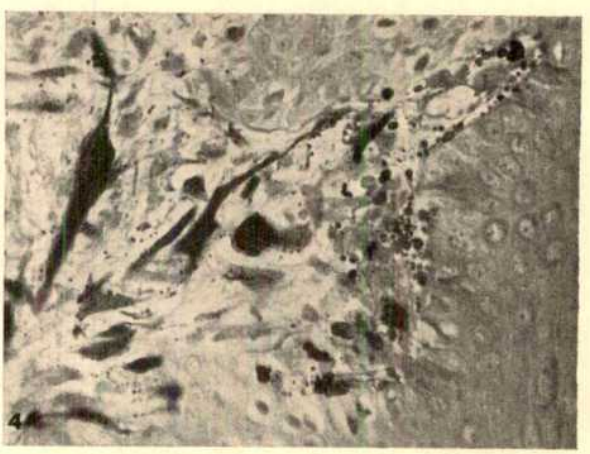

Fig. 4. Positive, black-stained interstitial cells of Cajal near capillaries in a dermal papilla. Champy–Coujard technique

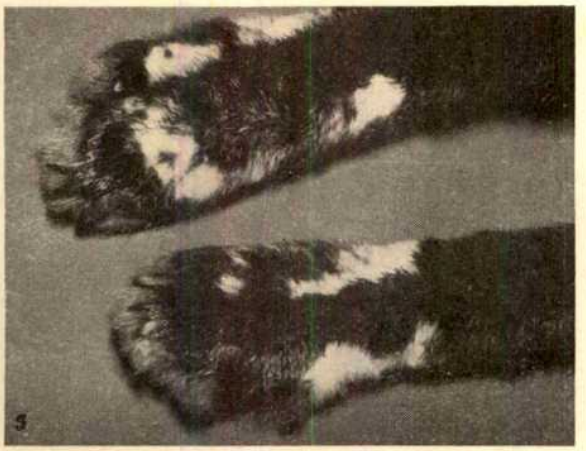

Fig. 5. The predilection places are marked after recovery, as the fur regenerates unpigmented

motor end-plates may also be detected by means of cholinesterase reaction.

In order to obtain an impression of the order in which the phenomena occur they have been set out graphically against time. Rabbit 9980 (Fig. 6) is an example of this. It is clearly visible that the phenomena in the skin arise first (within one week). The macroscopic and microscopic changes in the skin are so closely correlated that in the histogram the findings are combined. Then the reflexes decrease (three weeks after the dose of phenol). A muscle biopsy four weeks after the dose of phenol shows that, with strongly decreased reflexes, the motor end-plates, rendered visible by means of the cholinesterase reaction, are still about normal. The state of the peripheral vegetative nervous system in the muscles, however, is already considerably disturbed. After seven weeks clinical dystrophy is maximal, the reflexes have disappeared, yet the end-plates are still normal. The vegetative disturbance is now quite manifest, though only after eight and especially after 10–12 weeks, do the end-plates show a seriously disturbed picture together with strong reactions in the

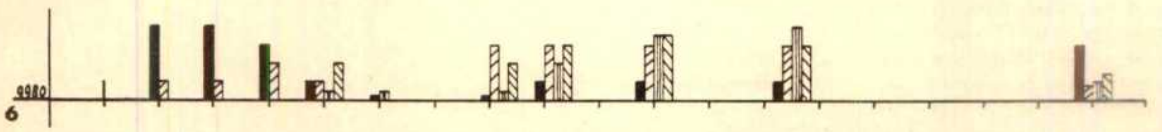

Fig. 6. Diagrammatic representation (rabbit 9980). Black, reflexes (high, normal); hatched, right down to left, clinical dystrophy and microscopic skin alterations; hatched (vertical), abnormal motor end-plate; hatched, left down to right, reactivity autonomic periphery in the muscle

Numerous post-mortem investigations have shown that the phenol did not penetrate to the cerebro-spinal plexus lumbo-sacralis.

Symptoms of post-traumatic dystrophy in the rabbit are: fur falling out, beginning on the dorso-lateral surface of the lower foot (Fig. 1), discoloration of the skin, œdema, and, later, wound formation (Fig. 2). Sometimes the area affected expands on the sole of the lower paw while, on occasions, the forepaws are also affected.

After some time a decrease of muscle reflex occurs in the hind legs. This reflex is occasioned by exercising a sudden pressure on the muscles of the lower legs while the hind legs are stretched. This decrease of the spread reflex indicates impotence in the muscles of the lower part of the foot, a phenomenon which also occurs with human patients (powerlessness in the hands). During later stages of the disease, club foot regularly occurs. With man the loss of power in the hand leads to a kind of claw-like appearance. In the rabbit, after some time a general recovery may take place. The regenerating fur is unpigmented (Fig. 5).

The first symptoms appear in the skin, commencing with loss of hair and œdema. In histological sections the strongly expanded capillaries in the skin are especially striking (Fig. 3). In sections of tissue, stained according to the Champy–Coujard method (a mixture of OsO_4 and ZnI_2), the peripheral vegetative nervous system appears to be in a very reactive stage (Fig. 4). This is especially evident from a far stronger coloration of the network of nervous fibres and interstitial Cajal cells, situated immediately below the cutis and within the internal cutis papillæ, mainly immediately along and around the capillaries. The basal layer of cells in the cuticle sometimes shows a black granulation, which has also been observed with some human patients, while the so-called Langerhans cells show a stronger reactivity. This is presumably connected with a strong increase of sensitivity to touch of the areas of skin affected.

In the further stages of the disease dystrophic changes also occur in the muscles. The findings of the muscle biopsies are described by Dr. Wiertz-Hoessels (following article). To sum up, it may be said that in the muscles, too, the reactivity of the peripheral vegetative nervous system increases while in the later stages changes in the vegetativum. After 18 weeks the symptoms have greatly decreased, the reflexes are normal again, and the condition shown by the muscles also subsides.

It appears that as a result of these experiments it can be stated that post-traumatic dystrophy can be provoked in an entirely vegetative manner. In contradistinction to Hackethal's ascending neuritis theory we would assume that the disease may be introduced as follows: the trauma, both a brief and a severe one (for example, a fracture) as well as a prolonged and moderate one (for example, excess strain), causes a local state of irritation to which the vegetative nervous system is sensitive. Should the level of irritation exceed a certain value, which is defined by individual sensitivity (vegetatively unstable persons), then a more general state of irritation occurs in which presumably the central part of the vegetative nervous system in the diencephalon is concerned. In the spots of least resistance the trophic supply becomes irregular and symptoms of post-traumatic dystrophy occur, with man in the hand and the shoulder, with the rabbit on the dorsal surface of the paws and the whole hind legs.

From this we would deduce, as a provisional conclusion, that the first therapy of a trauma should be directed to the stimulation of the blood supply to the area affected. With human patients, Thornban[3] observed as early as after three days over-filling of the subcutaneous capillaries when post-traumatic dystrophy was developing, otherwise not. Some rabbits, too, after four days already showed post-traumatic dystrophy. This is entirely in accordance with the view that the task of the peripheral part of the vegetative nervous system is above all a trophic one.

This work is being carried out in collaboration with Prof. J. F. Folkerts (Valeriuskliniek, Amsterdam) and Dr. E. L. M. J. Wiertz-Hoessels (Institute of Veterinary Anatomy, Utrecht). It was supported by the European Community for Coal and Steel in Luxembourg (Folkerts, Krediet, Sneep, Wiertz-Hoessels), and since 1963 by the Netherlands Organization for Pure Research (Z.W.O.), Den Haag (Folkerts, Krediet, Wiertz-Hoessels).

INFLUENCE OF TROPHIC DISTURBANCES ON SKELETAL MUSCLE INNERVATION

By Dr. E. L. M. J. WIERTZ-HOESSELS

Institute of Veterinary Anatomy, State University, Utrecht

TROPHIC disturbances may occur in man in connexion with traumata but also as a result of affections in the central nervous system or chest organs. In the patients examined, the cause was, respectively: neuritis of the median nerve, amputation of the right index as the result of an industrial accident, and a left hemiplegia in consequence of thrombosis cerebri. All are patients of Prof. J. F. Folkerts, Neurological Department, Free University of Amsterdam (Valerius Clinic). In laboratory animals—rabbits—similar symptoms were observed after section of the sciatic nerve, while it was possible to stimulate the symptoms experimentally by irritation of the stellate ganglion and the plexus pelvicus by means of phenol. The symptoms also appeared in the rabbit, once after surgical research into pregnancy and once after injection of methylene blue in the foreleg.

The trophic disturbances known as post-traumatic dystrophy (see preceding article), which in man are indicated as 'hand–shoulder syndrome', consist, among other things, of discoloration of the skin and falling out of the hair, pain, rigidity of the joints, œdema and paralysis of the muscles. With the experimentally stimulated syndrome in animals, falling out of the fur is first observed. A fixed sequence is proved of the most liable areas. In contrast to man, in the rabbit it is in the first instance the lateral and dorsal sides of the lower foot of the hind-leg. The symptoms of these animals are comparable with those in man.

With those affections, extensive disturbances are evident in the cerebro-spinal and in the neuro-vegetative innervation of the skeletal muscles in the region concerned.

In view of the character of the clinical symptoms, changes may be expected in the first place in the vegetative innervation of the muscles. This occurs mainly by way of the blood vessel- and capillary-innervation. As Meyling[1] has pointed out, the post-ganglionic ortho- and parasympathetic nerves do not end directly on the tissues which they innervate, but on a linked network of the interstitial cells of Cajal. This is formed by small ganglion-like cells with long varicose prolongations. The network is not adrenergic or cholinergic, but preponderantly either one or the other[2]. Slides of material treated with the Champy–Coujard technique gave results which may be better interpreted than those of material treated with the cholinesterase reaction. The latter was applied by us according to Koelle in the modification of Gerebtzoff, whereas, besides this, we applied silver impregnation (Bielschowsky-Gros and Bodian), intravital methylene blue staining (Coers and Woolf), and gold chloride staining (Gairns) to obtain an idea of the total innervation. In normal circumstances interstitial cells occur around the capillaries, the prolongations of which envelop the vascular tissue more or less densely (Fig. 1). When a post-traumatic dystrophy has developed, the aspect proves to be quite different. The innervation pattern is irregular with the Champy–Coujard reaction (Figs. 2 and 3). The capillaries which mostly have a very irregular course are, on the whole, strongly innervated. Moreover, it is striking that between the somewhat irregular muscle fibres numerous black cell elements occur, sometimes larger than the normal interstitial cells, though all belonging to this group. In contrast with the normal case, they very seldom have contact with capillaries. These cells with their prolongations sometimes form networks all over the muscle tissue. Sometimes they have granular contents and have a remarkable resemblance to the interstitial cells that Meyling[1] found in the normal intestinal wall after vital methylene blue staining. In the patients we repeatedly saw similar cells occur in the connective tissue round the muscle fibres and sometimes in contact with prolongations of pericapillary interstitial cells.

As will be pointed out in a more extensive article in preparation with Prof. J. F. Folkerts and Dr. P. Krediet, it was evident that in the rabbit changes in the adrenergic system were correlated with macroscopic changes of the

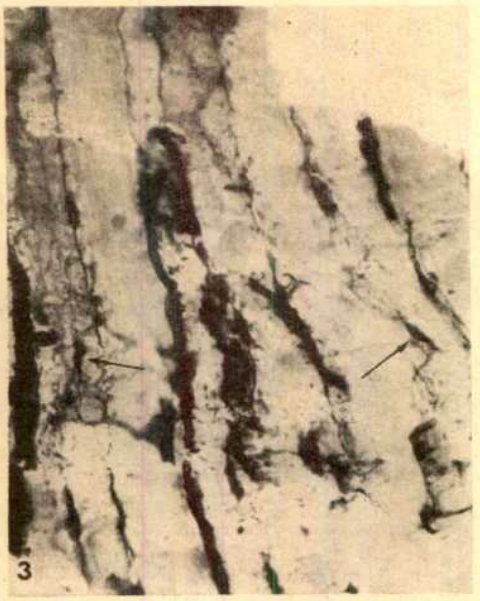

Fig. 3. Abnormal adrenergic muscle innervation in man in a case of post-traumatic dystrophy. Interstitial cells occur without contact with the capillaries (↗). (Champy–Coujard method)

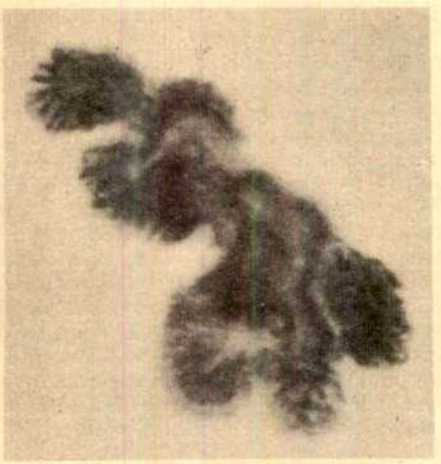

Fig. 4. Normal human motor end-plate, with several synaptic grooves and an irregular sub-neural apparatus of Couteaux. (Cholinesterase reaction)

skin and a pathological spread reflex. In the meantime it appeared that also in the cerebro-spinal innervation changes had taken place: here, attention was only given to the motor end-plates. With human patients where dystrophy had existed for a long time, a number of end-plates proved to be normal (cholinesterase reaction). Most, however, were more or less degenerated (Figs. 4 and 5). In the laboratory animals where dystrophy, after repeated phenol injections, had existed for a few months, preponderantly changed end-plates have been found as well (Figs. 6, 7 and 8). Not only with the cholinesterase reaction but also with methylene blue staining the motor end-plates look modified. The muscle tissue itself also, locally, has a pathological aspect. In some cases real paralysis of the hind-leg proved to exist while the motor end-plates were intact to a large extent. So the dysfunction of the end-plates must have a cause other than their morphology. Moreover, it may be mentioned that the motor end-plates may degenerate in very various ways. No single fixed sequence is to be observed in the progress. In later experiments, muscle biopsies have been taken after a short time. So far as we can now judge it would appear that a larger percentage of normal motor end-plates are to be found, though the adrenergic innervation shows a considerably varied pattern.

The fact that paralysis may occur with preponderantly intact motor end-plates, on which neither on the sciatic nerve nor on the spinal cord deviations appear, shows that we are dealing with functional disturbances. These probably precede morphological disturbances. This would explain why shortly after the beginning of the dystrophy still many, but afterwards considerably less, motor end-plates are intact. The functional disturbances of the

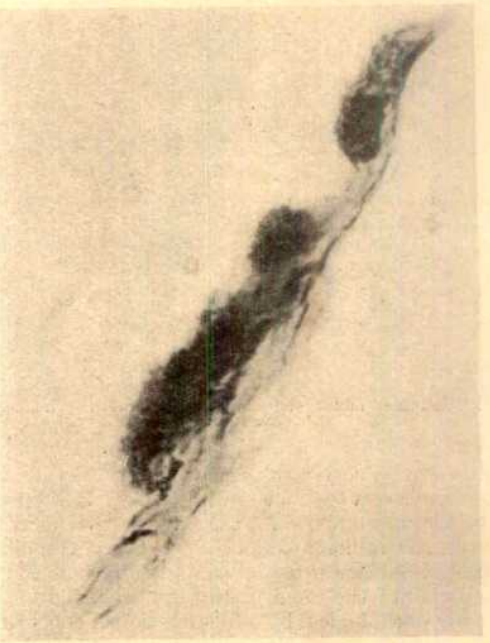

Fig. 5. Abnormal motor end-plate in man. (Cholinesterase reaction)

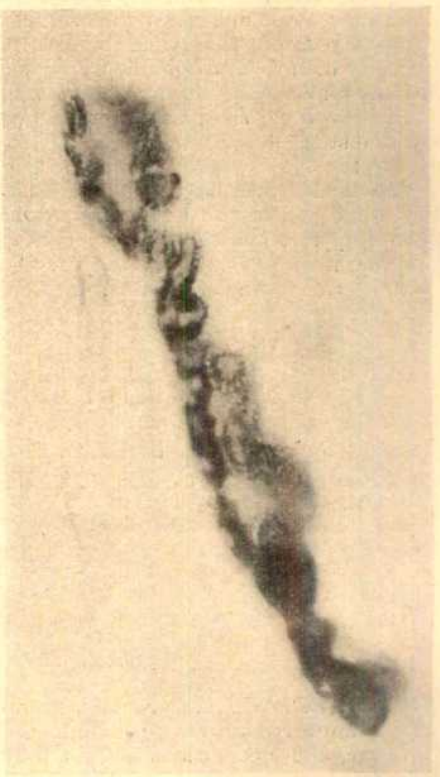

Fig. 6. Normal motor end-plate of the rabbit. The synaptic grooves are in communication with each other. There is a tiny sub-neural apparatus of Couteaux. (Cholinesterase reaction)

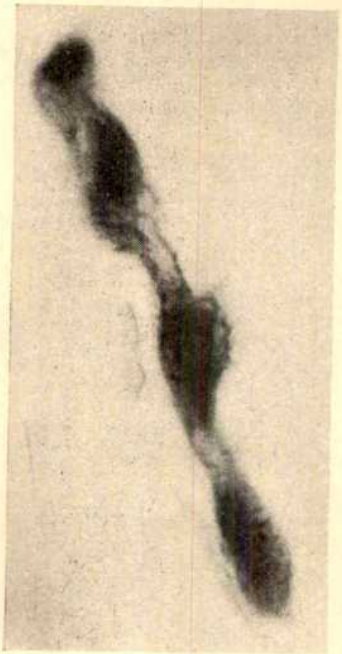

Fig. 7. Abnormal motor end-plate in the rabbit. (Cholinesterase reaction)

muscle, however, correlate very distinctly with deviations in the adrenergic vegetative innervation. If we now consider the strong influence that the vegetative nervous system has on the 'milieu intérieur' or, as Coujard[3] points out, the trophic influence it exercises on the tissues, it may be supposed that the end-plates are able to become secondarily pathological by a dysfunction of the vegetative nervous system. Morphologically, the myoneural synapse is still intact, though it is no longer able to function normally because its environment has been disturbed. In accord with this is Prof. Folkerts's observation, with one of the dystrophic patients, that while the electromyogram had been greatly disturbed, in the biopsy no such serious pathological anatomical changes in the muscle fibres were to be found. However, the adrenergic innervation had been seriously disturbed.

Exactly on the spot where the motor end-plate is located, a close contact can be demonstrated between the cerebro-spinal and the vegetative nervous system, as can be shown in Fig. 8, which illustrates a silver preparation of a normal muscle on which a capillary lies around the end-plate. In a number of Champy–Coujard preparations, too, the capillary loop as well as its vegetative innervation is to be seen round the sole nuclei of the end-plate. Meyling[4] also found in electron-microscopic preparations that the capillaries push with the axons into the sarcolemma.

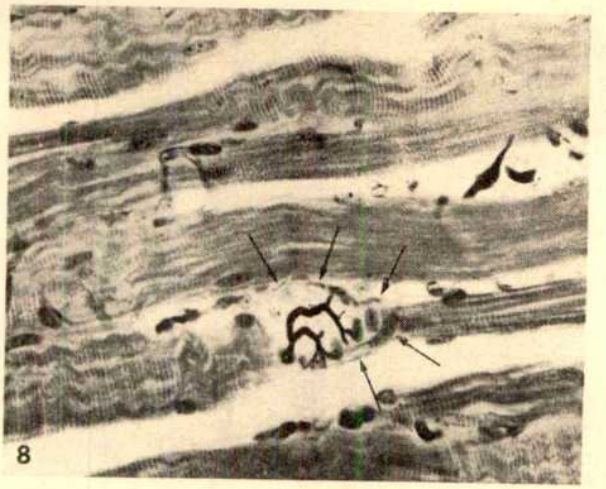

Fig. 8. A motor end-plate, surrounded by a capillary loop in a normal muscle. Bodian silver stain. The capillary is indicated by arrows

Judging from the results at present at our disposal, we gain the impression that trophic disturbances, which may be evoked by different causes, first influence the vegetative innervation in the muscle, not the cerebro-spinal as might have been expected. These symptoms may already be observed after a few days. In accordance with this is Thornban's[5] observation that changes in the capillary system of patients occur a few days after the injury. It is not until later that, secondarily, caused by the abnormal vegetative innervation, changes in the cerebro-spinal system also arise. First the function of the motor end-plate is disturbed; afterwards it also changes histologically.

This work is being carried out in collaboration with Prof. J. F. Folkerts (Neurological Department of the Free University, Amsterdam) and Dr. P. Krediet (Institute of Veterinary Anatomy, Utrecht). It was supported by the European Community for Coal and Steel in Luxembourg (Folkerts, Krediet, Sneep, Wiertz-Hoessels), and since 1963 by the Netherlands Organization for the Advancement of Pure Research (Z.W.O.), The Hague.

TOXICITY OF *Phalaris tuberosa* FOR SHEEP

By Dr. C. H. GALLAGHER and Dr. J. H. KOCH

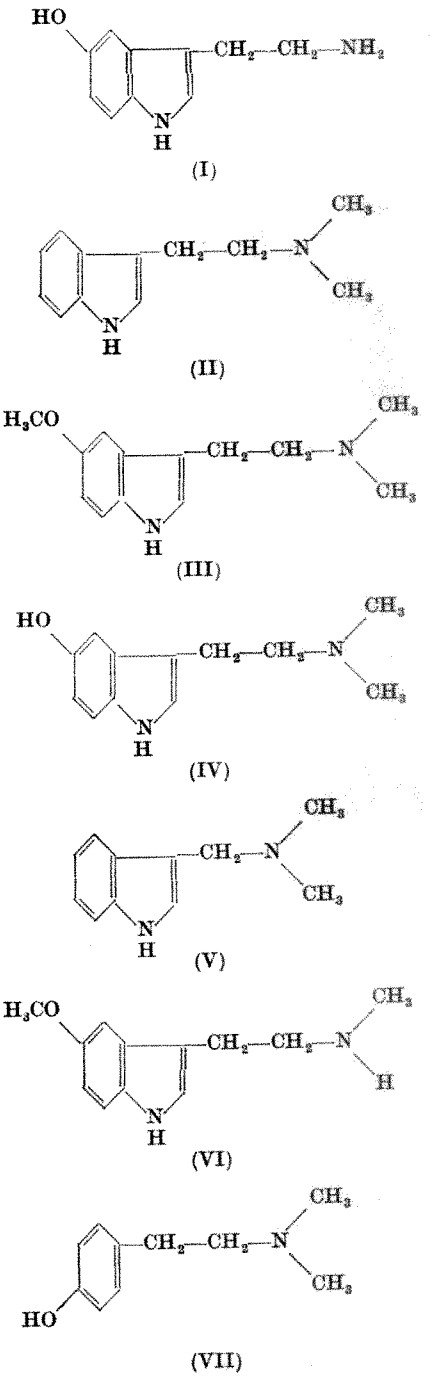
AND
Dr. J. D. STEEL
Faculty of Veterinary Science, University of Sydney

PHALARIS TUBEROSA is a valuable component of some of the improved pastures in south-eastern Australia. However, under conditions not yet fully defined, sheep grazing this grass have sometimes developed a peracute disease which causes sudden collapse and death[1–3], or a more chronic syndrome, phalaris staggers[1,4,5], which is characterized by neurological disorders. Recent observations on the peracute syndrome in sheep grazing *P. tuberosa* in the Australian Capital Territory have led to the development of a new hypothesis as to the ætiology and pathogenesis of poisoning due to *P. tuberosa*.

An outbreak of the peracute disease in autumn 1963 afforded the opportunity to examine clinical cases and to perform immediate necropsies. Five sheep were seen to collapse while exhibiting severe clinical signs. Two died quickly after the initial collapse, but three recovered. Two of the recovered animals died after subsequent attacks. All five sheep showed clinical signs of acute heart failure. Of those examined as soon as detected, three had ventricular fibrillation, and the other two had arrhythmic tachycardia which proceeded rapidly to fibrillation; the heart then stopped beating. The mucous membranes and skin became cyanotic during the period of fibrillation and cardiac arrest, but the animals remained conscious throughout, their reflexes responded to stimuli, and they continued to breathe. Recovery from this acute attack in three of the five sheep was initiated by isolated, infrequent heart beats, which accelerated to tachycardia over about 2 min, and then the animal could be forced to rise and walk away. Another clinically identical case was observed to die rapidly during an acute attack in autumn 1964.



Necropsy performed immediately on the three sheep which did not recover from their observed clinical episode revealed severe congestion of the abdominal viscera, particularly of the liver and kidneys, and petechial hæmorrhages in the epicardium and duodenum of one sheep. No other lesion was observed by either macroscopic or microscopic examination. In addition to these, four sheep which were grazing *P. tuberosa*, and which had been observed by stock attendants to collapse and die rapidly, showed abdominal visceral congestion, and two of them had epicardial hæmorrhages when examined soon after death. In all affected sheep examined, the heart had stopped in systole. The necropsy findings were indicative of acute heart failure of sudden onset.

These observations indicated that a substance with specific cardiopharmacological properties might be present in *P. tuberosa*. Culvenor *et al.*[6] reported the presence of a group of particularly interesting alkaloids from *P. tuberosa*, which are *N,N*-dimethylated indolealkylamines closely related to serotonin, 5-hydroxytryptamine (I). The major alkaloids found in *P. tuberosa* were *N,N*-dimethyltryptamine (II) and 5-methoxy-*N,N*-dimethyltryptamine (III), with variable amounts of 5-hydroxy-*N,N*-dimethyltryptamine (bufotenine) (IV) and traces of other indole derivatives. In addition, (II) and gramine (V) were found in the related grass, *P. arundinacea*[6], which had earlier been shown[7] to contain 5-methoxy-*N*-methyltryptamine (VI) and hordenine (VII). These and related methylated indolealkylamine and β-phenylethylamine derivatives have also been isolated from several other plant genera and from lower vertebrates, but have not been found in mammals[8].

Serotonin is highly active pharmacologically. It causes contraction of smooth muscle, influences cardiac activity and is concerned in the normal functioning of brain. It is probably the chemical transmitter in the parasympathetic component of the autonomic nervous system, performing an analogous function to that of acetylcholine[8,9]. Consequently, the hypothesis was formulated that the methylated tryptamine alkaloids present in *P. tuberosa* produced disease by interfering with the metabolism and pharmacological functions of serotonin.

Parenteral administration of solutions of pure 5-methoxydimethyltryptamine, dimethyltryptamine or gramine has been found to kill sheep, guinea-pigs, rats and mice due to acute heart failure, characterized clinically by arrhythmia, ventricular fibrillation and cardiac arrest. Less than lethal doses may cause cardiac arrest, from which the animal recovers in a fashion similar to the manner in which sheep recover from peracute poisoning with *P. tuberosa*.

The cardiac effects in sheep of the alkaloids present in *P. tuberosa* have been investigated more critically using a nine-lead electrocardiogram as described for the horse by

Steel[10]. Sample tracings are shown in Fig. 1. When it was ascertained that the main abnormality was a striking ventricular arrhythmia, most of the electrocardiographic data were obtained by continuously repeating tracings made from leads I, II and III. In order to minimize muscular spasms caused by injection of dimethyltryptamine and 5-methoxydimethyltryptamine and so prevent distortion of the ECG tracing by muscle potential, sheep were anæsthetized with 'Kemithal' and maintained on oxygen and nitrous oxide during the experiment. ECG recordings were taken after anæsthesia was induced, and prior to the administration of the alkaloid in order to obtain the normal pattern for each sheep.

All three alkaloids tested, 5-methoxydimethyltryptamine, dimethyltryptamine and gramine, caused a marked tachycardia with pulse-rates varying from 170 to 270/min (Fig. 1, *A* and *E*). This was usually followed by the occurrence of isolated and multiple ventricular extra-

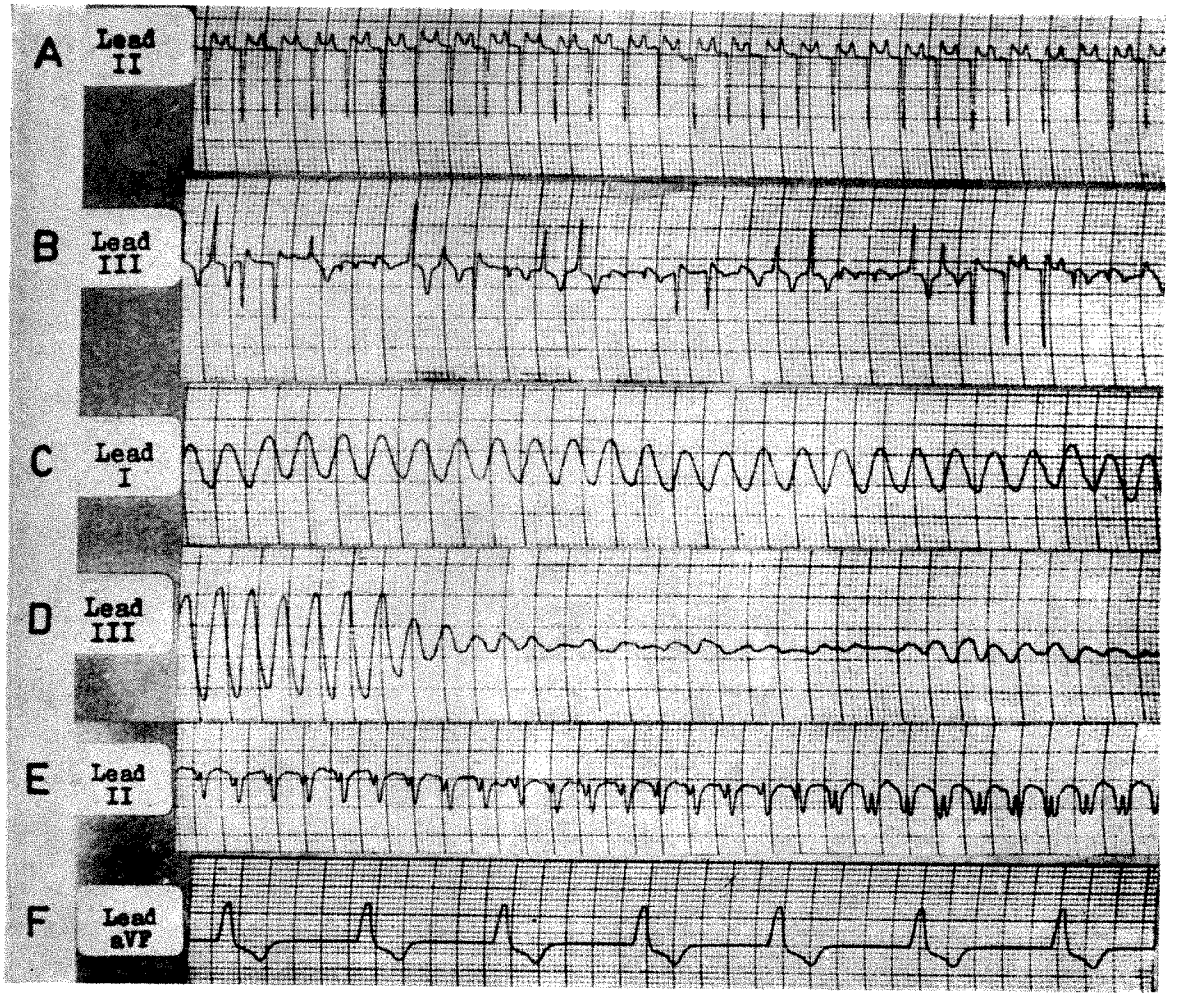


Fig. 1. *A*, Unanæsthetized sheep given 10 mg gramine/kg intravenously. Lead II showing paroxysmal ventricular tachycardia. Heart-rate 270/min. *B*, Lead III for *A* showing ventricular extrasystoles arising from multiple ectopic pacemakers and producing a chaotic heart action. The sheep survived. *C*, Anæsthetized sheep given 5 mg 5-methoxydimethyltryptamine/kg intravenously. Lead I showing the sine-like undulation characteristic of ventricular flutter. *D*, Lead III for *C* showing the transition of ventricular flutter into terminal ventricular fibrillation. The sheep died. *E*, Anæsthetized sheep given 5 mg 5-methoxydimethyltryptamine/kg intravenously. Lead II showing an intraventricular conduction defect during a period of tachycardia in which the heart-rate was 240/min. The *QRS* duration was 0·11 sec on the left side of the tracing and 0·13 sec on the right. The sheep died. *F*, Anæsthetized sheep given 10 mg dimethyltryptamine/kg intravenously. Lead aVF showing intraventricular block and a heart-rate of 60/min. The sheep died

systoles (Fig. 1, *B*), and succeeded by long or short episodes of paroxysmal, ventricular tachycardia. The heart action then became chaotic in some cases followed by ventricular flutter and fibrillation (Fig. 1, *D*). In other instances, after an initial arrhythmic tachycardia, the heart-rate slowed markedly to 60–70/min with the development of intraventricular block before a final, slow, ventricular fibrillation (Fig. 1, *F*).

The neurological syndrome of phalaris staggers may take an acute form from which recovery is possible, or may terminate in a chronic, degenerative disease. The acute form is common in New South Wales and the Australian Capital Territory, whereas the chronic form of the disease is said to be more common in South Australia. The most severe form of acute phalaris staggers results in lateral recumbency of the sheep with tetanic spasms and extensor rigidity of the legs, the digits are over-extended, resulting in splaying and dorsi-flexion, the head is dorsi-flexed, the pupils dilated, the face wrinkled, the jaws may be clamped and there is usually profuse, ropy salivation. Animals affected less severely with the acute syndrome show hyperexcitability, marked incoordination of gait often characterized by high-stepping with the front legs, splaying and dorsi-flexion of the digits, convulsive spasms, nodding of the head, salivation and twitching of the ears and tail. All the signs are exaggerated by enforced movement or fright, and the animal may fall as it runs. Sheep affected with chronic phalaris staggers may show all the signs shown by acute cases, but in addition show evidence of residual nervous lesions as, for example, the loss of co-ordination of the front legs, with the animal moving on its knees.

Parenteral administration of small doses of the alkaloids of *P. tuberosa* to unanæsthetized sheep and to small laboratory animals causes profound disturbances of the central nervous system, producing the same group of neurological signs displayed by sheep with acute phalaris staggers. The most potent of the alkaloids in producing central nervous system disorder is 5-methoxydimethyltryptamine, followed by 5-hydroxydimethyltryptamine, and dimethyltryptamine. Each of these alkaloids passes quickly into the brain from the blood, and produces neurological signs within 13–16 sec of injection into the jugular vein of sheep. The smallest dose used, 0·1 mg/kg, of 5-methoxydimethyltryptamine produced hyperexcitability, salivation, head-nodding, ear-twitching, tail-twitching, urination, dilatation of the pupils, stamping, circling, incoordination and backward movement. A greater variety of signs was shown by adult sheep given 0·5 mg 5-methoxydimethyltryptamine/kg intravenously. These sheep showed the development of the following clinical signs: hyperexcitability, licking of the lips,

salivation, chewing movements, ear-twitching, tail-twitching, urination, head-nodding, face-wrinkling, pupillary dilatation, flaring of the nostrils, stamping, circling, backward movement, collapse either in lateral recumbency with extended, paddling legs or in ventral recumbency with the hind legs stretched out backwards, the digits were over-extended appearing splayed and dorsi-flexed, breathing was stertorous and the rectal temperature rose to 108°–109° F. The animals took about an hour to recover. Larger doses, 1·5–2 mg, 5-methoxydimethyltryptamine/kg may prove fatal, the animal falling rapidly in lateral recumbency, with extensor rigidity, tetanic spasms, opisthotonos and dyspnœa. Death occurs from acute heart failure. Subcutaneous administration of the alkaloids produced the same syndrome with slower onset, less severity and longer duration. However, doses of 1–2 mg/kg of 5-methoxydimethyltryptamine may still prove lethal by this route. Oral administration of 5-methoxydimethyltryptamine produced central nervous system signs in sheep in about 6 min, showing that the alkaloid is rapidly absorbed from the gastro-intestinal tract.

It is considered that, according to the dose and mode of administration, the group of neurological signs exhibited by sheep with acute phalaris staggers can be produced by the alkaloids present in *P. tuberosa*. Chronic phalaris staggers with persistent, degenerative central nervous system lesions has not yet been reproduced by administration of the tryptamine alkaloids.

The hypothesis that the dimethylated tryptamine alkaloids are the toxic principles of *P. tuberosa* responsible for all manifestations of its toxicity is being investigated. The alkaloids have been found to inhibit the catabolism of serotonin by monoamine oxidase, and to exert powerful pharmacological effects on the central nervous system and the heart. The results presented here strongly support the hypothesis that the alkaloids present in *P. tuberosa* are responsible for the peracute syndrome of poisoning and for acute phalaris staggers.

We thank Dr. C. C. J. Culvenor of the C.S.I.R.O. Chemical Research Laboratories for gifts of the alkaloids.

SEQUENTIAL AND REVERSIBLE INHIBITION OF SYNTHESIS OF RIBONUCLEIC ACID IN THE NUCLEOLUS AND CHROMOSOMES: EFFECT OF BENZAMIDE AND SUBSTITUTED BENZIMIDAZOLES ON DIPTERAN SALIVARY GLANDS

By Dr. J. L. SIRLIN* and Dr. J. JACOB

Institute of Animal Genetics, Edinburgh

THE object of the work recorded here was to examine the relationship between nucleolar and chromosomal synthesis by means of chemical treatment. The chemicals used were 5,6-dichloro- and 4,5,6-trichloro-1-(β-D-ribofuranosyl)benzimidazole (DRB and TRB, respectively), and benzamide (the substituted benzimidazoles were a gift of Merck Sharp and Dohme, Rahway, New Jersey). Of these, TRB acts as an antagonist of purine ribosides[1].

Salivary glands were dissected from larvæ of the chironomid *Smittia parthenogenetica* at a stage[2] where the cells are fully grown but secretion increasingly accumulates in the lumen. The glands were incubated for different periods at 25° in a chemically defined medium[2], into which the chemicals were added at various concentrations (given as wt./ml.). The glands were then offered uridine (nominally 5 : 6 tritium, Radiochemical Centre, Amersham) usually for 30 min in medium containing chemicals as in the previous incubation, or without chemicals in some of the recovery experiments. Control glands were incubated similarly without chemicals.

Autoradiographs were prepared as described elsewhere[2]. Most of the radioactivity incorporated in the nucleus is removed from the preparations by ribonuclease[2]. The incorporation appears to be mainly into internal positions of the RNA, since the incorporation of tritiated uridine or tritiated guanosine is appreciably the same whether or not an excess of non-radioactive cytidine or adenosine, respectively, is present to reduce interconversion among nucleotides. Accordingly, the distribution of ^{14}C-uridine (in the absence of non-radioactive cytidine) to the other major nucleotides is negligible[3].

Selective inhibition of chromosomal synthesis. In chromosomes the synthesis was markedly inhibited after incubation of glands for 2 h with 10 μg DRB. The inhibition was greater with 20 μg, and total in practically all cells with 40 μg ($1·25 \times 10^{-4}$ molar) or more, as shown in Fig. 2. In the nucleolus the synthesis was slightly inhibited by 40–80 μg DRB (Fig. 2), and was reduced to only about three-quarters of the incorporation in controls by 200 μg (at this concentration DRB did not dissolve completely).

In time-sequence incubations with 20 μg DRB, the inhibition of chromosomal synthesis increased progressively to near completion at 2 h as found in the previous experiments, while the nucleolar synthesis was still not inhibited at 4 h. With 200 μg, synthesis in the chromosomes was already totally inhibited at 30 min, while in the nucleolus the synthesis was progressively inhibited from little at 30 min to about half the incorporation in controls at 4 h. The kinetics of inhibition of the chromosomal and nucleolar syntheses are different.

The specific inhibition of chromosomal synthesis is also produced by benzamide at higher doses. In time-sequence incubations with 1·3 mg benzamide ($10·7 \times 10^{-3}$ molar), chromosomal synthesis was suppressed at 30 min, while the nucleolar synthesis was gradually reduced and was only slightly reduced by 4 h. The two kinetics of inhibition with benzamide show a similar difference as with DRB.

* Member of the Agricultural Research Council Unit of Animal Genetics.

Table 1. Stimulation of Incorporation of Uridine into Nuclear RNA

Chemicals present during incubation with tritiated uridine	Incorporation (arbitrary values)
DRB (30 or 200 μg)	(+ + + +) × 100 see Fig. 5
No chemical	(+ + + +) × 10 see Fig. 4
No chemical, control	+ + + + see Fig. 1
Benzamide (0·5 mg) + DRB (50 μg) + TRB (50 μg)	+ + +
Benzamide (1 mg) + DRB (100 μg) + TRB (100 μg)	+
Benzamide (1·5 mg) + DRB (150 μg) + TRB (150 μg)	0

All glands, except controls, were previously incubated for 40 min with benzamide (1·5 mg), DRB and TRB (150 μg each).

Benzimidazole, the parent compound of DRB, does not cause a selective inhibition of chromosomal synthesis, but rather affects all nuclear synthesis uniformly. Glands incubated for 2 h with $1{\cdot}25 \times 10^{-4}$ molar benzimidazole showed slight overall nuclear inhibition of synthesis. With $10{\cdot}7 \times 10^{-3}$ molar benzimidazole the glands showed severe inhibition (and signs of damage to cells).

1,1,3-Tricyano-2-amino-1-propene (tricyamp) stimulates the incorporation into nuclear RNA by more than one order of magnitude[4]. 50 μg tricyamp (a gift of Upjohn Co., Kalamazoo, Michigan) and 150 μg DRB (not completely dissolved), offered simultaneously during incubation for 2 h, affected nuclear synthesis in opposite directions.

Sequential inhibition of chromosomal and nucleolar synthesis. The nucleolar synthesis, which resisted inhibition by DRB and benzamide when given separately, was inhibited by a mixture of benzamide (1·5 mg), DRB and TRB (150 μg each, not completely dissolved). After incubation for 15 min total inhibition was observed only in chromosomes, and in chromosomes as well as in the nucleolus after 30 min. Preliminary experiments, in which one inhibitor at a time was left out of the mixture, suggested that TRB is the most important of all three chemicals necessary to prevent nucleolar synthesis.

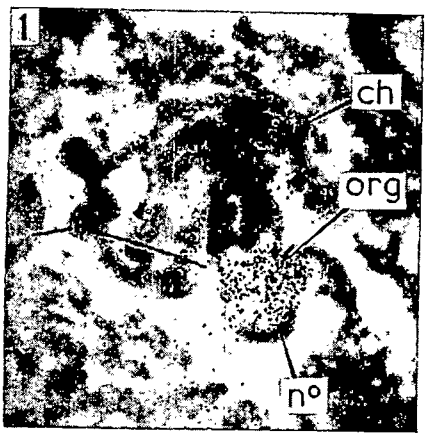

Fig. 1. Autoradiograph of squash preparation of control gland incubated first in standard medium for 2 h, and then in standard medium with tritiated uridine (40 μc./ml.; 3·0 c./m.mole) for 30 min. Exposure: 25 days (× 400). *ch*, chromosomes; *n°*, nucleolus; *org*, nucleolus organizer

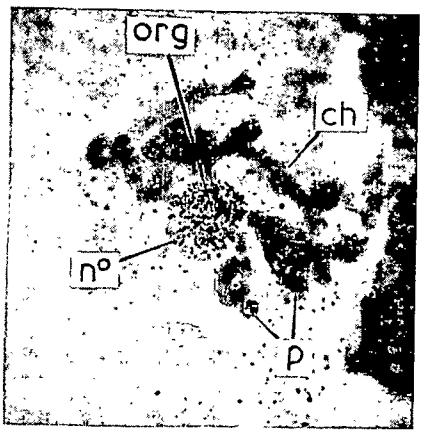

Fig. 2. Same as Fig. 1, except that 80 μg DRB was present throughout the incubations. *p*, pigment

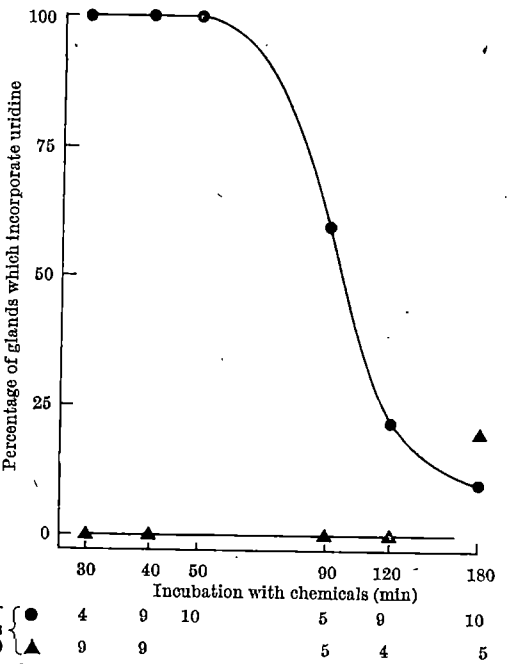

Fig. 3. Recovery of incorporation of uridine into nucleolar RNA after previous incubation with benzamide (1·5 mg), DRB and TRB (150 μg each) for different periods. Tritiated uridine was offered in the absence (●) or presence of the chemicals (▲)

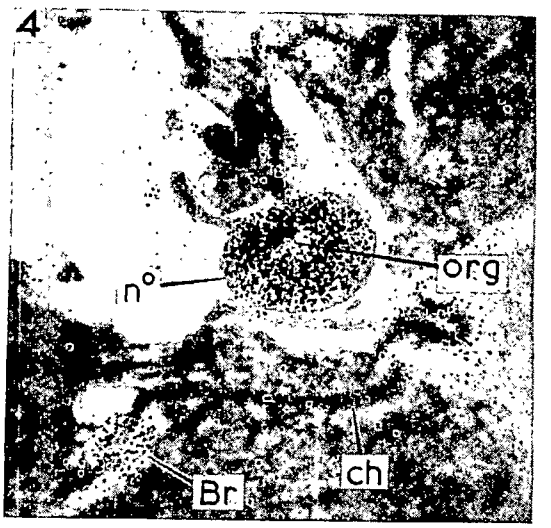

Fig. 4. Autoradiograph of gland incubated with standard medium containing benzamide (1·5 mg), DRB and TRB (150 μg each) for 40 min, and then with standard medium containing tritiated uridine (60 μc./ml.; 2·1 c./m.mole) alone for 30 min. Controls for this gland show a similar picture as in Fig. 1. Exposure: 20 days (× 400). *Br*: Balbiani ring

Restoration of nuclear synthesis. Nuclear synthesis was restored soon after withdrawal of the mixture of chemicals. As shown in Fig. 3, recovery fails after incubation for 90 min; thereafter the proportion of cells that recover falls, the amount of incorporation per cell becomes more variable, and signs of damage to cells appear.

As summarized in Table 1, incorporation in the recovered cells is frequently stimulated by about one order of magnitude, which is particularly clear in glands incubated for less than 90 min. The stimulation affects mainly the nucleolus (Fig. 4).

Stimulation by up to two orders of magnitude was generally found in the presence of 30 or 200 μg DRB

(Fig. 5). The stimulation is greater in the nucleolus than in chromosomes. Radioactive RNA now appears in the proximity of the nucleolus and chromosomes, and in the cytoplasm near to the nucleus. Because of probable displacement during squashing of the preparations, the origin in the cell of this RNA cannot be precisely determined. Incorporation in cytoplasm is clear.

The over-stimulation caused by DRB was unexpected, since the intention was to permit only restored nucleolar synthesis, while continuing to maintain inhibition of chromosomal synthesis. To examine further this possibility, DRB was replaced by different mixtures of benzamide, DRB and TRB (Table 1, lines 4 and 5), but the general effect was to reduce incorporation.

To summarize, on withdrawal of all three chemicals which inhibit synthesis, synthesis is recovered and is accompanied by stimulation, possibly as a 'rebound' phenomenon. The stimulation is accentuated if DRB alone remains present. Over the two observed levels of stimulation the nucleolus shows a greater stimulation than the chromosomes, which at the lower level of stimulation incorporate less than in the controls. The three chemicals which at high concentration inhibit synthesis permit restoration of synthesis at low concentration. However, as the concentration increases the overall synthesis ceases to be stimulated before it gradually disappears; concurrently, the greater stimulation in the nucleolus disappears. It would seem, therefore, possible to isolate a stimulated nucleolar synthesis only at the lower level of stimulation obtained by total withdrawal of chemicals, using shorter radioactive incubation than in Fig. 4 (compare with Fig. 2 where non-stimulated nucleolar synthesis is isolated).

The nuclear incorporation is restored first in the nucleolus (Fig. 6), as judged from the different stages of cell incorporation which are evident in glands after prolonged incubation with chemicals. It can also be seen that the incorporation starts in the nucleolus around, but not inside, the organizer (easily recognized in the chromosome that traverses the nucleolus), and that the radioactive RNA then moves towards the nucleolar periphery[5,6].

One conclusion which emerges is that the nucleolar synthesis displays an independence lasting for at least several hours of inhibition of chromosomal synthesis. The existence of a nucleolar synthesis was concluded originally from the kinetics of normal incorporation[7]. In the normal cell, as well as in the cell which recovers from inhibition, a significant incorporation into nucleolar RNA precedes that into chromosomal RNA.

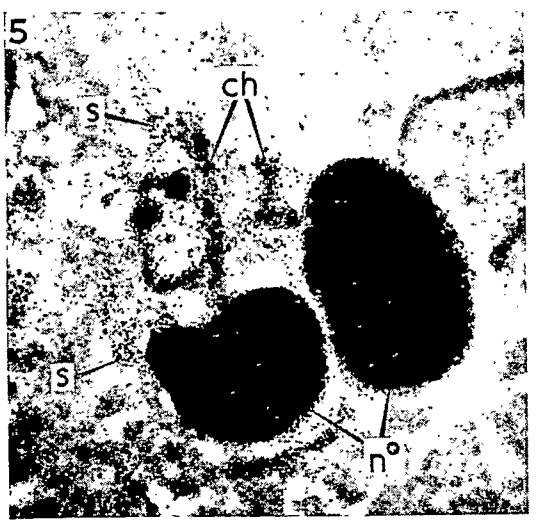

Fig. 5. Same as Fig. 4, except that the medium with tritiated uridine also contained 30 μg DRB. *s*, radioactive RNA

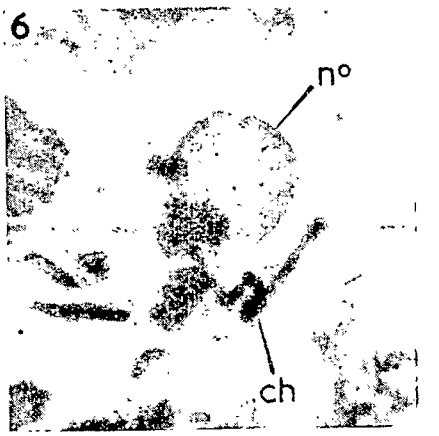

Fig. 6. Autoradiograph of gland incubated for 1·5 h with the same chemicals as for Fig. 4, and then in standard medium with tritiated uridine (60 μc./ml.; 3·0 c./m.mole) alone for 20 min. Exposure: 30 days (×400)

Kinetically, the nucleolar and chromosomal syntheses are different, both with respect to the kinetics of inhibition and of the stimulation that goes with reversal of inhibition. During inhibition the nucleolar synthesis is more resistant, and during restoration it is more stimulated, than the chromosomal synthesis. One explanation would be a different behaviour of the precursor pools for the two syntheses, as suggested by previous studies[8].

The restoration of synthesis begins in the nucleolus proper and not inside the organizer, as in normal synthesis[5,6] even during brief periods[7]. In the first step of stimulation shown in Fig. 4, the stimulation affects the nucleolus but not the organizer which incorporates no differently from the chromosome. (The reverse is true in the first step of inhibition shown in Fig. 2, where the incorporation is as much inhibited in the organizer as in the chromosome, but much less so in the nucleolus.) Conversely, substances, such as proflavine and actinomycin, that affect the nucleolar synthesis very specifically do not particularly affect synthesis in the organizer more than in the chromosome. All the evidence tends to indicate that in the nucleolus the synthesis is dissociable from the organizer, and therefore appears to be not immediately dependent.

A practical application comes from the virtual isolation of the nucleolar synthesis which is achieved within the cell (Fig. 2). Using this approach, the newly synthesized nucleolar RNA was characterized[9] avoiding cell fractionation. It would appear that a stimulated nucleolar synthesis can also be isolated. It is suggested that inhibition of chromosomal synthesis, particularly with low doses of DRB or TRB, can provide a tool for the reversible depletion of messenger (chromosomal) RNA without much affecting the nucleolus. It now seems probable that the inhibition of chromosomal synthesis, and the concomitant underproduction of moulting hormone, observed in an insect endocrine gland after feeding benzamide[10] in fact involved an effect of this kind.

ANTIGEN BARRIER OF THE MOUSE PLACENTA

By Dr. D. R. S. KIRBY and Dr. W. D. BILLINGTON
Department of Zoology
Dr. S. BRADBURY
Department of Human Anatomy, University of Oxford
AND
Dr. D. J. GOLDSTEIN
Department of Anatomy, Medical School, Johannesburg

THE placenta of mammals is a homograft since it differs genetically from the host. However, although it is intimately united with the maternal tissue, it is not rejected until parturition, a period usually far in excess of the time taken to elicit a homograft reaction. Several hypotheses have been put forward to account for the remarkable success of the conceptus as a homograft. They are: (*a*) the fœtus is antigenically immature; (*b*) the immunological reactivity of the mother is non-functional during pregnancy; (*c*) the uterus is an immunologically privileged site; (*d*) there is an anatomical barrier between mother and fœtus. These hypotheses have recently been fully reviewed by Billingham[1]. The first three of these hypotheses have been conclusively shown by various workers to be unsatisfactory, and Billingham concludes by stating that: "The only reasonable hypothesis . . . is that mother and fœtus are completely separated by an anatomical barrier". Such a barrier must logically reside in the placenta, where fœtal and maternal tissues come into intimate contact with one another.

The purpose of this article is to describe a structure which is considered to function as a barrier in preventing fœtal transplantation antigens from reaching the maternal tissues. A detailed account of our findings will be reported elsewhere. Our reasons for suggesting we have identified this barrier are as follows:

(1) *Electron-microscopical examination of the placenta.* The 16-day placenta from a *BALB/c* ♀ × *C57BL* ♂ mating was fixed in 1 per cent osmium tetroxide, buffered in veronal acetate to *p*H 7·3 for 1 h at 4° C. Dehydration was by a graded series of alcohols before embedding in 'Araldite'. Sections cut at approximately 80 mμ were stained for 10 min with a solution of lead citrate. It was found that the great majority of trophoblast cells were surrounded by a layer of amorphous, electron-dense material varying considerably in thickness from 0·1μ to 2·0μ. It was thick and conspicuous around the trophoblast giant cells which were in contact with the maternal decidual cells. Schiebler and Knoop[2] have described a similar distribution of this intercellular material in the rat placenta. The morphological evidence that this material overlies the free surface of the labyrinthine trophoblast bordering the maternal lacunæ is not so convincing. High-resolution electron-micrographs, however, show a very thin, ill-defined, filamentous layer in this position.

(2) *Histochemical identification of the intercellular material.* An exhaustive histochemical analysis of this material showed it to be of a mucoprotein nature, weakly sulphated and probably rich in hyaluronic and sialic acids. In its staining reactions it conforms in all respects to the material described in the placenta under the name of 'fibrinoid', which is reviewed in detail by Pearse[3]. In particular, the material showed a very strong positive reaction with the periodic acid–Schiff technique following diastase digestion, and with the Hale colloidal iron reaction (carried out as described by Barker and Anderson[4]). The latter reaction, as modified for the electron microscope by Gasic and Berwick[5], was performed in order to confirm that the amorphous layer seen in the electron-micrographs corresponded to the material examined histochemically. A positive reaction to this test can be visualized in the electron microscope by the deposition of cubic crystals of ferric-ferrocyanide at the sites of uptake of colloidal iron. In the mouse placenta the crystalline deposits appeared between the trophoblast cells, furthermore they also lined the maternal lacunæ in a position corresponding to the filamentous material already mentioned.

(3) *Comparison of the amounts of fibrinoid in hybrid and inbred placentæ.* From the histochemical analysis it was found that the periodic acid–Schiff reaction (following diastase digestion) and the Hale's colloidal iron reaction demonstrated the presence of fibrinoid most clearly. Consequently they were used as 'marker' stains in the following quantitative estimations of fibrinoid in hybrid and inbred placentæ. The following strain combinations of inbred mice were used: A_2G × *C57BL*, *BALB/c* × *C57BL*, *BALB/c* × *CBA*. The first of these strain combinations had been used previously by one of us (W. D. B.) to demonstrate clearly the influence of immunological dissimilarity of mother and fœtus on the size of the placenta[6]. The mice were mated so that each strain of each combination served as the mother. The placentæ were removed on the 16th day of pregnancy, fixed and sectioned at 8μ. Near mid-line sections of each hybrid placenta were compared for fibrinoid content with the similar sections of the corresponding inbred placenta—thus A_2G ♀ × *C57BL* ♂ compared with A_2G ♀ × A_2G ♂, etc.

In every case there was considerably more fibrinoid present, assessed subjectively by independent observers, in the hybrid than in the inbred placentæ. To eliminate the effects of heterozygosity, blastocysts obtained from A_2G × A_2G matings were transferred to the uterus of a pseudopregnant *C57BL* female. The placenta obtained by this method contained a greater amount of fibrinoid than did the *C57BL* × *C57BL* placenta obtained from a normal pregnancy. This indicated that the increase in fibrinoid is entirely due to the genetic dissimilarity between mother and fœtus. The origin of the placental fibrinoid is uncertain. Both the decidua[7] and the trophoblast[8] have been suggested as contributing the major amount, but since fibrinoid is present around extra-uterine trophoblast (see following), it seems to us more likely to be of trophoblastic origin.

(4) *Extra-uterine trophoblast.* It is now well established that mouse blastocysts will develop in an extra-uterine site to give rise to highly invasive trophoblast and normal embryos[9–11]. The success of the graft was in no way affected by genetic variation between donor and host

mouse. Indeed, mouse blastocysts will develop with a considerable degree of success beneath the kidney capsule of an adult male rat[12]. Simmons and Russell[13] have shown that presensitization of a host mouse by a skin graft from a genetically dissimilar donor strain does not affect the well-being of a subsequent trophoblast graft, whereas embryonic implants are promptly destroyed. These observations demonstrate that trophoblast transplanted to abnormal sites still retains its ability to prevent the sensitization of the host. Electron-microscopical examination of trophoblast which had been actively invading host kidney for between two and ten days revealed that the fibrinoid layer was conspicuously present around the cells of the graft (Kirby and Malhotra, unpublished results). Recent histochemical investigations show that the material has the same composition as that in the placenta.

(5) *Histochemical comparison of placental fibrinoid with the intercellular matrix of the hamster cheek pouch.* The hamster cheek pouch is an immunologically privileged site. Homo-specific and, not infrequently, hetero-specific tissue grafted into the cheek pouch quickly becomes vascularized and is accepted for prolonged periods of time. From their investigations of this phenomenon, Billingham and Silvers[14] suggest that transplantation antigens from the graft are prevented from reaching the host tissues by some sort of absorptive activity of the connective tissue matrix in the pouch skin. In view of the suspected functional similarity with respect to the antigen barrier between this absorptive matrix of the cheek pouch and placental fibrinoid it seemed of interest to determine if the two materials were chemically similar. Histochemical tests indicated that the intercellular matrix of the hamster cheek pouch dermis and placental fibrinoid were chemically very similar.

These observations lead us to conclude that the fibrinoid material in the mouse placenta prevents the escape of fœtal transplantation antigens into the maternal system. In view of the very thin layer of fibrinoid lining the maternal lacunæ, it might be argued that there is not sufficient material in this site to act as a barrier to antigen escape. Even if this is so, it does not invalidate our hypothesis. The route of transplantation antigens into the host is incompletely understood—tissue/tissue contact and lymphatic drainage are known to be important in this respect. That the vascular system is an ineffective route of antigen transfer is amply demonstrated by homografts into the hamster cheek pouch, in which, although the foreign tissue becomes richly vascularized, it nevertheless fails to sensitize the host.

The analogy between the hamster cheek pouch matrix and placental fibrinoid is justified only with respect to the blockade of transplantation antigens. Thus, whereas pouch skin homografts are susceptible to a state of specific immunity, elicited by proxy, for example, by a homograft of normal skin, the placenta seems insusceptible to a similar immunological state[13].

Fibrinoid lying between the maternal and fœtal tissues in the placenta has been described for a number of species including the rat[2,7], guinea-pig[15], the carnivora[16] and man[17]. In this last-named case the authors suggested that "the fœtal and maternal tissues usually are set off from one another by a local deposition of fibrinoid substance, the well-known layer of Nitabuch, which may behave somewhat as an immunological no-man's-land, walling the fœtus off from chemical interaction with its host". It is tempting to suggest that the phenomenon of antigen barrier by a mucoprotein material, commonly called fibrinoid, may be common in mammalian placenta.

It will be of interest to remove the investing fibrinoid from the trophoblast by enzymatic digestion and to determine if such 'divested' trophoblast will sensitize allogeneic hosts.

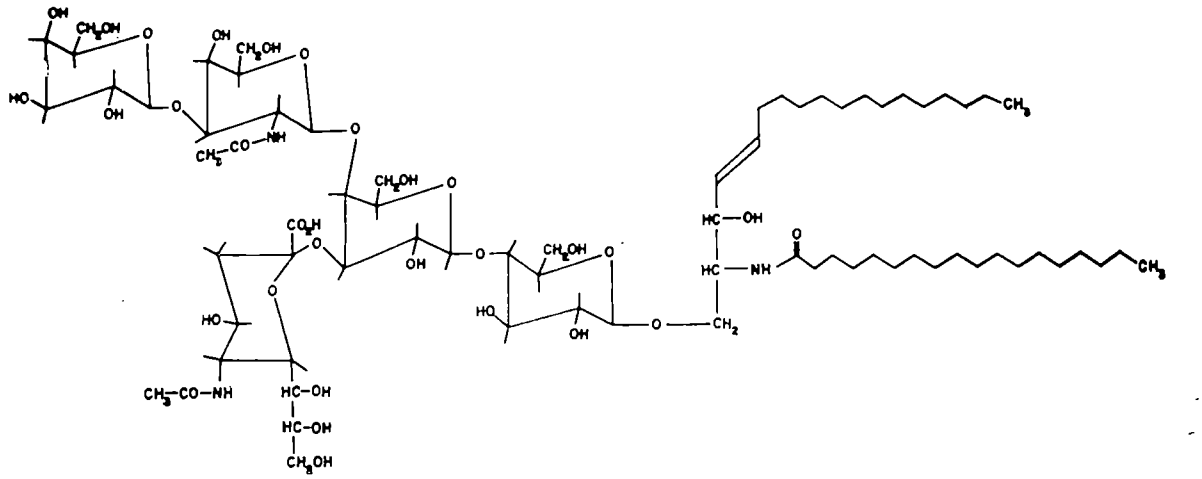
CHEMICAL ASPECTS OF INHIBITORS OF $Rh_0(D)$ ANTIBODY

By Prof. MATTHEW C. DODD, Dr. NANCY J. BIGLEY, GARLAND A. JOHNSON* and Prof. ROBERT H. McCLUER



Department of Microbiology, Ohio State University, Columbus

SINCE Landsteiner and Wiener[1] first described the $Rh_0(D)$ antigen, its chemical nature has been reported as lipid, protein or carbohydrate. The difficulties involved in the isolation of the antigen from erythrocytes have been the main reason why most attempts to identify it have utilized inhibition of agglutination of $Rh_0(D)$ cells in specific antiserum by substances isolated from other sources. Final evidence of antigenic specificity, of course, lies in the capacity of an inhibitory agent to stimulate specific antibody on injection.

The present article is concerned with the chemical nature of sialogangliosides from brain tissue, and a glycopeptide from a species of *Pseudomonas*[2], which inhibited the agglutination of $Rh_0(D)$ erythrocytes by specific antiserum, and stimulated the production of $Rh_0(D)$ antibody, in rabbits. The chemical structure of these substances is as yet incompletely known, but the immunological and chemical information available is sufficient to suggest that some substance similar to them exists in $Rh_0(D)$ cells. This, in turn, allows the suggestion of a possible structure for this antigen which can be reconciled, to some extent, with substances reported by others.

Howe[3] developed the concept in which the influenza virus receptor, Rh and ABO antigens are parts of a complex. Moskowitz and Treffers[4] and Morgan and Watkins[5] described the destruction of $Rh_0(D)$ antigen by periodate. Bigley, Chandler and Dodd[6] demonstrated inhibition of $Rh_0(D)$ antibody by eluates of erythrocytes treated with mumps virus or periodate. The failure of Mäkelä *et al.*[7] to repeat these results with mumps virus was shown in this laboratory to be due, not to differences in the hæmagglutinating capacity of their virus, but to its lack of enzymatic activity on urinary mucoprotein inhibitor[23]. This is related to the neuraminidase activity of the virus, which is the key to the production of inhibitory eluates. The possibility that *N*-acetylneuraminic acid (NANA) might be related to the $Rh_0(D)$ antigen suggested the examination

of sialogangliosides and NANA for the capacity to inhibit the specific antibody. Previously, Werner and Odin[8] had reported that NANA occupied a terminal position in gangliosides and mucoproteins, and Faillard[9] described a brain ganglioside containing 13·2 per cent NANA resistant to neuraminidase, which Gottschalk[10] considered to indicate a different linkage.

Ganglioside preparations. Gangliosides were prepared from acetone powders of human brain[11], by the methods of Kuhn and Wiegandt[13] who isolated a series of oligosaccharides from bovine gangliosides, obtaining in disaccharide form, each linkage existing in monosialogangliosides. One of the acetolysis products NANA (2 → 3) galactose (4 → 1) *N*-acetylgalactosamine is neuraminidase-resistant. The resistance of this NANA residue resides in the steric hindrance provided by the *N*-acetylgalactosamine residue linked at the C-4 of galactose which is *cis* to the C-3 linked NANA. NANA

Fig. 2. Ganglioside structures as proposed by Kuhn and Wiegandt. Notations in brackets refer to corresponding preparation used in the present study

(2 → 3) galactose and NANA (2 → 3) lactose, which are not substituted in the galactose (C → 4) position, are susceptible to neuraminidases from *Vibrio cholerae*.

The structures proposed by Kuhn and Wiegandt[13] are represented in Figs. 1 and 2. Their gangliosides G_0, G_1, G_3 and G_4 correspond in composition and chromatographic properties to the preparations *FM*, 1-*G*, 3-*G* and 4-*G*, respectively as used here. Ganglioside 2-*G* is similar to Kuhn's G_2, a positional isomer of G_3.

Homogeneous preparations of *FM*, 1-*G*, 3-*G* and 4-*G* were prepared from the crude mixture, gangliosides-I (ref. 14). Gangliosides 4-*G* and 3-*G* were converted to 1-*G* by neuraminidase. The NANA residues of *FM* and 1-*G* are resistant to the enzyme. Mild acid hydrolysis of 1-*G* produced galactose and the ganglioside *FM*. Calf and rabbit gangliosides are analogous to gangliosides-I. Neuraminidase-treated gangliosides-I was prepared from gangliosides-I by treatment with neuraminidase, dialysed, passed over 'Dowex-50-[H+]' and precipitated with acetone. It contained mostly 1-*G* and some *FM*.

Inhibition of Rh_0(D) antibody by gangliosides and NANA. Previous reports have shown that crude gangliosides containing NANA, and NANA alone, from several sources inhibited specific agglutination by Rh_0(D) antibody[15]. The data in Table 1 are representative of the results obtained with these substances and the homogeneous ganglioside preparations described here. It has been emphasized that the procedure for inhibition previously described[15] is essential for these results. For the data in Table 1, a 1 : 16 saline dilution of anti-D serum (Ortho) was used, representing the highest dilution of the serum producing complete agglutination of all the trypsinized, group O Rh_0(D) erythrocytes added. The use of this minimal 4+ dilution of serum has been stressed as an absolute condition for the sensitivity of the inhibition test, since lower dilutions with an excess of antibody require a disproportionate amount of inhibitor. These data were repeated with five different commercially prepared antisera and with sera from three different iso-immunized females. Red cells were obtained from Ortho Pharmaceutical Corporation, Rariton, New Jersey, and from the blood bank at University Hospital, Columbus, Ohio.

The data in Table 1 show that the homogeneous human gangliosides, 1-*G*, 3-*G* and 4-*G*, were superior inhibitors to the mixed gangliosides-I, ganglioside *FM* and gangliosides from calf and rabbit brains, while gangliosides lacking NANA did not inhibit at all. Crude NANA completely inhibited at a concentration much greater

Table 1. INHIBITION OF $Rh_0(D)$ ANTIBODY BY GANGLIOSIDES AND NANA

Inhibitor	Inhibition (μg/0·1 ml.) Complete	Partial

than for the gangliosides, but after mild hydrolysis, inhibition was only partial, while pure NANA from human plasma did not inhibit. It is suggested that NANA in the cruder preparations is more polymerized and forms a less dissociable complex with antibody. It is evident from the data that gangliosides 1-*G* and 3-*G* are the best inhibitors, requiring concentrations as low as 0·5–0·13 μg/ml. Gangliosides 4-*G* and *FM* were less effective.

The inhibition noted by NANA was confirmed by Boyd and Reeves[16], who also noted that colominic acid, a polymer of NANA produced by certain strains of *E. coli*, was also inhibitory. Inhibition by NANA was not observed by Springer *et al.*[17] or by Johnson and McCluer[18]. However, Dodd *et al.*[19] demonstrated that inhibition by NANA is dependent on the amount of antibody, time of incubation and the reversibility of the reaction. Incubation of NANA and antiserum for 30 min or longer prior to the addition of cells usually results in a lack of inhibition, which may account for the results of Springer *et al.*, McCluer and Johnson, and of Yokoyama *et al.*[20]. The latter incubated NANA and antiserum for 2 h at 23° C before the addition of red cells. The capacity of gangliosides to inhibit agglutination of $Rh_0(D)$ cells by specific antibody was confirmed by Yokoyama *et al.*[20], who also noted inhibition of anti-*A* and anti-*N* sera. No inhibition occurred with asialogangliosides. In all the work in this laboratory, inhibition was specific for anti-$Rh_0(D)$ except that 1-*G*, 3-*G* and mixed gangliosides-I, after treatment with neuraminidase, weakly inhibited anti-*c* in concentrations of 1,000 μg/0·1 ml. or more, which was not considered highly specific.

$Rh_0(D)$ specificity of anti-ganglioside serum. Bogoch[21] described the production of ganglioside antibodies by intravenous injection of ganglioside solutions. Yokoyama *et al.*[20] could not repeat this, but produced antibodies with gangliosides in a complete Freund adjuvant, injected along with foreign proteins; and with sheep or rabbit red cells coated with gangliosides. They did not find antibody for $Rh_0(D)$ cells although antibody to gangliosides was present.

Although the results are limited because of the small amount of ganglioside available, rabbit antiserum to ganglioside 1-*G* injected intramuscularly and subcutaneously in complete Freund's adjuvant, contained antibodies to both ganglioside and $Rh_0(D)$ cells. Two doses were given, 50 mg followed by 20 mg 21 days later. Apparently, such doses are not suppressive as with polysaccharide antigens, since Yokoyama *et al.*[20] also used 20 mg in adjuvant and 6 mg intravenously three weeks later. Antibodies for ganglioside were demonstrated as hæmagglutinins for ganglioside-coated human red cells, essentially by the procedure described by Yokoyama *et al.* For $Rh_0(D)$ antibody, normal and trypsinized $Rh_0(D)$ cells were used as previously described[6,15]. As indicated in Table 2, no antibody for any of the test cells was present before immunization. Rh antibody and antibody to the ganglioside appeared eleven days after the first injection, the maximum titre of the anti-ganglioside being 1 : 32 and 1 : 256 for trypsinized $Rh_0(D)$ cells. The latter was specific for the D antigen, the serum being negative with cells lacking it, such as dce/dce, dCe/dce and dcE/dce. Six rabbits injected with adjuvant produced no antibody specific for D cells.

Further evidence of the specificity of these antibodies is shown in Table 2 by absorption of the serum with *D*-negative cells coated with ganglioside, and with normal *D*-positive and negative cells for 10 min at room temperature using one volume of serum and cells. Absorption with *D*-negative cells failed to reduce the anti-*D* titre and the one-tube drop in the anti-ganglioside titre was not considered significant. However, *D*-negative cells coated with ganglioside 1-*G* removed all antibodies for this antigen and reduced the titre for trypsinized *D*-positive red cells from 1 : 256 to 1 : 8. Absorption with normal, group O, $Rh_0(D)$ cells removed all antibodies.

Apart from the weak inhibition of anti-*c* mentioned earlier, gangliosides 1-*G*, 2-*G* and 4-*G* were specific for anti-D. These three, as well as gangliosides-I and calf ganglioside, failed to inhibit agglutination by anti-A serum in concentrations as high as 1,000 μg/0·1 ml., nor did they inhibit the heterophile antibody in sera of individuals with infectious mononucleosis. The so-called *D*-like antigen present in both Rh positive and negative cells[28] was not involved since this antigen is destroyed by trypsin, and trypsinized cells were used both for agglutination tests and absorption.

Structural aspects of the $Rh_0(D)$ specificity of gangliosides. These results suggest that neuraminidase-resistant NANA residues, the 2 → 8 linked NANA, and galactose (Figs. 1 and 2), all contribute to the determinant structure of these substances for $Rh_0(D)$ antibody. The monosialo-(1-*G*) and the disialo-gangliosides (3-*G*) (Fig. 2) are more inhibitory than the trisialoganglioside (4-*G*) (Fig. 2), and since both 3-*G* and 4-*G* can be converted to 1-*G* by the action of neuraminidase, the basis of the determinant

Table 2. ANTIBODIES FOR $Rh_0(D)$ ANTIGEN AND HOMOLOGOUS ANTIGEN IN ANTISERUM TO GANGLIOSIDE 1-*G*

NH = O, $Rh_0(D)$ positive red cells. H Tryp = human O, $Rh_0(D)$ positive red cells treated with trypsin. N–H Gang = O, Rh negative (dce/dce) cells treated with ganglioside. N–H = O, Rh negative red cells (dce/dce). NH Gang = O, $Rh_0(D)$ cells treated with ganglioside.

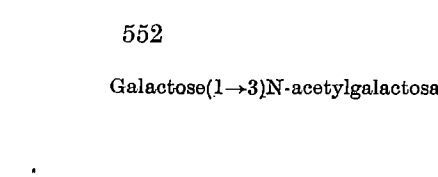

Fig. 3. Proposed immunological determinant of Rh_0(D) antigen

would seem to be the latter structure. The 2 → 8 linkage also seems to contribute since the second residue of 3-*G* increased the inhibitory capacity. It is of interest here that colominic acid contains 2 → 8 linkages[22]. The role of the terminal galactose of 1-*G* is indicated by the fact that the ganglioside *FM* (Fig. 2), which also contains the enzyme-resistant NANA, is less inhibitory than 1-*G*. The structure shown in Fig. 3 is suggested to be either identical with, or very similar to, the Rh_0(D) determinant of *D*-positive erythrocytes.

The third NANA residue in 4-*G* is terminally linked, and is neuraminidase-susceptible, being removed prior to the second NANA of 3-*G*. It decreased inhibition of anti-Rh_0(D), possibly by combining first with antibody, and the steric fit of this end of the molecule, structurally different from the NANA linkages of 1-*G*, interferes with the more effective binding of the latter. It was suggested that this third NANA linkage might offer an excellent substrate for viral neuraminidase. Since the enzyme converts 3-*G* and 4-*G* to 1-*G*, neuraminidase should cause a decrease in the viral–hæmagglutination-inhibiting capacity of the mixed gangliosides-I, and increase its anti-*D* inhibition, both of which were confirmed by the experimental results. Similarly, human Rh_0(D) cells treated with neuraminidase have lost the capacity to combine with indicator virus and are more agglutinable by antibody. Johnson[23] noted that urinary mucoprotein virus receptor inhibited Rh_0(D) antibody after treatment with trypsin, suggesting that neuraminidase and trypsin labile NANA perhaps acts as a viral receptor and that its removal exposes the more complementary resistant residues.

Rh_0(D) antibody inhibition by lipids, nucleotides and L-sugars. Some of the variety of substances reported to have similar Rh_0(D) specificity can be related to the structure proposed here. Elinin, a lipoprotein fraction of erythrocyte stroma, was associated with specificity for Rh as well as A and B antibodies[24,25], but further fractionation of the protein removed this capacity. Carter[26] described a water-insoluble lipid inhibitory for anti-Rh, extracted only from Rh-positive cells, which was not confirmed by Moskowitz *et al.*[25], while Hackel *et al.*[27] indicated that the Rh antigens may be partially nucleotide structures. Recently, Wolf and Springer[29] demonstrated inhibition of anti-Rh_0(D) by a fraction obtained from cells containing this antigen by the method of Calvin *et al.*[24]. It is interesting that this substance, like the gangliosides 1-*G* and 3-*G*, was also somewhat inhibitory for antibody to the *c* antigen.

Lack of information about these agents prevents any attempt to relate them to the structures reported here. However, Boyd *et al.*[30] noted weak but specific inhibition of Rh_0(D) antibody by the simple monosaccharides, L-glucose, L-mannose or D-gulose, and found that streptomycin (a natural glycoside of *N*-methyl-L-glucosamine) and rutinose ((6-) (β-L-rhamnosyl)-D-glucose) were more inhibitory. It was suggested that the terminal unit of the D antigen might be a sugar belonging to Group 4 of Mäkelä's classification[31]. NANA (5-acetoamido-3,5-dideoxy-D-glycero-D-galactomonulosaminic acid), although classified as a D-sugar because of the configuration of carbon-8, actually has the ring structure of an L-sugar, so that inhibition by NANA and substances containing it might be considered to be consistent with Boyd's suggestion.

Inhibition of Rh_0(D) antibody by a glycopeptide isolated from Pseudomonas. It was found[32] that a glycopeptide isolated from an as yet unidentified species of *Pseudomonas* inhibited Rh_0(D) antibody, and that rabbits immunized with it produced both saline and incomplete antibodies for Rh_0(D) cells. Flocculation, and eventual precipitation, were obtained when this substance was layered over some, but not all, anti-*D* sera. Absorption of anti-*D* sera reduced the titre for *D* cells significantly; but did not affect the titres of anti-*A* sera for *A* erythrocytes. Curiously, NANA inhibited agglutination of *D* cells by anti-serum to the glycopeptide, although it does not contain NANA. Furthermore, Dr. N. Bell and Dr. C. Randles of this department have shown that treatment of both glycopeptide and ganglioside 1-*G* (neuraminidase-resistant) with a crude bacterial enzyme preparation removed the inhibitory capacity from each of these substances. The effective enzymatic action is unknown.

The structure of this glycopeptide is unknown except that Lazen[2] has shown that it contains 56 per cent carbohydrate and 0·5 per cent of the amino sugar, *N*-acetylglucosamine. Obviously, only very general comparisons of the structure of this substance and gangliosides with reference to common inhibitory portions can be made. However, information provided by Dr. Randles shows that both substances contain glucose and galactose in 1,4 linkages, and free acidic groups. It is also possible that amino-acids in the glycopeptide could provide functional groups analogous to the acetylamino group of NANA and glycopeptide linkages with sugars, while evidence also indicates cross-linkages analogous to the cross-linkage from the sugar chain to NANA.

We thank Mrs. Virginia B. Geyer for serological work; Dr. Howard M. Johnson (now of the Taft Sanitary Engineering Center, Cincinnati, Ohio) for performing the viral inhibition investigations involving urinary mucoproteins and the ganglioside preparations; Dr. Chester I. Randles, Dr. A. G. Lazen (now at the Weismann Institute of Science, Rehovoth, Israel) and Miss Nancie L. Bell of this department for their help and their preparations of the *Pseudomonas* glycopeptide.

This work was supported by grant *AI*–03887–04 from the National Institute of Allergy and Infectious Diseases.

THE LIPID-PROTEIN UNIT IN MYELIN

By Dr. W. L. G. GENT and N. A. GREGSON

Department of Biochemistry and Chemistry, Guy's Hospital Medical School, London, S.E.1

AND

Dr. D. B. GAMMACK and J. H. RAPER

Department of Biochemistry, Institute of Psychiatry, Maudsley Hospital, London, S.E.5

AN investigation of the electrophoretic characteristics of the material obtained from the total solubilization of whole rat brain homogenate by lysolecithin[1] suggested that the principal component of the mixture was derived from myelin. Further work on rat brain homogenate, from which soluble proteins had been removed by buffer extraction at *p*H 8·6, followed by lysolecithin solubilization of the residue, indicated that it is probable that a ternary complex of lipid-protein-lysolecithin is formed[2], but indications of inhomogeneity were observed. This could be interpreted either as resulting from the separation of different lipid-protein-lysolecithin complexes from an originally uniform material or as being due to the presence of several classes of such complexes derived from the various kinds of membranes present in the brain. The development of subcellular fractionation techniques which result in the preparation of a highly uniform myelin fraction has allowed a more precise approach to the problem of myelin-lysolecithin interaction. The results suggest the possibility that myelin is composed of lipid-protein units, which are removed as such in the solubilization of myelin by detergents. Further evidence concerning the unitary nature of the lipid-protein complex is given, together with information as to its size and composition.

The Preparation of Rat Brain Myelin. The myelin-rich fraction was prepared from the crude mitochondrial fraction of rat brain as described previously[3]. This fraction was then re-suspended in distilled water, left to stand in the ice-bath for 20 min to release axonal contents, and re-sedimented at 20,000*g* for 25 min. Such treatment increased the cholesterol : protein ratio from 0·63 to 0·77, and electron microscopy of the material indicated almost complete disappearance of the axonal contents.

Solubilization of Myelin by Lysolecithin. Various volumes of a solution of lysolecithin (10 mg/ml.) in 0·05 M $NaHCO_3$ were added to aliquots of a suspension of myelin (2 mg/ml.) in the same salt solution, and the mixtures made up to a fixed volume. They were incubated at 37° C for 4 h and the turbidity was measured in the range 400–750 mμ on a Perkin–Elmer model 137 ultra-violet spectrophotometer. After storage of the solutions for a further 12 h at 4° C the turbidity curves were re-measured. No significant change was found; a typical set of such data is shown in Fig. 1, the turbidities being read at 550 mμ. The lower end of the turbidity (t) curve was found to show a linear relationship between $\log_{10}t$ and weight of lysolecithin (w) added. The weight of lysolecithin required to make $\log_{10}t$ just equal to the constant minimum value of this quantity observed at all larger additions of lysolecithin is defined as the minimum amount of lysolecithin required for maximum solubilization = w_m. Three estimations gave w_m = 36 ± 2 mg per 100 mg dry wt. of myelin.

Similar myelin-lysolecithin preparations were centrifuged at 14,000*g* for 30 min and the protein in the supernatant estimated by ultra-violet absorption[4] (the turbidity of these solutions at 550 mμ was equal to, or less than, that of the fully solubilized preparation (0·03), indicating that all large particles had been removed). The fraction of protein solubilized when plotted against the weights of lysolecithin used (Fig. 2) indicated that w_m = 36 mg of lysolecithin per 100 mg dry wt. of myelin.

Electrophoretic Study of Lysolecithin-solubilized Myelin. Samples of myelin suspended in 0·05 M $NaHCO_3$ were solubilized with various amounts of lysolecithin both less and more than w_m. After incubation the solutions were made up to a 1 per cent w/v myelin concentration and dialysed against the buffer for 48 h at 1° C. Where less than w_m was used the unsolubilized myelin was centrifuged off at 10,000*g* for 30 min. Solutions containing greater than w_m tended to precipitate lysolecithin slowly in the cold and were warmed before introduction to the electrophoresis cell. Electrophoretic investigations were made with a Perkin–Elmer Tiselius electrophoresis apparatus. At *p*H 8·6 (25° C), I = 0·1, it was found that irrespective of the amount of lysolecithin used a single peak only was observed. Where amounts of lysolecithin in excess of w_m were used the peak area increased proportionally (Table 1).

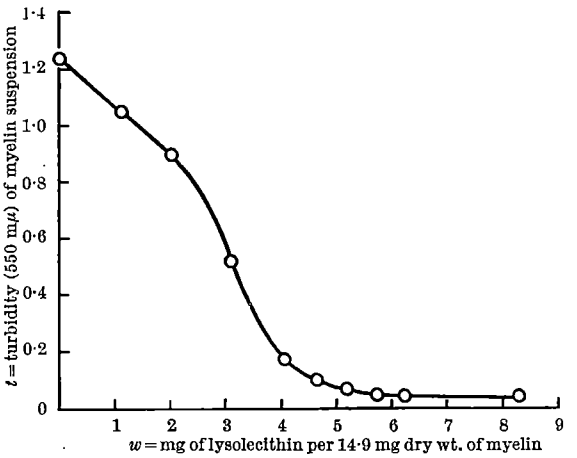

Fig. 1. The turbidity (t) at 550 mμ of myelin suspension treated with various amounts (w) of lysolecithin. Myelin, 14·9 mg dry wt. per 10 ml.

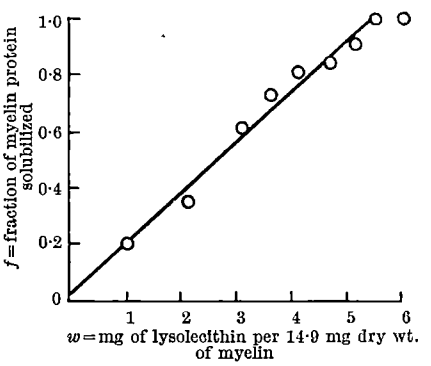

Fig. 2. The fraction (f) of myelin protein solubilized by various amounts (w) of lysolecithin. Myelin, 14·9 mg dry wt. per 10 ml.

Table 1. Electrophoretic Pattern Areas in cm²/10 mg Dry Wt. of Myelin per ml.

Wt. of lysolecithin per ml.	cm²	Mobility cm² V⁻¹ sec⁻¹
3·67	1·02	−5·7
5·48	1·21	−5·4
7·30	1·51	−5·2

Composition of Myelin. Aliquots of the suspensions of rat central myelin in distilled water were taken into 0·005 M NaOH and the ultra-violet absorbance measured at 215 and 225 mμ[4] on a Perkin–Elmer model 137 ultra-violet spectrophotometer. The absorbance difference was used to find the protein concentration from a calibration curve prepared from similar measurements on dilutions of Armour's Protein Standard Solution. Other aliquots of the myelin preparation were used to estimate the dry-weight concentration of myelin. Ten sets of dilutions on five batches of material gave the mean protein content as 33·1 per cent dry weight of myelin, *S.E.M.* ±1·82.

The detailed lipid analysis of the myelin is not relevant here and is in the process of being reported[5], but the following data are referred to in the discussion below: 100 mg dry wt. of myelin represents: cholesterol 48·6 μmoles; phospholipids 45·4 μmoles; amino-acids 253 μmoles; galactolipids 14·4 μmoles. This estimate of amino-acids is based on average amino-acid residue molecular weight from amino-acid analysis of myelin protein = 129.

Ultracentrifugal Study of Lysolecithin-solubilized Myelin. Solutions were prepared as for electrophoresis and examined in a Spinco model *E* analytical ultracentrifuge at 20° C. Sedimentation velocity experiments were performed with a rotor speed of 59,780 r.p.m. and sedimentation equilibrium experiments using short columns (3 mm) of solution according to the method of van Holde and Baldwin[6]. Results were calculated by their methods using partial specific volumes ($\bar{v}$) determined by direct pyknometry of the solutions.

A single symmetrical Schlieren peak was observed in sedimentation velocity experiments with various amounts of lysolecithin in excess of w_m, the minimum weight of lysolecithin producing maximum solubilization. However, the ratios of weight-average molecular weight (M_w) to the z-average molecular weight (M_z) determined at sedimentation equilibrium show (Table 2) that some degree of polydispersity exists in the solutions.

Table 2. Ultracentrifugal Data on Solubilized Myelin

Wt. of lysolecithin in mg/mg dry wt. myelin	M_w	M_w/M_z	$\bar{v}$
0·547 (*c.* $1·5 \times w_m$)	$3·44 \times 10^5$	2·75	0·894
0·745 (*c.* $2·0 \times w_m$)	$5·18 \times 10^5$	3·08	0·940
0·920 (*c.* $2·5 \times w_m$)	$7·53 \times 10^5$	3·09	0·944

Discussion. The fact that myelin is completely solubilized by lysolecithin and by other detergents (compare Hulcher[7]) implies that myelin contains relatively small protein units. Since only a single component is observed in both electrophoresis and ultracentrifugation it would seem probable that lysolecithin forms an addition complex with a lipid-protein unit present in the mature myelin. If lysolecithin sequestered one or more lipid components it is very unlikely that this would result in two or more particles identical in both mass and electric charge.

The direct proportionality of the fraction of total protein released to the amount of lysolecithin used indicates that only one kind of process is involved in the solubilization. Consequently, the complex shape of the curve relating the turbidity of the partly solubilized suspensions of myelin to the amount of lysolecithin must be due to changes of size and shape of the unsolubilized fragments. In a myelin suspension prior to the addition of lysolecithin a considerable range of fragment size is to be expected. The smaller pieces, having a relatively larger surface area, will tend to take up lysolecithin to form the soluble complex more readily. The turbidity will be due mostly to the larger fragments and will, therefore, diminish more slowly at first (Fig. 1) and then more rapidly as attrition of the larger particles results in their conversion to smaller and less light-scattering fragments. When these particles are small enough the Debye relationship should hold: $t = Knv^2$, where n = number of particles per unit volume and v = volume per particle. Part of t is due to the scattering action of the fully solubilized material and hence can be corrected, proportionally to the turbidity at w_m, to give a corrected turbidity T. If the action of lysolecithin is to progressively remove lipid-protein units from the surface (area = a) of the myelin fragments, then the smaller the surface area the smaller will be the amount of lysolecithin involved per fragment: $-da/dw$ = constant, hence $(w_m - w)$ will be proportional to a. Because the surface area is proportional to $v^{2/3}$ then it follows that $T = Kn(w_m - w)^3$. If the action of lysolecithin does not result in the division of larger fragments into more or less similar-sized pieces, then n will be constant, in which case T should be proportional to $(w_m - w)^3$. Fig. 3 shows that the relationship does hold for a typical set of data.

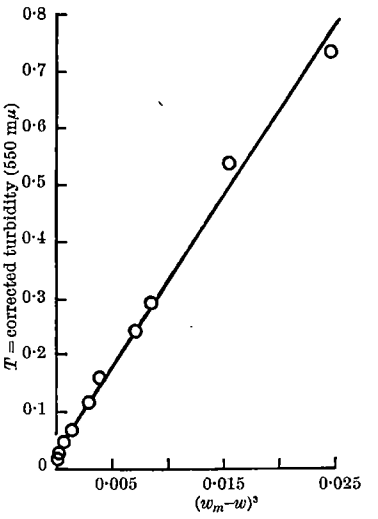

Fig. 3. The relationship between the corrected turbidity (T) of myelin suspensions treated with various amounts (w) of lysolecithin and $(w_m - w)^3$, w_m being the minimum weight of lysolecithin required for maximum solubilization. Myelin, 14·9 mg dry wt. per 10 ml.

The decrease of electrophoretic mobility with increase of amount of lysolecithin implies an increase of particle size, since the uncharged lysolecithin would not alter the absolute charge of the complex. This is in accord with the increase of pattern area noted in Table 1.

It is concluded that these experiments on the solubilization of myelin are consistent with the hypothesis that myelin is composed of relatively stable lipid-protein units which are removed by the action of lysolecithin to form a single species of a complex micelle composed of protein-lipid-lysolecithin.

From the data of Table 2 it appears that the increase of molecular weight is greater than that to be expected from lysolecithin addition. Two possibilities suggest themselves: first, that the addition of lysolecithin modifies the structure of the molecular unit as a whole so as to permit the inclusion of progressively more water or, secondly, that, although the addition of lysolecithin to the lipid-protein units increases their hydrophilic character and hence allows disaggregation, the dilution of negative charge density by inclusion of the electrically neutral lysolecithin will allow an increasing cohesion between the lipid-protein-lysolecithin particle. In either case the increment of molecular weight δM will be equal to $KM\delta m + \delta m$, δm being the mole increment of lysolecithin. Consequently

$\ln(M/M_0) = Km$ where M_0 = molecular weight of the lipid-protein unit in native myelin and K is a constant. The data of Table 2 fit such a relationship very well to give $M_0 = 109{,}000$. At the moment there is no definitive evidence to favour either of the two hypotheses concerning the exponential increase of molecular weight, but it may be noted that if M_z/M_w be taken as a measure of polydispersity this alters very little, implying that the molecules simply become larger rather than more aggregated. Furthermore, the partial specific volume, although initially less than that of lysolecithin alone ($\bar{v} = 0{\cdot}921$), finally becomes greater, an effect which could arise from progressive inclusion of water rather than aggregation of similar units.

On the assumption of an overall hydration of the native lipid-protein unit of 0·3 g H_2O/g dry wt. of unit and with the analytical data shown above, the molecular weights of the various components are as follows: protein = 28,000 (215 amino-acid residues), cholesterol = 16,000 (41 molecules), phospholipid + galactolipid = 40,000 (50 molecules). The protein molecular weight is of the same magnitude as that found for mitochondrial structural protein[8], with which myelin structural protein might well be related. An α-helical configuration of the protein, with the usually accepted dimensions for this conformation, would form a protein base of area 3800 Å^2, while the lipids in monolayer, with the dimensions given by Vandenheuvel[9], would require about 4000 Å^2. The lipid-protein unit, therefore, can be visualized as a flat plate of protein in the α-helical configuration about 60 × 60 Å^2, covered on one side by a micro-monolayer of lipid to give a thickness of about 40 Å. Such units could form parts of both myelin and other membranous structures; it may be noted that the unit is similar in size to the micelles observed through the electron microscope by Sjöstrand[10] in mitochondria.

Two conclusions are drawn from the results of this investigation: (1) the procedures outlined in this article may be generally applicable for the investigation of cell-membrane structure, and (2) it appears that there may be a sufficiently strong adhesion between lipid molecules and a protein molecule for the complex to be regarded as a unit, and hence for membranes to be regarded as aggregations of such units. In this case the Danielli hypothesis[11] of membrane structure may need modification, since it places emphasis primarily on the properties of a continuous bimolecular layer of lipid as determining the properties of a membrane.

More extended accounts of the information summarized here are in preparation. These will include supporting data obtained from the study of a number of vertebrate myelins and erythrocyte membrane. We thank the Multiple Sclerosis Society for a grant to one of us (N. A. G.) and the Medical Research Council for the provision of the Spinco analytical ultra-centrifuge and a grant for special research (D. B. G.).

FLEECE EVOLUTION IN DOMESTIC SHEEP

By Dr. M. L. RYDER

Agricultural Research Council Animal Breeding Research Organization, Edinburgh, 9

FURTHER specimens of ancient skin and wool have added to earlier findings[1-3] in such a way that a hypothesis covering what appear to be the main stages in fleece evolution can be formulated.

The new material described is as follows:

(*a*) A piece of cloth from the Danish Bronze Age dated *c.* 1200 B.C. supplied by Margrethe Hald.

(*b*) Six pieces of leather and four specimens of wool supplied by Prof. Y. Yadin, of the Hebrew University, Jerusalem, from the 'Cave of the Letters' near the Dead Sea[4]. These belonged to Jewish rebels against Roman rule who took refuge in the caves in A.D. 135. Observations on this material were completed while I was at New England University, Australia.

(*c*) Some cloth supplied by A. T. Lucas, of the National Museum of Ireland, from a body found in a bog in Co. Kildare, and dated as from "the first few centuries of this era".

(*d*) A sample of Anglo-Saxon cloth from a grave at Fonaby, Lincs, dated sixth or seventh century A.D. and supplied by Miss E. Crowfoot through the courtesy of Mrs. Sonia Hawkes.

(*e*) Five Roman, ten Norse and three medieval textile specimens (all but one from Scotland) from the National Museum of Antiquities of Scotland[5]. These were sampled by Miss A. S. Henshall through the courtesy of Mr. R. B. K. Stevenson.

One of the specimens of leather (No. 51/2) from Israel had been sewn, suggesting that it had come from some clothing; the remainder came from water bottles. The four specimens of wool comprised one apparently unspun (7/17/2 dyed maroon), one of yarn (7/10 maroon) and two of cloth. One of these (2/33) was dyed green, and the other (2/87) was pale yellow. Such a colour often occurs as a discoloration in archæological specimens of wool, but this was brighter than the yellow discoloration of the Altai wool[3].

To the naked eye the individual fibres in the wool specimens appeared to be fine, and that most fibres were, in fact, fine was confirmed by microscopic examination, but the microscope revealed the unsuspected presence of 15–20 per cent of fibres of medium diameter. Only one naturally pigmented fibre was seen, and the distribution of pigment granules in it was sparse. There was variation between individual fibres in the extent of dye uptake, particularly in the green wool, but no evidence of bilateral asymmetric dyeing was seen. There was no evidence of blue or yellow colouring: the individual fibres appeared uniformly blue-green under the microscope, although the green colour almost certainly resulted from a mixture of blue and yellow dyes.

The scale pattern of the surface cuticle of the fibres was clear, particularly in the medium fibres, in which an irregular-waved mosaic pattern could be discerned, the wave being indicated by the frequent diagonal orientation of the scale margins. Some of the medium fibres in the leather, however, had an irregular mosaic pattern lacking a wave. This accords with recent work by Burns[6], which

suggests that a waved pattern derives from mosaic pattern as a result of wear in the fleece. Thus, what had been thought to be a fundamental difference apparently has no evolutionary significance.

The wool from the two Jewish cloth specimens was non-medullated, but a few of the medium fibres from the unspun wool, and the yarn specimen, had a fragmental medulla. Some fibres from the yarn specimen had an interrupted medulla, while a few had an unbroken medulla for an appreciable length, and could therefore be regarded as fine hairs. For example, a fibre 44μ in diameter had a medulla 12μ wide. It is not common for medium fibres in modern breeds to have an unbroken medulla; but the foregoing measurements compare with fibres in the Soay sheep ranging from one 29μ in diameter with a medulla 6μ wide to one 46μ in diameter with a medulla 16μ wide. They were not as fine as a fibre in a parchment from the Dead Sea Scrolls apparently from a hairy sheep[7], which was only 16μ in diameter, yet had a medulla 12μ wide. Nor were they as coarse as the relatively fine hairs of the Altai sheep[3], which had a diameter about 80μ and a medulla about 40μ wide.

Diameter measurements were made of 100 fibres from each wool specimen, and the mean diameters were as follows: unspun wool, 24μ; yarn, 30μ; green cloth, 24μ; and yellow cloth, 25μ. These compared with approximate values from the Soay (frequency in brackets) of 20μ (3), 24μ (2) and 30μ (3), also 38μ in a sample of Cheviot wool, a breed probably partly derived from the Soay. The range of fibre diameter was similar in each specimen, being from about 10μ to 48μ, but that of the yarn ranged up to 54μ. The diameter frequency had a skew distribution in each instance, the greatest number of fibres being in the fine diameter range. This explains why the specimens appeared fine to the naked eye. The frequency distribution of fibre diameters in the specimen of unspun wool is shown in Fig. 1. A similar skew distribution was found in the Soay, Shetland and in the Cheviot, but not in the Southdown and Suffolk Down, nor in the Romney and Leicester Longwools, which had a more symmetrical diameter distribution.

This skew distribution very probably arises from an appreciable difference in diameter between the primary and secondary fibres. In fact, in the distribution shown in Fig. 1 there is a suggestion of a second peak among the medium fibres which may be due to the primaries. Here the mean diameter of the fine fibres was 21μ, and that of the medium fibres was 38μ. It is noteworthy that the mean diameter of fine fibres approaches 20μ and that of medium fibres approaches 40μ in different breeds of sheep and at different periods in history.

It would be useful if one could calculate an S/P ratio from the number of fibres in each peak of a bimodal distribution of fibre diameters like that in Fig. 1. But, in fact, the ranges of the diameter of the primary and secondary fibres are likely to overlap, and so in the intermediate diameter range any division made between the two would be arbitrary. Calculations made with two possible and apparently suitable points of division on the diameter distribution of the yellow cloth gave values of 1·6 and 8, that is, outside the S/P range of most modern breeds. The clearest division between fine and medium fibres was that shown in Fig. 1, and an S/P ratio of 4·5 was obtained from this distribution. The yarn specimen and the green cloth gave S/P ratio values of 4·5 and 5·6, respectively. These values are what one would expect from a medium wool and so support its identification as such. An S/P ratio of 5 was estimated from the medium-woolled type of follicle grouping found in parchment of similar date from the nearby site of Murabba'at (shown in Fig. 4 of ref. 1). The (identified) fibres in this parchment had a similar range of diameter to those in the foregoing wool specimens: secondaries 16μ–24μ and primaries 32μ–42μ. An S/P ratio of 5 compares also with a mean value (from the skin) of 4·5 for the Cheviot breed[8], and

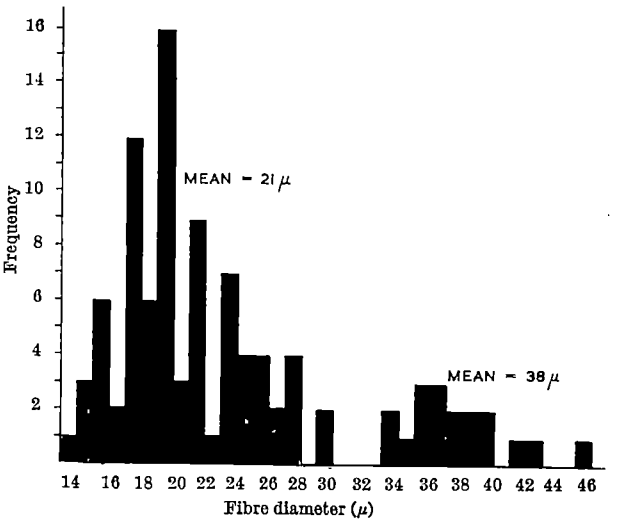

Fig. 1. Distribution of fibre diameters in un-spun wool from cave near Dead Sea, A.D. 130

individual values of 3·8 and 4·7 for the Soay[9]. But as a reminder that the above S/P ratios obtained from the wool could have been fortuitous, one might mention that S/P ratios of 4·8 and 2·1, respectively, were obtained from the wool of these two Soay sheep.

Four of the leather specimens (51/2, 61/2/1, 61/2/21 and 7/68) were relatively thick and hard with a dark-brown skin surface (grain side), which suggests vegetable tanning. Two (61/2/18 and 19) were pale brown in colour, and were thin and soft like chamois leather which is oil tanned, but these specimens could have been degraded. All the specimens gave a modified staining reaction showing increased basophilia that has been associated with vegetable-tanned leather[7]. But this staining reaction has since been found to occur also in untanned material entirely as a result of burial.

Whereas leather has hitherto yielded fewer follicle remains, when sectioned, than parchment, only one of these Jewish specimens (6/2/19) had no remains. Although one might expect that the cloth specimens would comprise the best wool available, the leather could have been from any type of animal. In fact, four of the specimens were from sheep of the same medium-woolled type as those from which the wool specimens must have come, and one was apparently a fine type. One medium-woolled specimen had medium follicle remains and fibres 42μ and 46μ in diameter. The three other leather specimens had fine and medium follicle remains, one of which had fibres 10, 16, 18 and 20μ in diameter, and another of which had fibres 12, 15, 36 and 46μ in diameter. The fine type, on the other hand, had relatively large complete groups of fine follicles, and the fibres that could be measured had the following diameters: 16μ (2), 18μ (5), 19μ (2), 20μ (2) and 26μ; there was not one fibre or follicle of medium diameter. This fine-woolled type therefore seems to be the same as that found in the parchment from the Dead Sea Scrolls; the specimen illustrated by Ryder[1] had large groups of mostly empty follicles; the few fibres that could be measured had diameters as follows: 10μ (2), 13μ, 26μ and 28μ.

The findings from the Jewish specimens of skin and wool indicate a predominance of a medium-woolled sheep like that which predominated in parchment from the Dead Sea Scrolls and from Murabba'at. This type o sheep is attested by the range of fibre diameters in bot the wool and the skin. The existence of a primitive medium-woolled sheep in that time and place is therefore amply confirmed, and this invalidates the suggestion[3], based on the investigation of the Altai skin, that the medium type in the Dead Sea Scrolls could have been

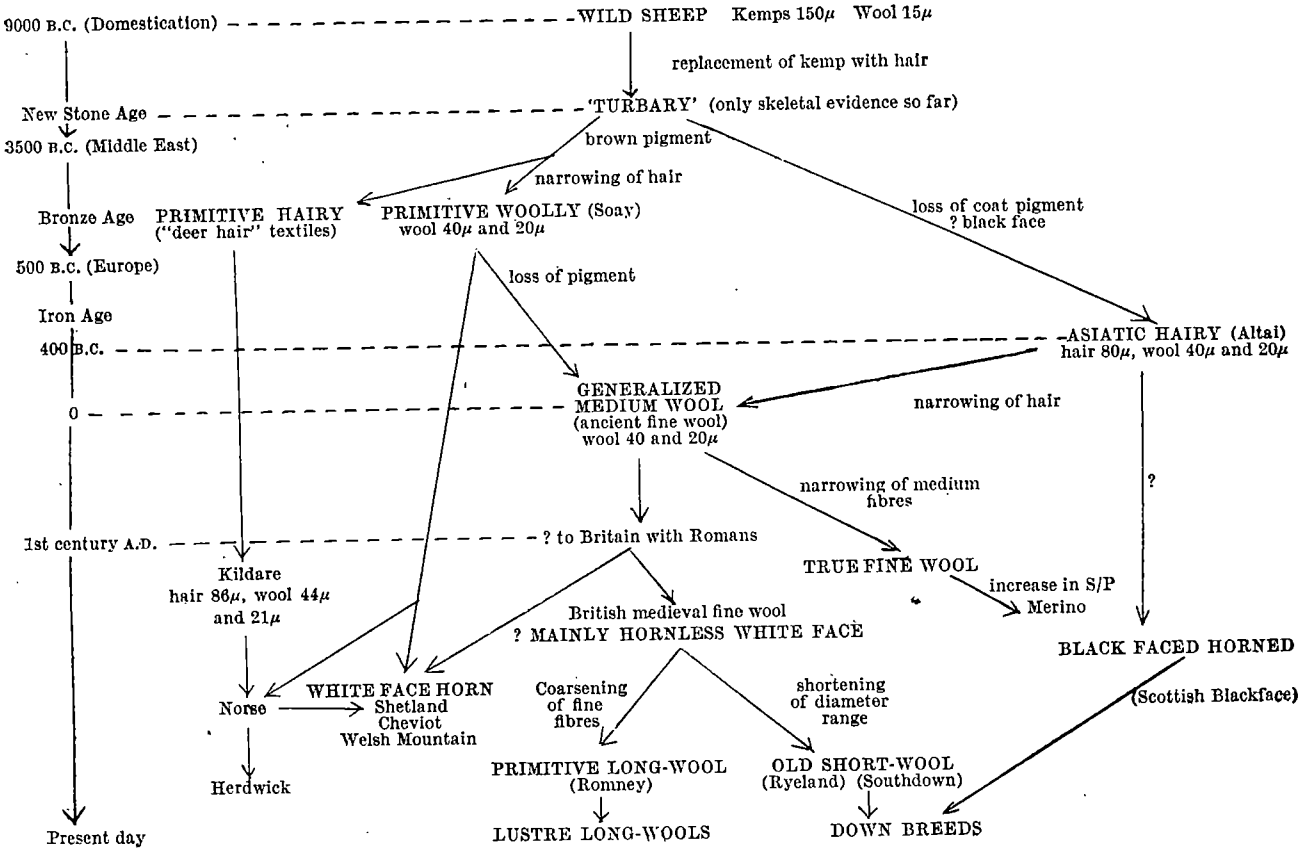

Fig. 2

merely a hiray type in which the coarser fibres had narrowed preparatory to shedding.

As with the Altai specimen, the wool in this investigation added much to the findings from the skin; in particular, it emphasized the much greater fibre diameter variation in the past compared with modern medium wools (Down and long-wool breeds). The observations recorded here indicate that the four specimens among the Dead Sea Scrolls described as being fine to medium[1] could have been medium wools. Two more, identified as fine wools from a few fibres of extreme fineness (12μ) alone, could have been medium wools. But the existence of the fine wool is confirmed by one specimen from the Dead Sea Scrolls, and one among the present specimens, with large complete groups of fine fibres only. So far, therefore, from the Dead Sea area the following totals have been identified: hairy sheep or goat, 4; medium wool, 21; fine wool, 2.

The hypothesis that can be put forward from these findings is that this medium wool seems to be a generalized fleece type that appears to lie in an intermediate position along the evolutionary scale between the more primitive hairy type (represented by the Altai sheep of 400 B.C.[3]) and the apparently more highly evolved fleece types of to-day. The medium-woolled type could have arisen from the hairy type by a narrowing of the primary fibres so that medium fibres grew instead of hairs. The Altai sheep, for example, did not have a very coarse fleece, and had an S/P ratio of 5 similar to that of the medium wool, so it could readily have given rise to the medium wool by a replacement of the hairs with medium fibres, which were already present in small numbers in the Altai wool. Further support for such a link can be gained from the finding of 'fine hairs' in the Jewish medium wool. Affinities with the Soay have been indicated in Fig. 2 to show that the crossing and admixture of different types are likely to have been important. The main change along this possible link is a loss of pigment from the coat.

The generalized fleece of the medium wool could in turn have given rise to various modern fleece types as follows. It could have given rise to the fine-woolled type by a further thinning of the primary fibres so that medium fibres were replaced by fine fibres. The two fine wools discussed in the present account suggest that this change was already taking place in the Near East about A.D. 100, and the S/P of 7 in the specimen from the Dead Sea Scrolls suggests that the S/P ratio had already begun to increase towards the average of about 20 found in the modern fine wool, the Merino.

Before considering how this medium wool could have contributed to the fleeces of modern British sheep I must briefly state how it could have reached Britain. It is likely that the Ancients regarded this medium wool as fine wool: in the investigation recorded here the presence of a proportion of medium fibres was completely unsuspected until a microscopic examination was made, so convincing was the impression of fineness given by the wool to the naked eye. It is therefore possible that this medium wool was, in fact, the renowned fine wool of the Near East that spread around the Mediterranean[10]. This may have been among the sheep that the Romans brought to Britain. Until the Romans came, the best-woolled sheep in Britain are likely to have been of Soay type, that is, medium-woolled, but brown. Crosses between the white Roman medium-woolled sheep and the brown, horned Soay could have given rise to the white-faced, horned breeds such as the Cheviot and Welsh Mountain[11], which, if coloured, have a brown pigment.

The persistence of the generalized medium wool into the Middle Ages as a distinct type is suggested by the English medieval parchments identified as coming from fine-, and fine- to medium-woolled sheep[12]. When these were examined originally the possibility of a wide range of diameter within a medium wool was not realized; parchments having fibres less than 18μ in diameter were regarded as indicating fine-woolled sheep, and fibres

18–35μ in diameter were described as fine-to-medium; wool 35–55μ in diameter (comparable with modern long-wools) was termed medium.

The present investigation provided a clue to the identity of the unidentified parchment illustrated in Fig. 2 of ref. 12. This had primary fibres ranging from 34μ to 48μ and secondary fibres ranging from 14μ to 24μ, which compare with the generalized medium-woolled type, and the brown pigment suggests a sheep more akin to the Soay.

In Britain, the generalized medium type could on its own have given rise to the short-wool fleece type (for example, modern Down) by a shortening of the range of fibre diameter, and it could have given rise to the diameter range found in the long wools by a coarsening of the fine fibres. The existence of this generalized medium fleece makes it unlikely that short-wools were derived from long wools, as was suggested by Fraser and Hamada[13]; instead, both appear to have had a common ancestor.

The specimens now to be described were examined as a first attempt to check the aforementioned hypothesis. It is intended to describe these more fully elsewhere. The only Bronze Age specimen examined so far in the work recorded here was one of the Danish textiles in which the presence of hairs or kemps was first erroneously thought to indicate an admixture of deer hair. In fact the proportion of hairs (50–88μ in diameter) and medium fibres (32–44μ in diameter) in this specimen was low, being together only about 5 per cent compared with more than 15 per cent in the typically hairy Kildare specimen described here. Although the total range of diameter was 8–88μ, the mean in the two yarns was as low as 16μ and 19μ, respectively. This fleece structure is not typical of a hairy, medium or fine type, but it occurred in later times (see following) and will be described at the moment as a hairy medium wool. More prehistoric specimens must be examined before suggestions can be made about this stage of evolution. Although in hand-spinning the wool is usually spun direct from the staple, one could imagine an attempt being made to remove the hairs. But this was not done with the Kildare specimen mentioned here, and could not explain the smaller proportion of medium fibres in the Bronze Age specimen*. Although, like the Soay, the fibres had a dense distribution of pigment granules, these were of the black rather than the red type, as the cloth appeared black in contrast to the chocolate colour of Soay wool.

The Kildare wool and the Roman specimens were of similar date to those from Israel. The Kildare specimen was from a hairy sheep (fibre diameter range 10–130μ) and some of the coarsest fibres are likely to have been kemps. There was moderately dense pigmentation, which varied between fibres. Such a fleece type lies further back than the Soay on the evolution diagram (Fig. 2) and is probably represented to-day by the Herdwick breed, which is the hairiest of the British white-faced horned group.

The Roman specimens from Scotland yielded seven yarns: three of these were white and four had slightly to moderately pigmented fibres, suggesting Soay influence. Two of the wools (one pigmented, one not) showed the same skewed-to-fine distribution as the Jewish medium wool, and three (two pigmented, one not) had the same distribution with a few relatively fine hairs (for example, 60μ in diameter with a medulla 30μ wide). Whereas the means of these five specimens ranged from 18μ to 23μ, the remaining two specimens had means of 17μ and 28μ, and the diameter distribution of these specimens tended to be symmetrical on each side of the mean. Thus, the Roman specimens show a variation of type from a slightly hairy medium wool, through the generalized medium wool, to a true yet pigmented medium wool (mean 28μ) similar in diameter distribution to the modern long-wool, and to a white short-wool (mean 17μ and non-pigmented), although the diameter range of this particular specimen was like that of the Merino rather than that of a modern British short wool.

The York specimen, although described as Roman[5], may be somewhat later in date[14]. This yielded two similar types of heavily pigmented wool with means of about 24μ and 33μ. The diameter range was 8μ to 64μ and both wools had a few hairs like the Bronze Age and Roman specimens mentioned here, that is, they were not as hairy as the Kildare wool. The Saxon wool from Fonaby had a finer diameter range (mean 18μ) than the generalized medium wool, but had the same skewed-to-fine distribution. Its moderate-to-dense pigmentation suggests Soay type.

The first group of Norse wools came from the Orkney Hood[5]. These comprised nine yarns, all with slight or moderate pigmentation. Five of these had fibres within the range 10–80μ, and had a skewed-to-fine distribution with only a few hairs like the slightly hairy Roman and York specimens, but four were true hairy types with hairs (or kemps) ranging up to 114μ, that is, more like the Kildare wool. The second group of Norse specimens from Kildonan comprised four yarns, all slightly to moderately pigmented. Two of the yarns had fibres in the diameter range 14–60μ with means of 25μ and 28μ and a few fine hairs as previously described. The distribution of the remaining Kildonan specimens was more difficult to interpret. One of the other yarns had a continuous distribution of fibre diameters of 16–58μ with a mean of 36μ. Some fibres were medullated, and so this may be another hairy medium wool. The fourth yarn had a diameter range of 12–46μ with a mean of 28μ, and although superficially symmetrical around this mean, as in a true medium wool, the distribution was slightly skewed towards the fine part of the range, identifying it with the generalized medium wool.

A medieval cloth from Closeburn yielded two moderately to heavily pigmented yarns with a fibre diameter range of 10–54μ and means of 23μ and 26μ. It had a skewed-to-fine diameter distribution which, with the pigment, suggests a Soay-type sheep. The two yarns in another medieval specimen, from Loch Trieg, had fibres with only slight pigmentation ranging from 8μ to 34μ in diameter and with means of 18μ and 20μ, respectively. The diameter distribution was symmetrical and typical of a short wool, which shows that some of the medieval parchments[12] could have been from true fine wools. A third medieval fabric, from Kelso, had fine and medium fibres with slight pigmentation, but these were too degraded to be measured.

These textiles, therefore, provided evidence supporting the hypothesis in that the generalized medium wool was found in Britain, and the suggested divergence from it towards the long wool and short wool was apparently occurring, unexpectedly, as early as Roman times. Further evidence was gained of the persistence of the Soay type in Scotland at least until the Middle Ages. An interesting finding is the predominance of hairy wool among the Norse specimens, as this supports the opinion that the Danes made a separate introduction of sheep akin to the Herdwick. This would explain the difference of the Herdwick from the remainder of the British white-faced horned group of breeds and its similarity to some modern Scandinavian sheep, notably in the high gene frequency for hæmoglobin A (ref. 15). Although it does not affect the argument, it should be mentioned that the later part of the Norse occupation of the northern and western parts of Scotland was, in fact, contemporary with the medieval period farther south.

When the third main group, the hairy black-faced horned sheep, arrived in Britain is still a mystery[11]. Hairy sheep lacking pigment in English medieval parchments such as that dated 1403 illustrated in Fig. 1 of Ryder[12] possibly belonged to this group, but its source (possibly originally Asia) is unknown.

An attempt has been made in Fig. 2 to illustrate the changes discussed here. The evidence for some of the affinities shown is discussed by Ryder[11], and other known changes have been omitted for simplicity and relevance.

* *Note added in proof.* In the moult of the Soay the hair sheds later than the wool, so wool plucked during the moult contains little hair.

AUXIN TRANSPORT IN ROOTS

Vicia faba

IT has been tacitly assumed, since the work of Went[1] and van der Weij[2], that the response of roots to gravity is mediated by the auxin, indolyl-3-acetic acid (IAA), which originates in the root tip and is transported thence to the elongating cells, more being deflected to the lowermost part of the organ where it inhibits growth and induces positive geotropic curvature. However, there is little experimental evidence in roots for such auxin movement or deflexion under gravity, and a series of researches carried out in this laboratory have strongly indicated that IAA may not be a key substance regulating either the extension growth of roots[3–5] or their response to gravity[6,7]. For these reasons work was started some two years ago on IAA transport in segments of the roots of *Vicia faba*, a species much used in the aforementioned investigations.

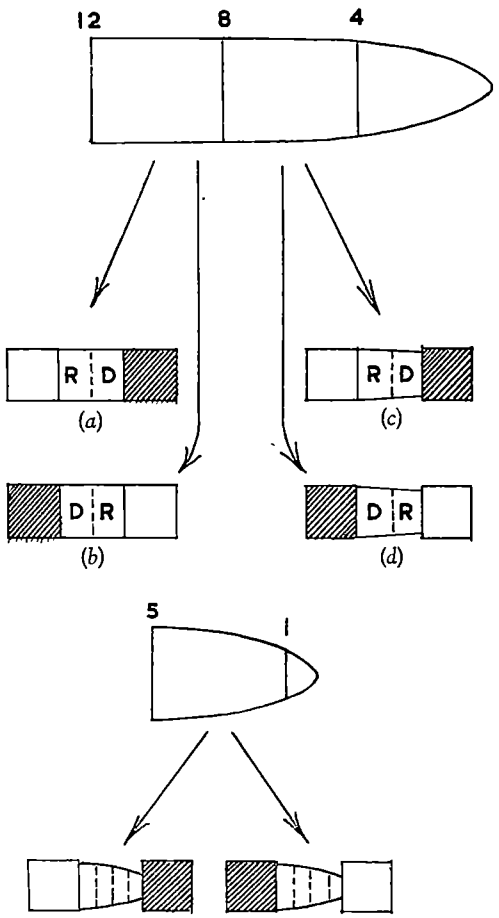

Fig. 1. Diagram to scale showing the methods used in studying the movement of ^{14}C-labelled IAA in 4-mm root segments of *Vicia faba* radicles. The figures represent the distances from the root tip in millimetres. The donor blocks are shaded

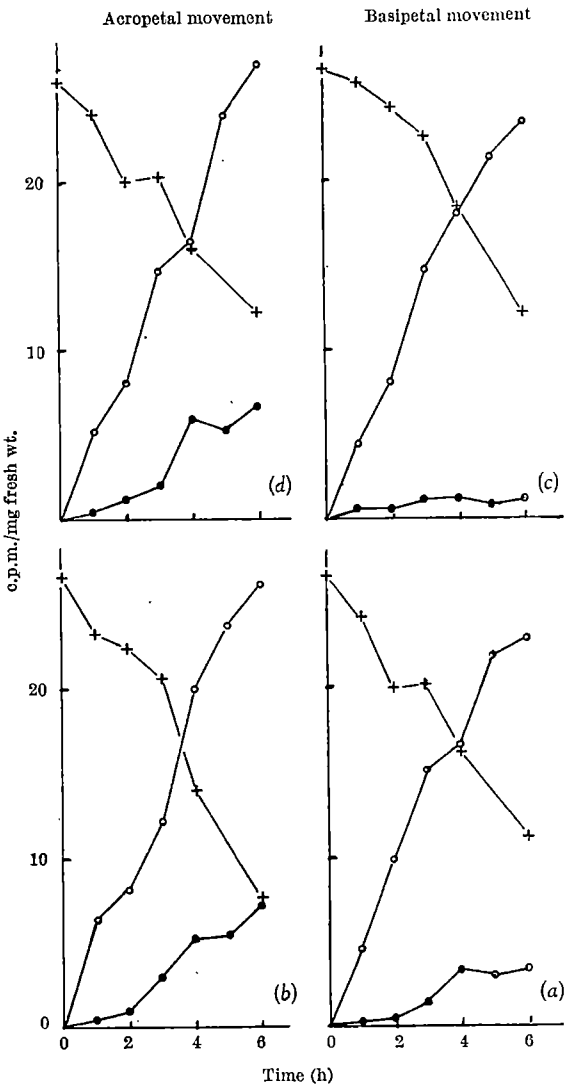

Fig. 2. Result of a typical experiment using segments cut between 4 and 8 mm (above) and between 8 and 12 mm (below) from the root tip. (*a*), (*b*), (*c*) and (*d*) correspond to the four treatments shown in Fig. 1. +, IAA concentration in donor block; ○, IAA concentration in half of segment at donor end; ●, IAA concentration in half of segment at receiver end. No radioactivity could be detected in the receiver block

The movement of radioactive IAA, ^{14}C-labelled in the carboxyl group (1·75 mc./m.mol), has been examined in 4-mm segments cut from various regions of the primary

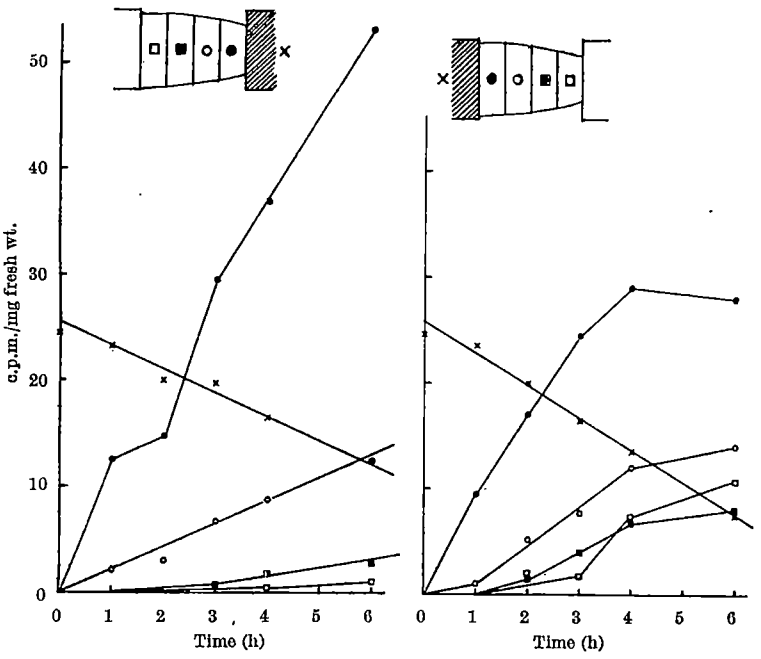

Fig. 3. Result of an experiment using extreme apical (1–5-mm) segments. The IAA content of quarter segments was determined, the keys to the graphs being shown at the top of the figure. ×, Concentration in donor block

radicle, using the technique of McCready[8] exactly as described in his papers. The IAA was obtained by alkaline hydrolysis of the nitrile and was shown by paper chromatography to have a high degree of purity. The donor blocks were of 0·02 ml. volume and contained 0·2 μg of IAA (≡ 5,450 c.p.m.). Sufficient replicates were set up to allow sampling at hourly intervals and counts were made of radioactivity in both donor and receiver block and also in the segments. In most experiments the segments were cut transversely into 2 or 4 equal parts, which were assayed separately so that the IAA gradient down the segment could be accurately ascertained.

In a root, cell differentiation proceeds rapidly as one moves away from the tip and segments cut near the tip are bound not to be homogeneous. Comparisons of acropetal and basipetal movement of auxin applied to the proximal or distal ends respectively of exactly similar segments could be as much a reflexion of uptake or absorption differences at the two ends as of a polarity of movement in the segment. To get more information on this the classical technique was modified and segments were cut in pairs from the seedling root and IAA movement in both directions followed in both segments (Fig. 1). In this way we could examine acropetal and basipetal movement into approximately the same tissue at a point in the root where the two segments had been contiguous. In segments very near the root tip such a technique could not be used because the two segments would not be of comparable dimensions. For these apical root segments (Fig. 1) only basipetal movement could be examined in the apical tissue; no attempts have yet been made to follow acropetal movement into the extreme 1-mm tip, which is constituted almost entirely of root cap.

Fig. 2 shows the result of a typical experiment using contiguous segments cut at 4 and 8 mm from the root tip, that is, in the region of active extension growth. The first thing which is striking about the results is that during the course of 6 h no appreciable passage of IAA occurred completely through these 4-mm segments since no counts significantly above background were ever detected in any receiver blocks. On the other hand, movement into the donor end of the segment was rapid and, as will be seen from a comparison of concentrations in the donor block and its adjacent half of the segment, this was against an overall concentration gradient from about 4 h onwards. This accumulation of IAA showed little change in characteristics with position along the root axis (that is, at 4, 8 or 12 mm from tip).

In the absence of measurable transport through the whole segment, the progress of accumulation in the half of the segment remote from the donor block can be used as a measure of transport rate in the root tissue. Accumulation here is a very small fraction of that in the half at the donor end, but it provides clear evidence that acropetal movement is greater than basipetal in both segments. The curves also show that, while acropetal movement varies little with position of the segment on the axis, basipetal movement (that is, away from the tip) is much smaller in the more apical segments.

These differences, although still small, become more marked in the 1–5-mm segment. Fig. 3 shows the results of another typical experiment in which the progress of IAA movement in both directions has been followed during 6 h in these segments, which are composed of the root meristem and the region of early cell expansion. These segments were divided into four 1-mm pieces for the analysis of concentration gradient changes. The curves show clearly that uptake of IAA into the extreme apical end is at the same rate as, but continues longer than, that into the basal end. On the other hand, the gradient of concentration in the basipetal direction is at all times much steeper than in the acropetal direction, which clearly demonstrates the distinctly preferential movement of IAA towards the apex.

The nature of this very marked accumulation of IAA in root tissue has been examined by experiments of the sort outlined here, but carried out either under nitrogen

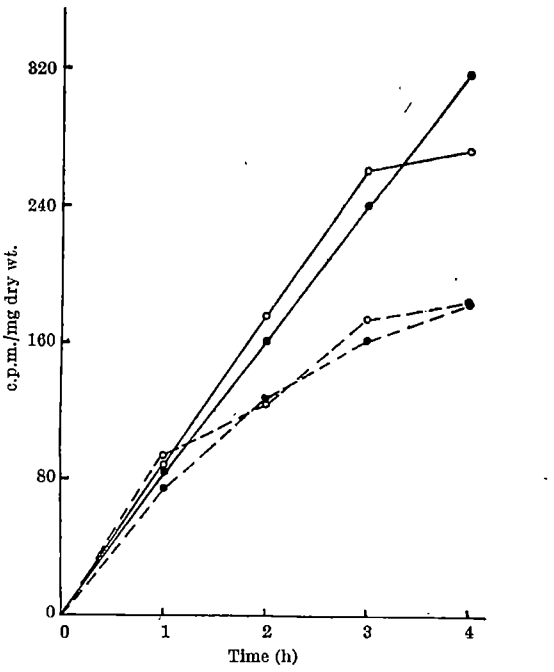

Fig. 4. Effects of pretreatments with 2,4-dinitrophenol on IAA movement into 4–8 mm and 8–12 mm segments. ——, Untreated segments; – – – –, segments pretreated 30 min with 10^{-4} M dinitrophenol; ●, acropetal movement—treatment (*d*) (Fig. 1); ○, basipetal movement—treatment (*a*) (Fig. 1)

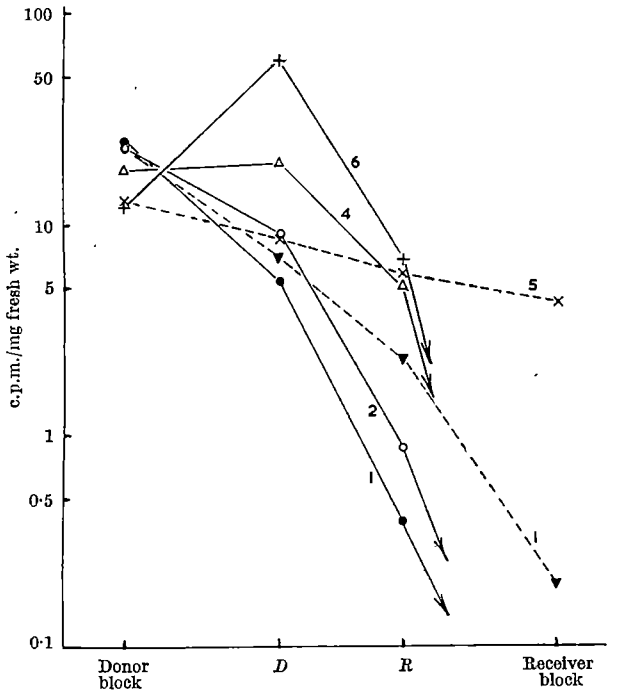

Fig. 5. Time-course of movement of IAA in 8–12-mm root segments and in agar cylinders of the same dimensions. ——, Root segments—treatment (*b*) (Fig. 1); – – – –, agar cylinder. The numbers by the graphs represent the time (h) after the application of the donor blocks

gas or with roots pretreated with solutions of potassium cyanide and 2,4-dinitrophenol (DNP) at concentrations which normally prevent active solute accumulation. All three treatments yield virtually the same result, which is illustrated by Fig. 4 (segments pretreated for 30 min with 10^{-4} M dinitrophenol). It will be seen that for movement in either direction into a 4-mm segment uptake during the first hour was unaffected by DNP, this presumably being diffusion into the free space in the tissues. Thereafter accumulation is depressed and, after 4 h, the overall concentration in the tissues is still not greater than that in the donor-block. The difference between the two sets of curves gives a measure of the active accumulation of IAA.

The rate of movement of IAA in the root tissue has been compared with the rate of diffusion in cylinders of 1·5 per cent agar of the same dimensions. Analyses have similarly been made of IAA concentrations in the donor and receiver blocks, and also in the two halves of the agar cylinder. The two sequences of 'flow' during the period of 1–6 h are compared in Fig. 5. There is no doubt of the restrictive influence of the accumulation process on the flow of IAA through root tissues, which is not otherwise inconsistent with diffusion. There is no evidence whatsoever for an active polar transport. The difference observed in acropetal and basipetal movement in these root segments can be most plausibly explained in terms of a positive gradient of accumulation potential as one moves towards the root tip. Since accumulation provides a 'sink' for diffusive flow this gradient would automatically retard basipetal movement and accelerate acropetal movement.

'These results throw further doubt on the classical theories of auxin control of root growth, in particular the role of IAA. The phenomena described seem to be associated more with the prevention than the promotion of IAA movement in root tissues and add further support to the suggestion that a quite different molecule may be the main growth regulator involved.

Lens culinaris

The transport of auxin is less well defined in roots than in other parts of the plant[1–3]. On the whole, endogenous auxin seems to be translocated in both directions along the main axis[4] and sometimes transport towards the root tip may be greater than away from it[5]. In *Lens* roots, I[6] found evidence of a completely cyclic transport involving transverse and longitudinal movements, both to and from the tip.

It is clear that our knowledge of the situation is very imperfect, and in the work to be described the powerful techniques of ^{14}C-labelling have been brought to bear on the problem. In principle the basic method used was the classical technique of Went[7] and van der Weij[8]. An agar block containing β-indolyl-3-acetic acid with carbon-14 labelled IAA was applied to one end of a segment cut from a root and the transport estimated by observing the labelled IAA accumulating in another agar block applied to the opposite end of the segment. This is essentially the method described by McCready and McCready and Jacobs[9].

Plants of *Lens culinaris* grown under uniform conditions[10] were selected for uniform length of root (18 ± 0·6 mm). Segments 5 ± 0·2 mm long were used. The agar gel was made with Oxoid 'Ionagar No. 2' at 1·6 per cent w/v. All experiments were carried out at 25° C in dim green light. Thin-layer chromatography[11] showed that the labelled IAA finally used was at least 97·4 per cent radiochemically pure. Each experiment was repeated six times.

In the first series of investigations six different experimental conditions were used (for details see Fig. 1) in order to investigate the effect of orientation of segment in relation to gravity on the labelled IAA transport. The results are shown in Table 1, from which it can be concluded: (*a*) That the rate of transport is extremely low in all treatments. (*b*) In some cases (namely, treatments 1, 4 and 5) there is a small significant accumulation of

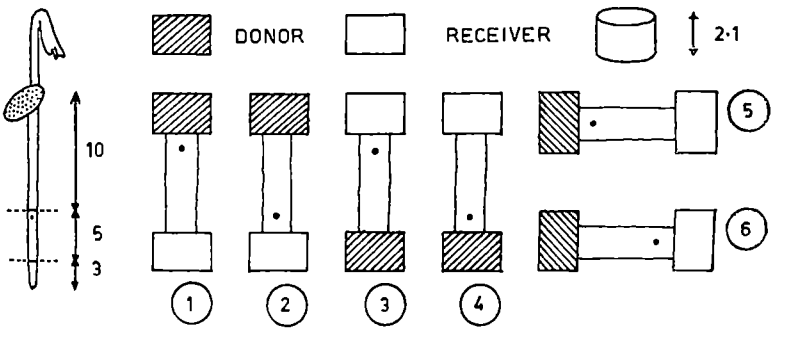

Fig. 1. Diagram showing principle of transport experiments (Table 1). The apex of each segment is distinguished from the base by the convention of marking it with a black dot

labelled IAA in the receiver block. (*c*) This accumulation occurs only in those applications at the proximal end of the segment and is not related to orientation with respect to gravity. (*d*) There is thus a weak polar movement of applied labelled IAA towards the root tip.

* Fragments of *Lens* roots (5 ± 0·5 mm) were used

The poor translocation of the labelled IAA in the root segments cannot be explained by a weak penetration of the labelled IAA into these segments. It was previously demonstrated that the uptake of labelled IAA by the root segments can be very high. In Table 2 it can be easily observed that the characteristic decrease of the radioactivity in the donor blocks is not exactly correlated with the weak increase in the receiver blocks (Table 1).

Table 2. RADIOACTIVITY IN THE DONOR BLOCKS

Table 3. TIME-COURSE OF MOVEMENT OF LABELLED IAA INTO RECEIVERS
(Radioactivity in c.p.m./mg dry wt.)

	Time of diffusion (min)			
Exps.	240	480	720	960
1	97 ± 12	150 ± 37	164 ± 40	167 ± 54
4	89 ± 10	146 ± 20	173 ± 32	170 ± 42
5	92 ± 11	157 ± 29	175 ± 42	181 ± 57

In the second series of experiments the time-course of labelled IAA transport was analysed using essentially the same technique. It can be seen in Table 3 that the initial accumulation in the receiver blocks began to slow down between 4 and 8 h and had practically ceased by 12 h. These results can easily be explained by the unavoidable drying-up of the root segments and also, as will be seen below, by the *in vivo* destruction of the labelled IAA.

In a third series of experiments two kinds of labelled IAA were used, one labelled in the carboxyl group (I) and the other in the α-position of the indole ring (II). In these investigations an agar plate containing labelled IAA (in a Petri dish) was used instead of individual agar blocks. The segments (Exp. 4, Fig. 1) were placed in a special support by a technique already described[13] (Fig. 2). In Fig. 3 is plotted the time-course of accumulation of the two molecules in the donor block. In both cases the rate remains steady with time over an 8-h period but the rate of accumulation of labelled IAA (II) was about twice that of labelled IAA (I).

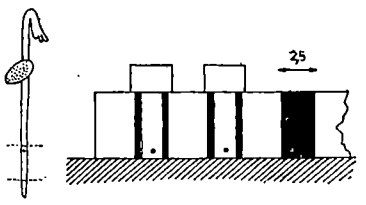

Fig. 2. Diagram showing principle of rapid transport experiments (results Fig. 3). The donor blocks are replaced here by an agar plate which contains labelled IAA. White, receiver; hatched, donor

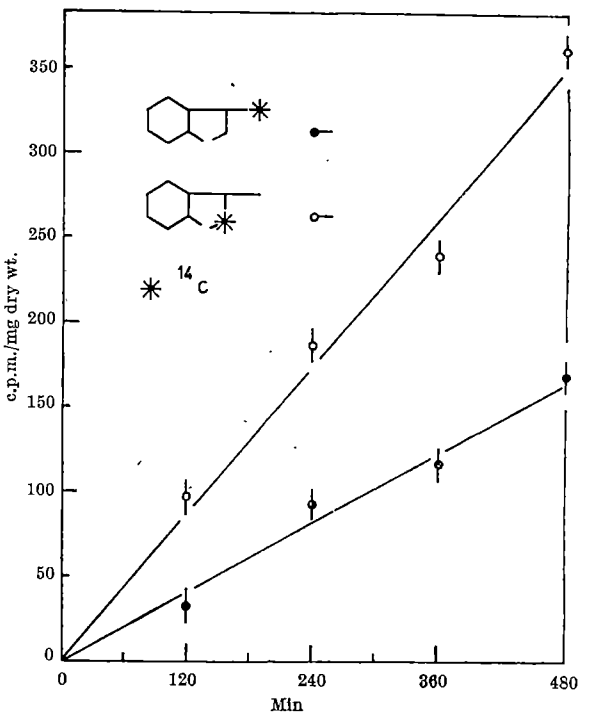

Fig. 3. The time-course of movement of carbon-14 from IAA supplied in the donor plates. ●, IAA labelled in —COOH; ○, IAA labelled in α-ring. Radioactivity in the receiver blocks in c.p.m./mg dry wt.

These results suggest that IAA during its transport is destroyed in *Lens* root segments. It has already been shown that *Lens* roots contain an active enzyme system which catalyses the inactivation of IAA both *in vivo* and *in vitro*. It was also demonstrated that the IAA-oxidases from *Lens* roots can not only remove the side-chain but also open the ring of IAA although the first process is faster than the second[15].

Since the translocation of auxin was analysed only by measurements of the transport of carbon-14, the difference between the rate of accumulation of labelled IAA (II) and labelled IAA (I) can easily be explained in terms of IAA destruction, the decarboxylation occurring more readily than the opening of the ring. The weak translocation of IAA in the root of *Lens* may be closely related to its rapid destruction. It might be that only a little of the radioactivity in the receivers is due to the accumulation of labelled IAA and that most of it is in related compounds formed *in vivo* by the action of the IAA–oxidase system.

In general conclusion it is clear that the applied labelled IAA is very weakly transported in *Lens* root tissue although the techniques used succeed in revealing a polarity of movement towards the tip.

LETTERS TO THE EDITOR

PHYSICS

Detection of the Onset of Instability in a Cylindrical Magnetohydrodynamic Flow

DURING the past few years the classical small perturbation analysis for the prediction of criteria of stability in hydrodynamic flows has been extended to cover several cases where the fluids are electrical conductors and magnetic fields are present[1].

The experiment described here concerns the circular flow between stationary cylinders of a conducting liquid which is driven by the interaction of an axial magnetic field with radial currents. If the gap between the cylinders is small compared with their radii, the drop in voltage across the gap for simple laminar flow is approximately:

$$\Delta V = \frac{Id}{2\pi L R_1 \sigma}\left\{1 + \frac{M^2}{12}\right\} \qquad (1)$$
$$= \Delta V_\Omega + \Delta V_\eta$$

where I is the total current passed between the cylinders (if the current in the liquid is axially and azimuthally constant), d is the gap, R_1 is the inner cylinder radius, L is the cylinder length, σ is the conductivity, and $M = \sqrt{\frac{\sigma}{\eta}}\,Bd$ is the Hartmann No., η is the viscosity and B the axial magnetic flux density (all in M.K.S. units). ΔV_Ω and ΔV_η are the drops in voltage due to ohmic and viscous dissipation, respectively. The small perturbation analysis gives equations identical to those for pressure-driven circular flow with an axial magnetic field. For these the theoretical stability criteria have been established[2]. There is a critical value of k for any given M: where

$$k = Re \cdot \sqrt{\frac{d}{R_1}}$$

$$\text{and } Re = \frac{\rho u_m d}{\eta},\ u_m = \frac{\Delta V_\eta}{Bd}$$

The magnetic field has a stabilizing influence, and lengthens the cells of the post-critical flow. If B is fixed,

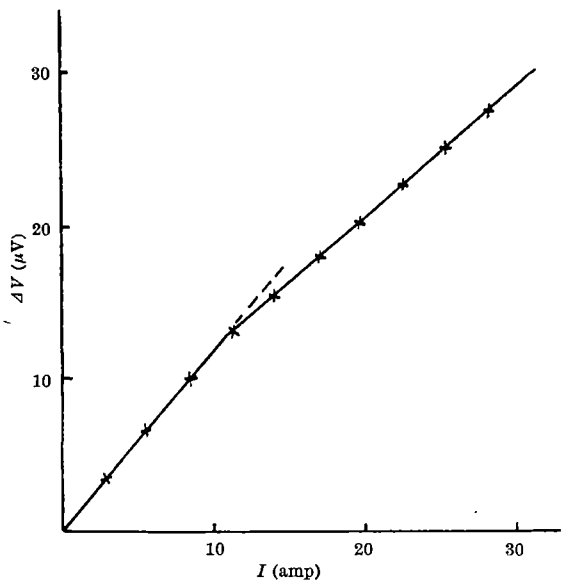

Fig. 1. B, 0·3; M, 9·3

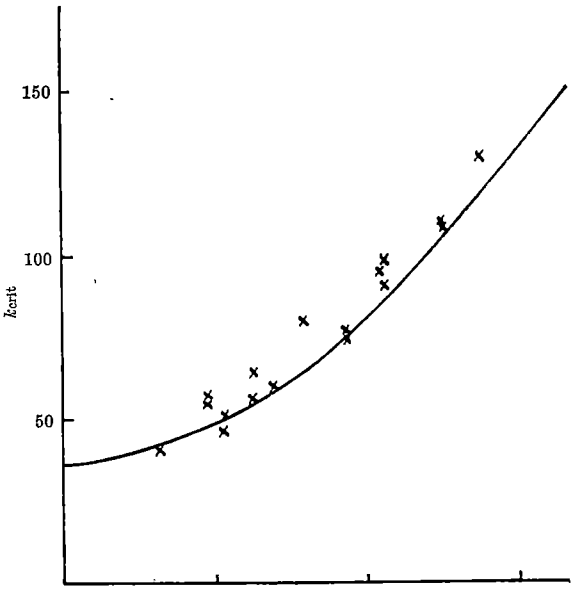

Fig. 2

ΔV should fall progressively below the value given by expression (1) above the critical point.

In the apparatus $R_1 = 0{\cdot}026$ m, $L = 0{\cdot}05$ m, $d \simeq 0{\cdot}0012$ m (three values were used). The maximum field obtainable was 0·5 webers/m². The cylinders were of high conductivity copper and the liquid was mercury. Fig. 1 shows the results of a typical experimental run. Fig. 2 shows the experimental values of k_{crit} and the theoretical curve for perfectly conducting walls. The chief source of experimental error was the variations in d due to the mercury–copper amalgam layer. The experimental points tend to lie above the theoretical curve, and this is probably due to the small gap assumption.

Electron Transfer in Irradiated Vacuum Cavity Chambers

GREENING[1] has explained the residual current in an ionization chamber, when the pressure is reduced to very low values, in terms of the transfer of slow electrons between the electrodes. He has proposed a theory for the saturation characteristics of evacuated chambers under irradiation. On the basis of a review of experimental data, he suggested an electron energy spectrum emitted from the walls, namely, the low-energy part of the electron spectrum from 0–41 eV could be represented by $KE^{\frac{1}{2}}e^{-E/S}$ per unit energy interval and the high-energy part of the electron spectrum from 41–∞eV by $\frac{64{\cdot}5K}{E^2}$ per unit energy interval, where E is the electron energy and K is a constant. Generally it is necessary to know the directional distribution of the electrons emerging from the wall before the saturation characteristic of a vacuum

chamber can be calculated from Greening's theory. Notwithstanding this, it is possible to calculate the saturation characteristics of a spherical vacuum chamber without any knowledge of the directional distribution of the electron emitted from the walls, because of the threefold symmetry in this case. A spherical vacuum chamber, with the radii of the inner and outer electrodes being 3·13 cm and 5·08 cm respectively, has been constructed and a theoretical saturation characteristic calculated, using the electron energy spectrum suggested by Greening, and is represented by the curve labelled *A* in Fig. 1.

The copper vacuum chamber was irradiated in the γ-ray field from a 2,000-c. cobalt-60 unit. The wall thickness of the outer electrode, 2·64 mm of copper, was sufficient to establish electron equilibrium. The polarizing voltage was supplied by dry batteries and a potential divider, and the current was measured on a vibrating reed electrometer. The pressure during the measurement was 0·9–1·1 × 10^{-5} mm of mercury, which according to Taylor[2] is well below the pressure at which ionizing events will contribute significantly to the current. The temperature was 23·2° ±1° C. The experimental results are represented in Fig. 1 by curve *B*.

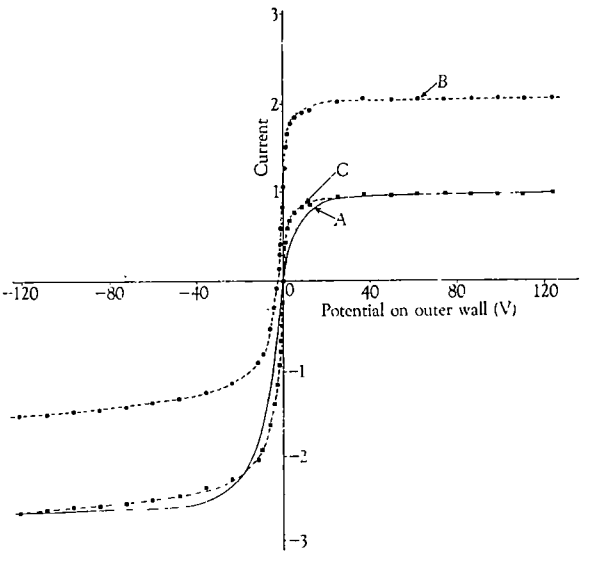

Fig. 1

The experimental curve is displaced from the theoretical curve, and in particular, it is noted that there is a finite current when zero polarizing voltage is applied. This is provisionally attributed to the attenuation of the γ-radiation by absorption and the inverse square law giving rise to unequal emission of electrons per unit area from the two electrodes, whereas the theory assumes equal electron emission per unit area. The current at zero voltage has therefore been subtracted from the measured values of the current and the experimental values replotted in curve *C*. The theoretical curve, *A*, and the adjusted experimental curve, *C*, have been normalized on the value of the current at +120 V to the outer electrode. The experimental curve *B* has been normalized on the same value as curve *C*.

The experimental results are now in general agreement with the theoretical predictions. At the higher values of the polarizing voltage (above 100 V), the agreement between experiment and theory is very close. In this region, the theoretical results are only slightly influenced by the shape of the electron energy spectrum. It therefore appears that Greening's theoretical suggestions are substantially correct. At lower values of the polarizing voltage the theoretical curve is in large measure determined by the shape of the electron energy spectrum. It is noted that the experimental curve *C* has a steeper ascent toward the plateau than the theoretical curve *A*, which suggests the electron energy spectrum occurring in practice tends to be more concentrated in the lower energies than that used in the theoretical calculation. Similar results were obtained when a telecæsium-137 unit was used to irradiate the chamber, but the agreement between theory and experiment at −120 V to the outer electrode was not so close. Thus, while Greening's explanation of the residual current in ionization chambers at low pressures and his basic theory are correct, the energy spectrum he postulated appears to be too heavily weighted at the higher energies, at least in this particular case.

We thank Mr. D. E. A. Jones for allowing us to use the radiation facilities at Mount Vernon Hospital, Northwood, and Prof. J. F. Fowler and Mr. J. Yarwood for their advice.

GEOLOGY

Evidence for a Considerable Depression of the Vegetation Belts during the Upper Pleistocene on the East African Mountains

Preliminary analyses were made of a core from the sediments of Sacred Lake, which lies in the montane rain forest zone at an altitude of 2,440 m at 37° 32′ E. and 0° 03′ N. on the north-east flank of Mount Kenya. A carbon-14 age determination of 15,400 ± 180 B.P. (GrN–3614) was obtained from the −12·30 m level. To base this date on the half-life 5,730 ± 40 years, it was multiplied by 1·03, thus converting it to 15,862 ± 185 B.P. (All other dates mentioned have likewise been converted.) On the assumption of a constant sedimentation rate, the age of total core is calculated to be 18,626 B.P. The European chronostratigraphy was used for calibration with the pollen stratigraphy of the core.

Pollen sum. The pollen sum consists of pollen from the regional vegetation belts of the mountain, namely, the Gramineae, Compositae, species of the ericaceous belt, forest trees and shrubs. Pollen produced by the aquatic plants and plants of the edge of the lake is excluded from the sum, being only of local importance. Five hundred pollen grains from each level were counted. It was possible to recognize the following typical vegetational belts of the mountain[1] in Fig. 1: (*a*) the montane forest belt consisting of the lower semi-tropical rain forest, the montane rain forest and the *Hagenia–Hypericum* zone of the tree-line at about 3,350 m; (*b*) the ericaceous belt above the forest which occurs up to about 3,660 m; (*c*) the alpine belt of grassy moorland and other Compositae which extends from about 3,660 m to 4,500 m.

As in the case of the equatorial Andean Mountains[2] and at the Cherangani Hills of East Africa[3,4], high percentages of Gramineae indicate open vegetation with conditions of the Afro-alpine belt. *Hagenia* pollen gives a good indication of the position of the tree-line and high percentages of the rest of the forest indicate more favourable humidity and temperature conditions. *Podocarpus* pollen is over-represented in the deeper levels because of its high pollen production and long-distance transport.

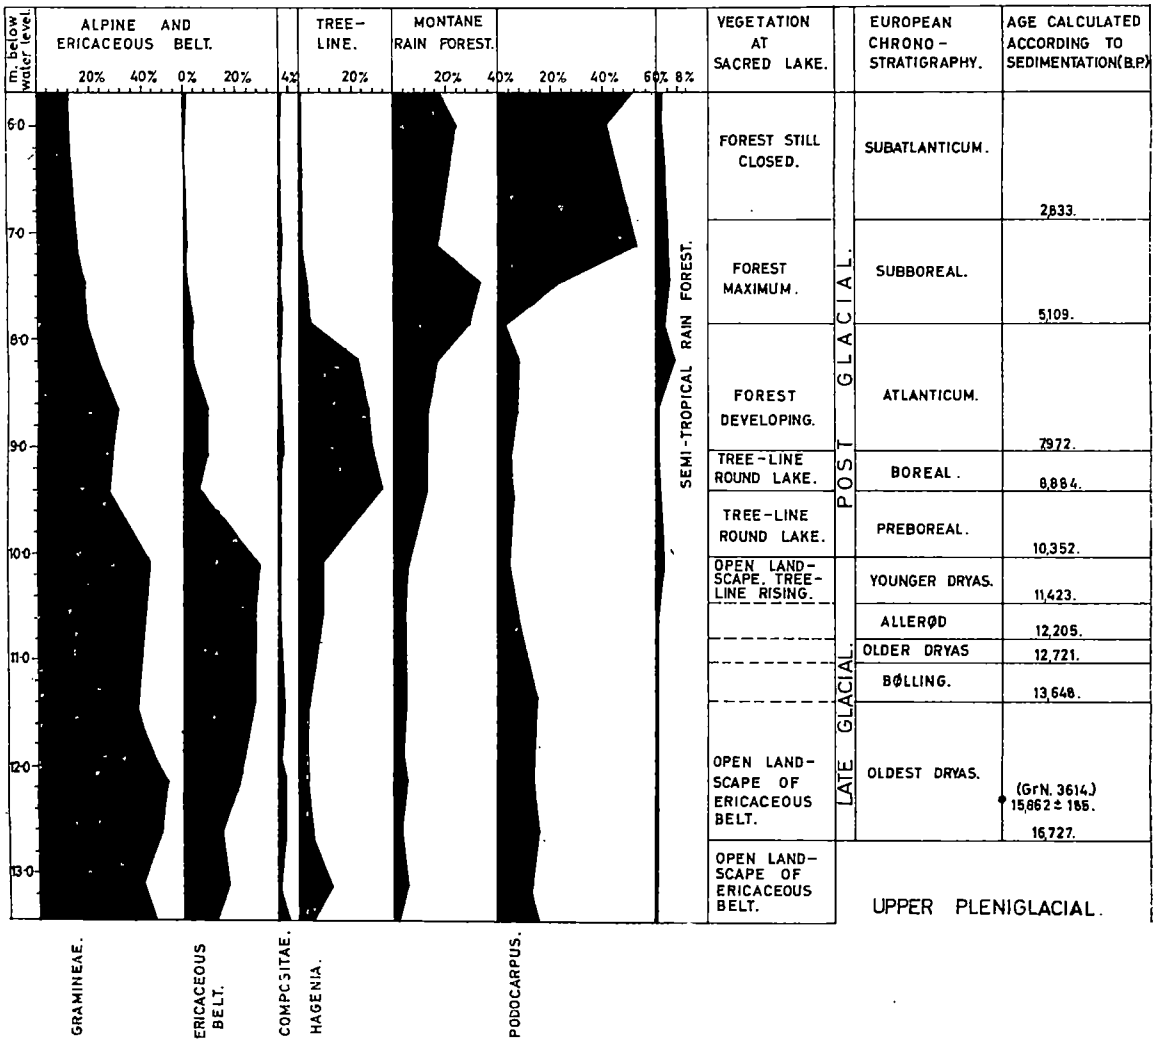

Fig. 1. Species identified: (*a*) Ericaceous belt: *Artemisia, Cliffortia, Stoebe, Myrica, Ericaceae, Anthospermum.* (*b*) Montane Rain Forest: *Rhamnus, Afrocrania, Proteaceae, Ilex, Macaranga, Olea, Rhus, Olinia, Cassipourea, Urera, Neoboutonia, Dombeya, Chrysophyllum, Pygeum, Apodytes, Juniperus, Xymalos Toddalia, Maytenus.* (*c*) Semi-tropical Rain Forest: *Celtis, Cylicomorpha, Trichilia, Trema, Ehretia, Galiniera, Chlorophora, Lovoa, Canthium, Bersama, Clausena*

Pollen diagram. The dated sample falls within the oldest *Dryas* period of the European time-scale. The vegetation round Sacred Lake during this period consisted mainly of Gramineae and species from the ericaceous belt, indicating an open landscape exposed to severe diurnal changes of temperature and humidity. This phase was contemporaneous with the retreat of the Ruwenzori glaciers of East Africa as dated by Livingstone to be 15,141 ± 298 B.P. (Isotopes Inc.). The Würm glaciers in Europe and the Wisconsin glaciers in North America also diminished in size from that time onward[5]. So far the equivalents of the Bølling and Allerød oscillations have not been detected. Analyses at shorter intervals will have to be made in this connexion.

The most remarkable point of the diagram is found at the level −10·10 m, where a significant change occurs in practically all the curves. From here upwards the pollen of the grasses and ericaceous belt shows a clear decline whereas *Hagenia* rises rapidly and the montane rain forest starts to show a definite development round the lake. This horizon has a calculated age of 10,583 B.P. and is coeval with the end of the Late Glacial and the beginning of the Preboreal period of Europe. During Preboreal times *Hagenia* is dominant on the site and is accompanied by the tall Compositae shrubs which are typical at the upper limit of the forest. This succession indicates a rapid rise in temperature. Conditions remain practically the same during Boreal times (from levels −9·42 to −9·07 m). During the period which is coeval with the climatic optimum of the Atlanticum of Europe, conditions are very favourable for the growth of the forest. It only becomes closed, however, at a later stage as is clearly shown by the forest maximum and the definite minima of the ericaceous belt and *Hagenia* at about −7·50 m. This establishment of the montane rain forest occurs after 5,100 B.P., which date is generally accepted to be the beginning of the Subboreal in Europe. It indicates more favourable conditions during the Subboreal than during the Atlanticum.

In the upper part of the diagram, the forest is still closed. The rapid rise of the *Podocarpus* curve indicates climatic changes which occurred during the Subatlanticum. The semi-tropical rain forest is represented in the diagram from the beginning of the Preboreal and shows a definite maximum during the latter half of the Atlanticum.

Conclusions. The results of the pollen analysis of the Sacred Lake sediments now give definite proof that the time-scale of the Late Glacial and Post Glacial periods of Europe can be applied in tropical East Africa. It shows that similar climatic changes occurred simultaneously in these regions.

Contemporaneous with the cold Oldest Dryas of Europe, there was a considerable depression of the vegetation belts of Mount Kenya. At the level of the dated sample, the pollen spectrum clearly shows a vegetation round Sacred

Lake similar to that found at present above the tree-line in the open ericaceous belt. This indicates a 1,000–1,100-m downward shift of this vegetation and a probable drop in temperature of about 8° C in this high mountain area, if the temperature calculation method for the equatorial Andean Mountains is applied[2].

A deeper core has since been made at Sacred Lake. Judging by the age of the deepest level, namely 33,350 ± 1,000 B.P. (GrN–4194), the total core probably represents the period from before the Paudorf interstadial of the Interpleniglacial of Europe to the present time.

Relationship of Palæomagnetic Reversals and Micropalæontology in Two Late Cænozoic Cores from the Pacific Ocean

Recent investigation has revealed palæomagnetic reversals preserved in the clayey radiolarian ooze of two deep-sea cores from the equatorial Pacific Ocean. The cores are:

MSN 12*G*; position 3° 01′ N., 174° 02′ W.; depth, 5,230 m.

MSN 142*G*; position 5° 20′ N., 146° 13′ W., depth, 5,089 m.

The cores are illustrated, their lithologies briefly described, and Radiolaria listed by Riedel and Funnell[1].

Palæomagnetism. The uppermost parts of both cores are thought to be normally magnetized with respect to the present Earth's field. As the cores come from equatorial positions and were not orientated on collection it is not possible to be certain that this is so. There is, however, no evidence of erosion or non-deposition at or near the tops of either sequence. The first reversal occurs in *MSN* 12*G* between 74 and 95 cm, and in *MSN* 142*G* between 78 and 87 cm. Other reversals occur below these levels in both cores. Assuming that the uppermost magnetic vector is normal, the magnetization of the cores is as follows:

MSN 12*G*; 6–74 cm (N, 5 samples), 95–116 cm (*R*, 7 samples), 119, 123 cm (N), 133 cm (*R*), 135 cm (N), 138–146 cm (*R*, 7 samples).

MSN 142*G*; 15–78 cm (N, 8 samples), 87–107 cm (*R*, 3 samples), 116, 125 cm (N), 134, 142 cm (*R*).

The palæomagnetic results below the first reversed zone (*R*1) do not seem to be consistent with the hypothesis that reversals of the Earth's magnetic field have occurred about every million years, unless extremely slow ratios of deposition are assumed for the lower portions of these cores. However, recent results from continental rocks[2–5] are also inconsistent with this hypothesis, and it seems likely that below the *R*1 zone reversals occurred more rapidly than was formerly suggested.

Micropalæontology. In *MSN* 12*G*, Radiolaria between 0 and 43 cm are similar to Recent assemblages and indicate a Quaternary age. Specimens of *Pterocanium prismatium* occur rarely at 90–92 cm, and commonly from 127 cm to the bottom of the core. Some re-worked Eocene, Miocene and possibly Oligocene forms are present throughout. In *MSN* 142*G*, a Quaternary age is indicated by the Radiolaria between 0 and 76 cm, but from 94 cm to the bottom of the core *Pterocanium prismatium* is rather common. In this core some re-worked Miocene forms are present throughout.

In both cores examined the first reversal appears to correspond more or less exactly with the upper limit of occurrence of *Pterocanium prismatium*. Lithologically there does not seem to be any break in accumulation at this level in *MSN* 12*G*, which consists throughout of a vaguely mottled, brown clayey siliceous ooze, but in *MSN* 142*G* there is a burrow-mottled gradation, between buff or brown ooze above and grey-brown ooze below, at approximately 85 cm.

In recent investigations of the palæomagnetic polarity of basalts from the continents and oceanic islands, normal magnetization has been found to characterize all rocks up to 0·98 m.y. B.P., prior to which a period of reversed magnetism (*R*1) is found extending back to 1·9 m.y.[2–5]. The reversal at 0·98/0·99 m.y. would appear to fall within the Quaternary, as defined in accordance with the recommendations of the International Geological Congress 1948 (refs. 4 and 6). If, as seems most likely, the first reversal recorded in the cores corresponds to that found on land, an intra-Quaternary age of 0·98/0·99 m.y. is implied for the level of the reversal in the cores.

The upper limit of occurrence of *Pterocanium prismatium* has hitherto been regarded as approximating to the Tertiary–Quaternary boundary[1,7]. In the Pacific it corresponds rather closely with the disappearance of *Discoaster* spp. from the calcareous nannoplankton, a phenomenon which has also been attributed to the Tertiary–Quaternary boundary in the Atlantic[8].

The association of a first magnetic reversal with the upper limit of occurrence of *Pterocanium prismatium* in the two Pacific cores suggests that this level has an age of very slightly less than 1 m.y. and that it is intra-Quaternary in terms of current stratigraphical definitions.

New Species of *Schizaea* Spore from the Upper Mesozoic of Kashmir, India

During the study of samples collected from Wakkachu Traverse, Ladhak District, Jammu and Kashmir, I obtained a new type of striated bean-shaped spore belonging to the family Schizaeaceae together with a number of other spores and pollen grains having an upper Mesozoic affinity. The detailed results of this work will be published elsewhere. The samples were crushed and treated with hydrofluoric acid followed by concentrated nitric acid and hydrogen peroxide solution. The polyspores were separated by a heavy liquid (specific gravity, 2·3) and mounted in glycerine jelly.

The spore is large, bilateral and bean-shaped; monolete, laesura long; exine sculptured with unbranched broad striations. Striations 4μ thick are spaced about 3·5–4μ

a *b*

Fig. 1. *Schizaea kashmiriensis* sp. nov. *a*, Camera lucida drawing; *b*, photomicrograph (× 400)

and parallel to each other and run along the long axis of the spore. Length, 85·8μ; breadth, 39μ; broad end, 42·9μ; narrow end, 31·2μ (Fig. 1).

From the available knowledge of the morphology of the recent and fossil Schizaeaceae spores, bilateral bean-shaped, striated, monolete spores are met with only in the genus *Schizaea*. No *Schizaea* spores previously described, recent or fossil, from Tertiary or Mesozoic beds[1–10], resemble the spore described here. The new species is named *Schizaea kashmiriensis* sp. nov.

I thank Mr. A. K. Ghosh for advice, and Shri L. L. Bhandari for the samples collected by him.

GEOCHEMISTRY

'Impact Contamination' of the Mokoia Carbonaceous Chondrite

In the course of inspection of a specimen of the stone from New Zealand, in the Museum of Paris, a rather unusual yellow chondrule-like grain, 1·7 mm in diameter, was detected on what appeared to be fresh fractured surface, some 23 mm from the nearest visible crust on the specimen. On closer examination the grain proved to consist of resinous material soluble in ether, and with volatiles of 92·7 per cent; 4·1 per cent fixed carbon and 3·2 per cent ash. The terrestrial origin of this blob of resin is supported by the ample fragments of wood, spores, Radiolaria, and other typical micro-fossils.

The foregoing observation indicates that in the course of the impact of a given meteorite, foreign bodies can penetrate to considerable depth, particularly in the case of the porous and soft carbonaceous stones. Beside this physical penetration process, illustrated by this work, distillation of surrounding plant remains could be brought about by the hot stone, and the products may become deeply absorbed as a result of vacuum forming through the cooling-down of the meteorite and condensation of vapours of water, etc., in its pores. I consider that this factor of 'impact contamination' should be investigated in greater detail, in order to assess the value of searches for molecules whict are generally believed to be exclusively or almosh exclusively biogenic.

I have found[1] that the Cold Bokkeveldt meteorite contained no optically rotating molecules, within the limit of sensitivity of the equipment used, which was of the order of 1 p.p.m. The same conclusion was reached regarding the Mokoia meteorite[2], with measurements made approximately with the same range of sensitivity. B. Nagy[3], using more refined experimental methods, detected optic rotation in the Orgueil meteorite, and G. W. Hodgson and B. L. Baker[4], utilizing elaborate experimental techniques, found also porphyrins in the same meteorite. Although the actual amounts detected were not mentioned by the foregoing workers it appears to me that they may have been of the order of perhaps 0·01 p.p.m. of the whole stone. One should ask the question whether such data are within the range of terrestrial impact and storage contamination. The fact that, according to the aforementioned authors, the Brudenheim and Peace River non-carbonaceous chondrites proved to contain no porphyrins has relatively little significance on account of the much less porous nature of these stones. The absence of chlorins in Orgueil and old terrestrial carbonaceous sediments, claimed by the authors as evidence for the extra-terrestrial origin of the porphyrins, may be due to the fact that, in the course of distillation of plant matter following the impact, the chlorins would be decomposed by the hot surface crust of the meteorite, and therefore mainly the more resistant porphyrins would penetrate to the deeper zones of the stone.

The foregoing questions could be investigated with a more positive approach through simulation of actual falls of meteorites; silicates of the composition of chondrites could be impregnated with synthetic organic polymers, carefully tested for traces of optically active molecules or porphyrins; afterwards such 'synthetic meteorites' could be ejected from high-flying aircraft or preferably satellites, and the degree of contamination of falls to different types of terrain could be examined. The extent of 'storage and handling contamination' could be also determined on the samples in question.

I consider that we must be on uncertain ground in our search for molecules. which are at present believed to be exclusively living products, until the effects of 'impact' and 'storage' contaminations are experimentally evaluated, unless, among the 20 or so carbonaceous stones hitherto not investigated, one is found which contains the substances in considerably higher concentration than in the Orgueil meteorite.

I thank Prof. J. D. Bernal for his advice and Prof. J. Orcel for providing me with facilities to examine the meteorite collection of the Museum of Paris, and placing material at my disposal for experimental work.

Depth of Source of Lead

We have recently introduced the idea of the liquid fraction value. As defined elsewhere[1–4], this term indicates the quantitative fraction which a liquid at a certain stage of solidification occupies relative to the amount of initial liquid which for the liquid fraction value is taken as unity. As self-evident from the

definition, the liquid fraction value never surpasses unity, and diminishes steadily as solidification or crystallization proceeds.

In addition, it has been pointed out[5] that, if several assumptions are made, there is a possibility of reducing the value of the liquid fraction obtained to the dimension of depth within the Earth. These assumptions are as follows: (1) the mantle was formed as an aggregate of crystals separated from the liquid with starting composition like chondritic oxide; (2) the solids (crystals) separated from the liquid in the course of formation of mantle precipitated successively inwards; (3) the transfer of material by convection or diffusion did not occur on a large scale after the formation of the mantle; (4) the magma represents the material produced by partial melting within the mantle. If these conditions are assumed, the original depth (ΔR) of source of a primary magma can be related to its liquid fraction value (f_w) relative to initial chondritic oxide melt by:

$$f_w = \frac{\left\{1 - \left(\frac{R-\Delta R}{R}\right)^3\right\}\rho'}{\left\{1 - \left(\frac{\gamma}{R}\right)^3\right\}\rho} \qquad (1)$$

where R and γ = the radii of the Earth and its core, respectively, ρ = the mean density for the mantle plus crust, and ρ' = the mean density for the spherical zone shallower than ΔR from the Earth's surface. From the results provided by Bullen[6] on the density distribution within the Earth, the diagram as shown in Fig. 1 was obtained in conformity with equation 1.

Based on the foregoing assumptions, the liquid fraction values obtained from the abundances of lanthanides in a South African eclogite, and a Polar Ural peridotite, were reduced to dimension of depth. As a result of such a calculation, we have obtained[5] $\Delta R = 160$ km and 400 km, respectively, for the eclogite and the peridotite in question. It may be said that this result conforms with petrological observations.

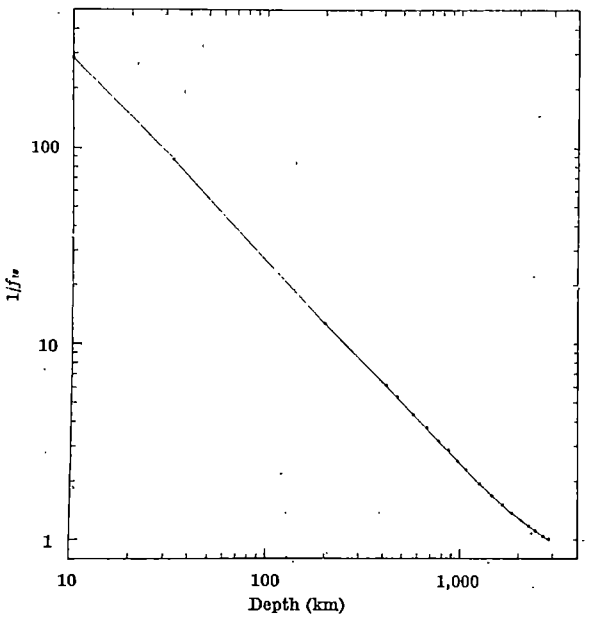

Fig. 1. Diagram for relation of liquid fraction value to depth (after ref. 3)

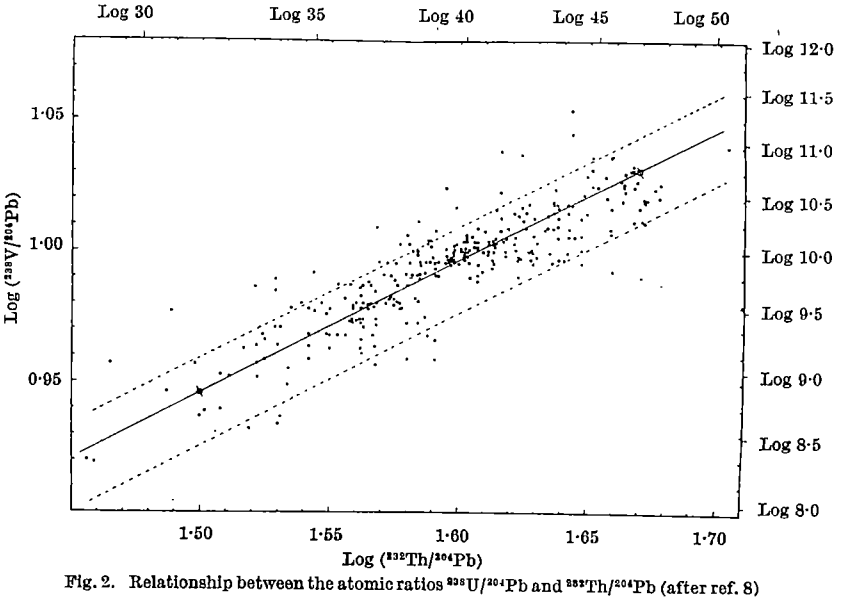

Fig. 2. Relationship between the atomic ratios $^{208}U/^{204}Pb$ and $^{232}Th/^{204}Pb$ (after ref. 8)

In this communication, an attempt has been made to evaluate the liquid fraction values for the source materials of leads and to reduce them to depths by assuming the conditions already mentioned. However, it is thought[7] that the source of lead originated from such material which had been produced by partial melting shortly after the formation of mantle material, and pocketed *in situ*. Meanwhile, the following theoretical equation holds good[2]:

$$\log (C_{Th}/C_{Pb}) = \log (C^0_{Th}/C^0_{Pb}) - (k_{Pb} - k_{Th}) \log f_w \qquad (2)$$

where C refers to the concentration of subscripted element in a melt, C^0 to the concentration in initial chondrite-like oxide melt, and k to the partition coefficient. Since $C^0_{Th} = 0{\cdot}048$ p.p.m. (refs. 2 and 10), C^0_{204} (the initial concentration of lead-204) $= 0{\cdot}00199$ p.p.m. (ref. 2), $k_{Pb} = 0{\cdot}292$ (ref. 2), and $k_{Th} = 0{\cdot}0733$ (ref. 3), equation (2) becomes:

$$\log (C_{Th}/C_{204}) = 1{\cdot}383 - 0{\cdot}219 \log f_w \qquad (3)$$

where (C_{Th}/C_{204}) refers to the weight concentration ratio between thorium and lead-204. At this point, let us direct our attention to Fig. 2, which shows the abundance relationship among uranium, thorium, and lead-204, estimated[8] from the isotopic composition of lead of ores. (The abundance ratio in this diagram refers to atomic ratio.) According to the data shown in Fig. 2 the average value for log [$^{232}Th/^{204}Pb$] is 1·5965, which is equivalent to log $(C_{Th}/C_{204}) = 1{\cdot}6522$ whereas log $(232/204) = 0{\cdot}0557$. Introducing log $(C_{Th}/C_{204}) = 1{\cdot}6522$ into equation (3) gives us log $f_w = -1{\cdot}233$ ($f_w = 1/17{\cdot}1$). According to Fig. 1, $f_w = 1/17{\cdot}1$ corresponds to $\Delta R = 150$ km. This suggests that the most frequent seats of original sources from which lead in ores was derived are at about 150 km. It should be noted that this dimension coincides with the depth of low velocity layer. As seen in Fig. 2, the points are very rare for log [$^{232}Th/^{204}Pb$] $< 1{\cdot}50$ and for log [$^{232}Th/^{204}Pb$] $> 1{\cdot}668$. These values correspond to $f_w = 1/6{\cdot}3$ and 1/36, and, in turn, to depth = 400 and 75 km. This fact indicates that the original source material for lead of ores is seated rarely below 400 km and above 75 km. Emphasis must be placed again on the fact that the range of depth of 75–400 km is involved by the range of position thermodynamically inferred for the origin of magma[9]. These conclusions are thought to suggest that the approach newly presented, and the model necessary for it, deserve further consideration.

In the foregoing calculation, the effect of convection was regarded as virtually negligible. If convection on a large scale exists within the mantle, the resultant values of depth for particular leads do not necessarily indicate the present situation of their original source. Even if such is the case, it will not be necessary to modify the conclusion that the common range of depth of magmatism is 75–400 km.

The foregoing results may be interpreted also as suggesting that material of the continental crust which has an average value of f_w of about 1/80 (refs. 1 and 4) is being developed from a layer which was composed of primary liquid-type materials corresponding to $f_w = 1/6{\cdot}3 \sim 1/36$ (1/17·1 on an average). This interpretation does not necessarily contradict our model.

MINERALOGY

Far Infra-red Spectra of Montmorillonite, Kaolinite and Illite

ALTHOUGH infra-red spectra of many of the common rock-forming minerals have been presented by several investigators[1–5], few results are available for the diagnostic analysis of clay minerals in the far infra-red spectral region (below 400 cm^{-1}). This communication presents the far infra-red spectra of montmorillonite, kaolinite, and illite for the portion of the spectrum between 90 and 400 cm^{-1}.

Absorption maxima in this region most likely reflect the presence of complex molecular librations and low frequency stretching and bending modes. Inasmuch as relationships between the different clay structures and their far infra-red spectra are essentially unknown, to speculate at length on probable assignments of different absorption bands would be premature. Only qualitative results have so far been obtained.

The samples examined were obtained from the following sources: montmorillonite and kaolinite from American Kaolin Products Co., Aiken, South Carolina; illite (Fithian) and bentonite from American Colloid Co., Skokie, Illinois. Relative purity of the samples was checked by both X-ray diffraction and conventional infra-red methods.

The infra-red patterns for the conventional range are presented in Fig. 1. Referring to these spectra, it is apparent that the samples utilized are of reasonable purity. Fithian illite, even though known to be a mixture of mica, expansible layers, quartz and kaolinite, was chosen because references to it and its characteristics are common in the general literature of clay mineralogy. Bentonite, owing to its usually high montmorillonite content, served as a check on those absorption bands obtained with the 'normal' montmorillonite sample.

An examination of the spectra in Fig. 1 shows that quartz (indicated by the characteristic doublet at 800 and 780 cm^{-1} and absorption at 700 cm^{-1}) is a common impurity in all samples. X-ray diffraction studies indicate quartz to be present in amounts less than 10 per cent in all samples. The presence of some kaolinite (< 10 per cent as confirmed by X-ray diffraction techniques) is indicated in both the montmorillonite and illite samples. On the basis of X-ray diffraction and infra-red studies, it is felt that the major absorption bands present in the far infra-red region (90–400 cm^{-1}) are likely characteristic of the clay minerals studied and not of the impurities present.

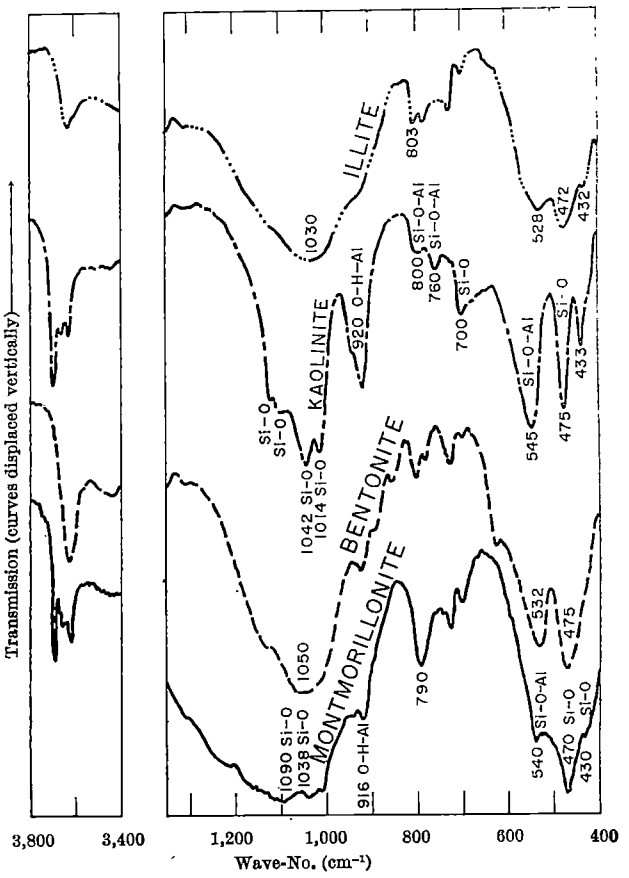

Fig. 1. Spectra of clay minerals investigated (conventional range). Assignment of absorption peaks indicated where known

The samples were prepared by grinding with a mortar and pestle (with ethanol) to a size of 5 microns or less. Mineral oil ('Nujol') was added to form a thick mull (to enhance any weak absorption bands) and a portion of the mull was then pressed between two 0·51 mm thick polyethylene plates. Measurement of the spectra in the range 33–800 cm^{-1} was made on a Beckman *IR*-11 spectrophotometer.

Afterwards, the thick mull was thinned by the addition of more 'Nujol', a portion of this mixture pressed between polyethylene plates and a scan again made from 150 to 800 cm^{-1} (Beckman *IR*-11). This latter step was made to bring the more intense bands 'on scale'. A second portion of the thin mull was pressed between thin (2–3 mm) CsI plates and run in the conventional range (400–4,000 cm^{-1}) on a Beckman *IR*-9 unit.

The spectra of montmorillonite and bentonite and of kaolinite and illite are shown in Figs. 2 and 3 respectively. Assignments (Fig. 1) for the main absorption bands in the 400–600 cm^{-1} region are indicated where known[6]. It is not possible at present to make definite assignments of the absorption peaks beyond 400 cm^{-1}. The primary purpose of this communication is to present the far infra-red spectra of these compounds.

Although possible weak absorption peaks were indicated, the region below 80 cm^{-1} showed more noise than signal to be diagnostic. Absorption in the range 530–555 cm^{-1} (noted in all samples) has been assigned[6] to the Si-O-Al group for montmorillonite and kaolinite; that in bands

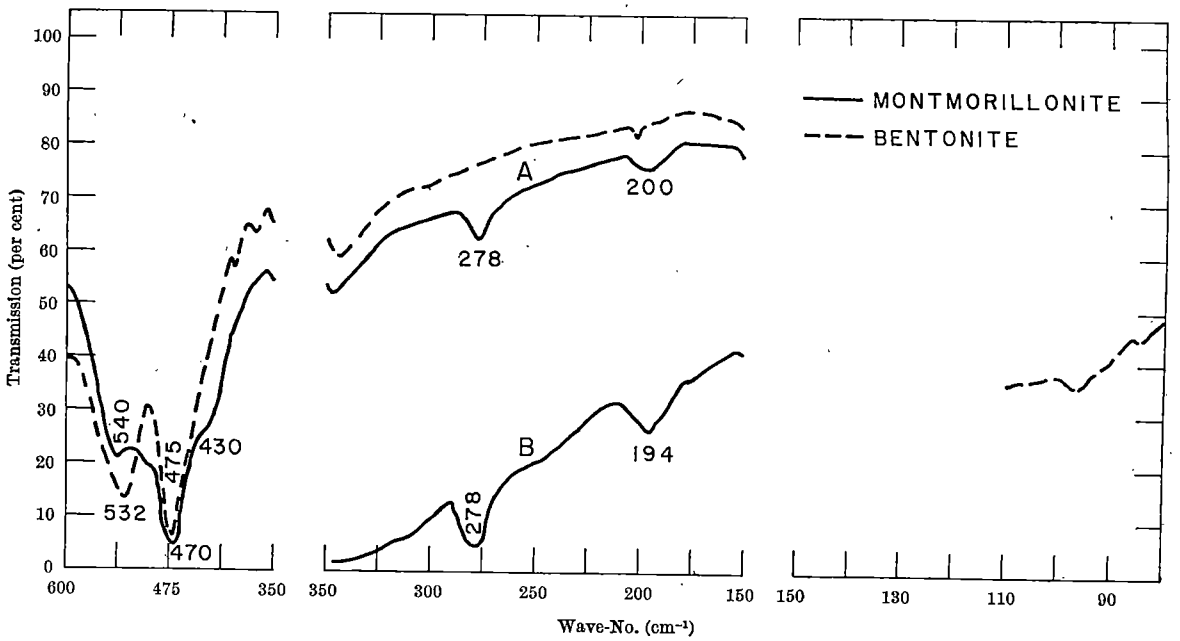

Fig. 2. Far infra-red spectra of montmorillonite and bentonite. Curve *A* and 350–600 cm^{-1} thin mull between polyethylene plates; curve *B*, thick mull between polyethylene plates

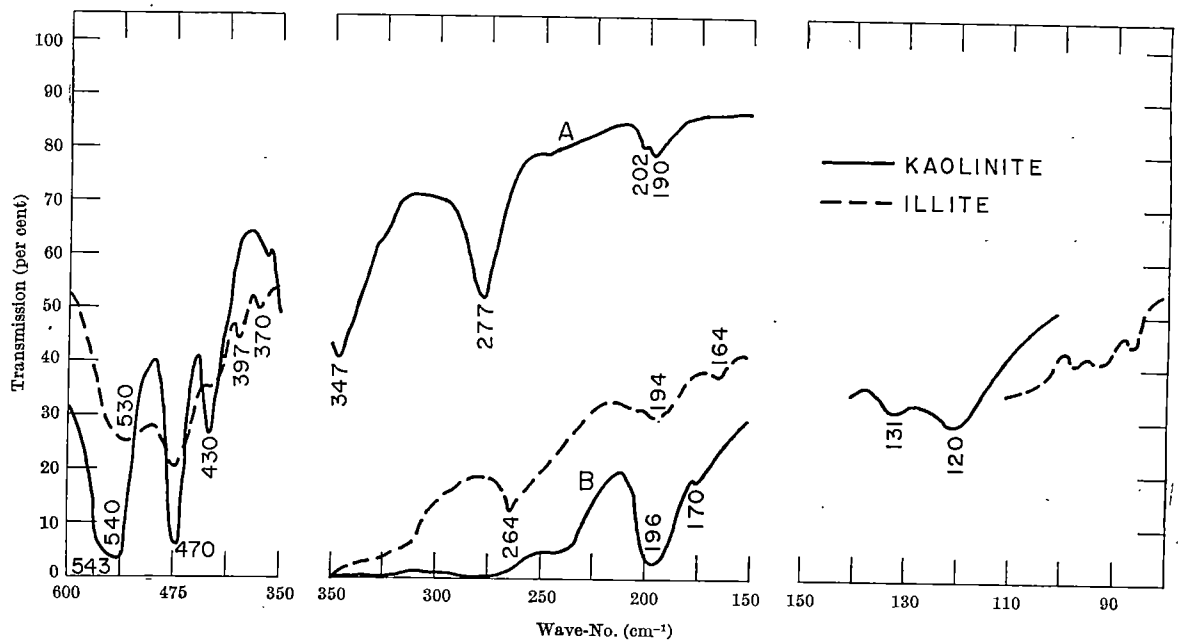

Fig. 3. Far infra-red spectra of kaolinite and illite. Kaolinite, curve *A* and 350–600 cm^{-1} thin mull; curve *B* and 90–150 cm^{-1} thick mull. Illite thin mull 350–600 cm^{-1}, thick mull 80–350 cm^{-1}

470–475 cm^{-1} and 430–433 cm^{-1} has similarly been assigned to Si-O for the same minerals. It is likely that these vibrational modes in the illite, owing to its compositional make-up, are due to the same atomic groupings. Bentonite, being dominantly montmorillonite, would be expected to show an absorption pattern similar to montmorillonite.

Normally in the range 400–4,000 cm^{-1}, it is difficult to distinguish montmorillonite and illite in the same sample. The identification of these two minerals is commonly based on the presence of strong partially overlapping absorption bands centred at 1,040 and 1,030 cm^{-1} respectively. Examination of the far infra-red spectra of these two clay minerals reveals the presence of one major and several minor and distinct non-overlapping absorption bands (illite-major 264 cm^{-1}, minor 164, 397 cm^{-1}, etc.) which might allow positive easy identification of these minerals.

Although several of the major bands of kaolinite and montmorillonite are similar, the relatively strong absorption of kaolinite at 120 and 131 cm^{-1} (these peaks are absent in montmorillonite) should likewise allow positive identification and separation of this pair.

The absorption maxima at 344–348 cm^{-1} in montmorillonite and kaolinite might be a fundamental vibrational mode, but more likely they are difference bands—in kaolinite 543 – 196 = 347, in montmorillonite 540 – 194 = 346. The band at 194–200 cm^{-1} was noted in all spectra and although assignment of this peak cannot be made at present, its ubiquitous nature suggests its probable relation to some common structural feature of the phyllosilicates.

At present the far infra-red spectra of clay minerals are of limited usefulness for the purposes of quantitative

analyses. However, their potential value for qualitative work is clear. Investigations of the far infra-red spectra (below 400 cm^{-1}) of the different clays and rock-forming minerals could open a whole new range of possibilities in the investigation of rock-forming compounds.

I thank Kenneth E. Stine of Beckman Instruments, Inc., Fullerton, California, for making it possible to obtain runs on the *IR*-11. This work was supported by the Office of Naval Research No. *NONR*–2119(04).

CHEMISTRY

Determination of Carbon in Steels by Measurement of the Prompt γ-Radiation emitted during Proton Bombardment

CONVENTIONAL techniques of activation analysis usually require the measurement, some time after the completion of the irradiation, of the radiation emitted by a radioactive nuclide manufactured during the irradiation, with or without prior separation of the radionuclide to be determined, and sensitive analytical methods have been devised for most elements using thermal neutrons as bombarding particles[1,2]. However, for the light elements, low cross-sections and inconvenient half-lives of the product nuclides often preclude the use of thermal neutron irradiation as the basis of an analytical method, and charged particles, γ-photons[2,3], and neutrons of non-thermal energies[4] have been used instead.

A further possible application of the techniques of nuclear spectroscopy to analytical problems would be to measure the prompt radiation emitted during the de-excitation of the excited states of certain nuclei, rather than the radiation emitted by a radionuclide after the irradiation stage has been completed. Irradiation and detection could then be carried out simultaneously, thus offering the opportunity of more rapid analysis and, further, since radiation corresponding to energy transitions in excited states of stable nuclei could be measured by this means, it would no longer be necessary to choose a nuclear reaction which provided a suitable radionuclide.

Measurement of prompt γ-rays is complicated by the radiation of radioactive nuclides which build up during the course of the irradiation, but in view of the potentialities of prompt γ-ray measurement, particularly for the determination of the light elements, a programme of work has been instituted in this laboratory with a view to assessing the feasibility of the method. Charged particles were used for irradiation in spite of their low penetrating power, as the prompt γ-rays could be measured with relatively simple counting equipment and the coulomb barrier prevented nuclei of high atomic number reacting, thus simplifying the γ-ray spectrometry required. This work will be reported in detail elsewhere, but we give as an example of the technique the determination of carbon in steels using low-energy proton irradiation.

The determination of carbon by means of the reaction $^{13}C(p,\gamma)^{13}N$ measuring the 10 min positron emitter ^{13}N is well known[5], and the reaction has a resonance at the rather low proton energy of $E_p = 0{\cdot}456$ MeV. During reaction a 2·3-MeV γ-ray is emitted[6], and this was measured

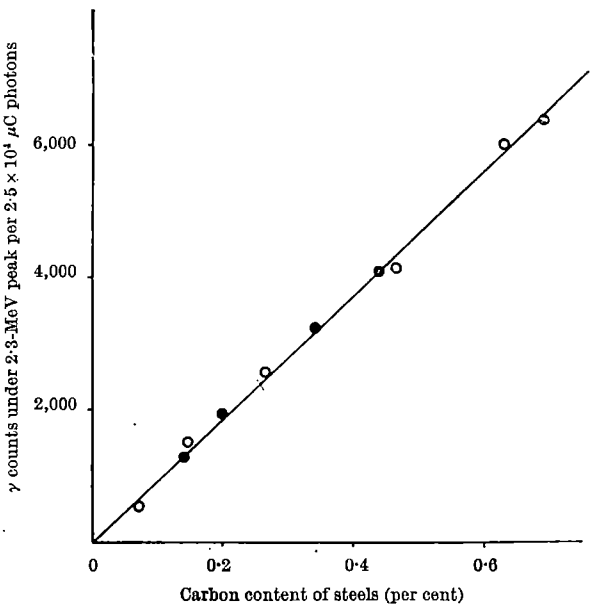

Fig. 1. Counts under the 2·3-MeV γ peak as a function of the carbon content of the irradiated steels. ○, Spectrographic standards; ●, analysed samples supplied by A.E.R.E., Chatham

in these determinations. Although the thick target yield is not high ($7{\cdot}5 \pm 0{\cdot}5 \times 10^{-10}$ disintegrations/proton at $E_p = 1{\cdot}00$ MeV (ref. 7)), the low energy of the bombarding particles results in a relatively low background, and the prompt γ-rays can be determined easily.

Targets were in the form of steel disks, and were of known carbon content. Five were a set of commercial spectrographic standards (Bureau of Analysed Samples, Ltd., Nos. *SS* 31–35 Plain Carbon Steels), and the others were cut from lumps supplied by the A.E.R.E. Outstation, Chatham. The spectrographic standards were 1·75 in. diameter by 0·5 in. thick, and fitted directly on to the O-ring of a specially constructed target holder; the other samples were smaller (0·75 in. diam. × 0·1 in.) and fitted into the well of a brass target assembly.

Targets were wobbled and air cooled, and a liquid nitrogen trap was placed in the vacuum system just ahead of the target to reduce interference from the carbon background of the accelerator, but investigations showed that the two machines used for this work (5-MeV and 3-MeV Van der Graaff electrostatic generators) did not produce appreciable interference at the rather high levels of carbon (> 700 p.p.m.) present in the samples. The detector was a 3 in. × 3 in./NaI (Tl) crystal at 0° angle of observation placed 1½ in. away from the irradiated face of the target, and was connected to a 100 channel pulse height analyser. The beam falling on the target was monitored and the total proton dose recorded by a beam integrator. Throughout these experiments 0·8 MeV protons were used for the irradiation, and targets were irradiated to the same constant dose of 25,000 μC. Irradiations took about 13 min, and the time could have been reduced, if required, by increasing the beam current.

Results obtained from proton irradiations are summarized in Fig. 1, where the counts under the 2·3-MeV prompt γ peak are plotted against the known carbon content of the steels. Data for the two sizes of steel disks are plotted on the same graph, for although targets and holders imposed slightly different counting geometries in the two cases the effect was too small to be significant.

From Fig. 1 it can be seen that good correlation was obtained between the prompt γ-rays counted and the carbon content of the steels, down to the lowest value determined (700 p.p.m.), indicating that measurement of prompt γ-rays can be used as the basis of an analytical method for carbon.

We thank the Nuclear Physics Division, A.E.R.E., for making accelerator time available, and for the generous loan of electronic equipment; and also Dr. G. A. Jones for advice, Mr. T. E. Sparrow for machine operation, Mr. H. I. Shalgosky for providing steels of known carbon content, and Messrs. H. D. Hitchcox and A. H. G. Boram for preparing samples for irradiation.

Infra-red Absorption of the Hydroxyl Radical

Although the vibration–rotation structure of the hydroxyl radical emission spectrum in the infra-red has been observed both from flames[1] and from the chemiluminescent reaction[2] of hydrogen atoms with oxygen molecules:

$$H\cdot + \cdot O_2\cdot \rightarrow HO_2\cdot$$
$$H\cdot + HO_2\cdot \rightarrow 2\ \cdot OH\dagger$$

(where ·OH† denotes a vibrationally excited hydroxyl radical), there has been no report of the infra-red absorption spectrum of ·OH. The purpose of this communication is to suggest that the absorption of both ·OH and ·OD has been recorded without the identity of the carrier being discovered.

In investigations[3–5] concerned with the infra-red absorption of water molecules trapped in noble gas matrices at 4° K, there have been observed two sharp absorption lines, at 3,574 cm^{-1} in H_2O experiments and 2,635 cm^{-1} in the case of D_2O, both of variable intensity relative to other spectral features. These frequencies are close to the zero lines of the gas phase, calculated from electronic spectra[6] to be 3,569·6 cm^{-1} and 2,632·5 cm^{-1} for ·OH and ·OD, respectively.

Again, in experiments[7] in which were frozen at 4° K the products from a discharged mixture of 50 per cent hydrogen (or deuterium) and 50 per cent argon reacted with a small amount of nitric oxide, an absorption band at 3,596 cm^{-1} (or 2,680 cm^{-1}) was observed besides the other absorption bands conclusively assigned[5,8,9] to nitroxyl, HNO. (In connexion with the assignment in ref. 9 of 3,380 cm^{-1} as the N—H stretching fundamental of HNO, better agreement with the infra-red emission from the hydrogen atom–nitric oxide reaction[10] would result from the alternative assignment of the feature at 3,450 cm^{-1} as this fundamental.)

There are three points to be considered in the proposed assignments for the hydroxyl radical: the mechanisms of formation, the frequency shifts in the solid matrices, and the absence of vibration–rotation structure.

In the case of the hydrogen atom reaction with nitric oxide, the hydroxyl radical could result from reaction of hydrogen atoms with nitrogen oxide impurities stated[7] to be present:

$$H\cdot + \cdot NO_2 \rightarrow \cdot OH + \cdot NO$$

or

$$H\cdot + N_2O \rightarrow \cdot OH + N_2$$

the former bimolecular reaction being particularly rapid[11]. Less easily solved is the mechanism of hydroxyl production in experiments in which 0·2–0·35 per cent water in argon is simply deposited on a window at 4° K (refs. 3–5). Possibly significant are the facts that the 3,574 cm^{-1} absorption feature is absent when H_2O in argon is deposited at 20° K (refs. 12, 13), and that the thermal conductivity of solid argon is a maximum at 8° K (ref. 14), enabling greater deposition rates without loss of optical transmission and isolating power. A possible mechanism is that the friction of the gas mixture flowing about 5 m/sec through glass tubing toward the cold window could produce static electricity in the form of discharges in the gas, noble gases having comparatively small breakdown potentials. The principal effect of these discharges would be to cause dissociation of water in the gas phase either directly or sensitized by metastable argon atoms in the $^3P_1$ state. The energy of the metastable argon atoms could also be transferred to the water in the solid[15] through the intense band systems existing in solid noble gases[16]. The necessity for the discharge to be weak or sporadic is indicated by the results[5] of an experiment in which the products deposited at 4° K from a leak-tester discharged mixture of 0·5 per cent H_2O in argon showed no infra-red absorption attributable to hydrogen–oxygen species.

The observed frequencies of the matrix-trapped hydroxyl radicals are in all cases blue-shifted, being 3–4 cm^{-1} for H_2O and D_2O in argon[3–5] and 26 and 48 cm^{-1} for H_2O and D_2O in the argon–hydrogen mixed matrix[7]. The shift in the former case is small, and comparable to the shifts experienced with water itself[3,5]. In the latter case, the presence of about 50 per cent hydrogen in the solid causes the lattice sites to be smaller, thereby augmenting repulsive interactions of the trapped radical and hence tending to increase its stretching frequency, again in general concord with spectra of both water[3,5] and formaldehyde[17] bond-stretching fundamentals for these substances in noble gas matrices.

By analogy with HCl in argon at 4° K (ref. 18), one might expect to observe additional lines due to some reorientation process of ·OH, particularly in the argon matrix. However, no absorptions near 3,611 cm^{-1} or 2,655 cm^{-1}, the expected positions of $R(0)$ for H_2O and D_2O, have been observed, despite the intense absorptions at the Q-branch positions. That the observed matrix absorptions are blue-shifted is again relevant in that rotation of a solute molecule is unlikely if matrix conditions cause the molecule to be compressed.

Finally, the presence of the paramagnetic hydroxyl radicals in solid argon matrices also containing water provides a simpler mechanism for ortho-para nuclear spin conversion than the postulated oxygen impurity[3,4] certainly present (unless deliberately added) in a much smaller concentration than hydroxyl.

Hydrogen-bonding Patterns and Ice Nucleation

INVESTIGATIONS of hydrogen-bonding patterns of organic crystal surfaces in these laboratories have shown that the ability to nucleate ice can be predicted reliably if the complete crystallographic structure is known. Both 'parametric' fit and the density of hydrogen-bonding groups are essential factors conferring nucleative ability, and it is on these principles (which will form the subject of a more detailed presentation in the near future) that a new organic highly effective nucleating material has been forecast for the first time.

A consideration of the crystal structure[1] of the α-isomer of 1 : 3 : 5-*cyclo*hexanetriol dihydrate (α-phloroglucitol dihydrate) led us to expect high nucleative power, which was confirmed by cloud chamber tests. Counts of up to 10^{11} nuclei/g were obtained at a temperature of −12° C, although owing to the high solubility of the compound tests could not be run above −8° C. In comparison, the most active organic nucleators known at the present time (phloroglucinol dihydrate and α-phenazine) produce 10^{11}–10^{12} nuclei/g under identical conditions, whereas silver iodide is slightly more active still.

Each oxygen atom in the 111 plane of the rhombohedral α-phloroglucitol dihydrate corresponds to an ice oxygen, the disregistry being 4·8 per cent. The density of oxygen groups is very close to that of ice and about 50 per cent greater than on the 100 plane of phloroglucinol dihydrate. α-Phloroglucitol, being a polyalcohol, shows a much higher solubility in water and it is also more difficult to sublime without decomposition. It does not, however, possess a sweet taste like phloroglucinol as stated in Beilstein.

The compound was prepared by the method of Wislicenus[2] in which phloroglucinol is hydrogenated with sodium amalgam. After removing all traces of phloroglucinol as well as the β-isomer of phloroglucitol, the correct m.p. of 184° C was obtained.

Because of its alicyclic nature and polyalcoholic character, α-phloroglucitol is probably non-toxic.

High-pressure Polymorph of Zirconium Pyrophosphate

ZIRCONIUM pyrophosphate is one of a group of isostructural compounds of the Type $X^{+4}\ P_2O_7$ where X may be zirconium, hafnium, titanium, silicon, tin or uranium[1,2]. It is cubic (Type $K6_1$) with zirconium octahedrally, and phosphorus tetrahedrally, co-ordinated with oxygen. The structure may be compared with that of NaCl (Type B1) by considering the zirconium ions and P_2O_7 groups to be at sodium and chlorine sites, respectively.

Reagent grade ZrP_2O_7 containing ~12 per cent of water, which corresponds to $ZrP_2O_7 \cdot 2H_2O$, was obtained from Bios Laboratories, Inc., New York. This material was heated in air at 700° C for 4 h, and its identity as anhydrous cubic ZrP_2O_7 was confirmed by X-ray powder diffraction ($a_0 = 8{\cdot}26$ Å in agreement with the observation by Harrison *et al.*[3]). The anhydrous ZrP_2O_7 was subjected to pressures between 25 and 100 kbars and temperatures of 750° and 1,000° C in a 'belt'[4,5] and a 'girdle' apparatus[6]. The samples were quenched under pressure and then examined optically and by X-ray powder methods. The conditions and results of these experiments are given in Table 1.

One hundred per cent conversion to a new quenchable high-pressure polymorph of ZrP_2O_7 was effected at 55 and 100 kbars. The new phase is colourless under the microscope and white in powder form. It is uniaxial positive with $\varepsilon = 1{\cdot}773$, $\omega = 1{\cdot}755$, both $\pm 0{\cdot}003$, and $\varepsilon - \omega = 0{\cdot}018$. The crystallites have an average size of about 20μ, but a few crystals as large as 40μ were observed. The crystallites are anhedral so there is no direct indication whether this phase is tetragonal or hexagonal. X-ray powder diffraction data are given in Table 2. The density of the new phase is $3{\cdot}62 \pm 0{\cdot}02$ as determined by float-sink methods using Clerici's solution. The high-pressure phase, therefore, is 15·7 per cent denser than the cubic form, which has a density of 3·13, calculated from its lattice parameter.

The high-pressure phase inverts to the cubic form within 3 h when heated at ambient pressure in air at 1,000° C.

Table 1. HIGH-PRESSURE HIGH-TEMPERATURE EXPERIMENTS ON ZrP_2O_7

Pressure (kbars)	Temperature (°C)	Time (h)	Product
25	1,000	18	Cubic ZrP_2O_7
35	750	19	Cubic ZrP_2O_7
55	750	20	High-pressure polymorph
100	1,000	3	High-pressure polymorph

The 100-kbar run was made in a 'girdle' apparatus; the others were made in a 'belt' apparatus

Polymorph	Mean refractive index (n)	Density (d) g/c.c.	Molar refraction $\left(\frac{n^2-1}{n^2+2}\cdot\frac{M}{d}\right)$	Specific refractivity $\left(\frac{n-1}{d}\right)$
Cubic	1·661	3·13	31·31	0·211
High-pressure	1·761*	3·62	30·17	0·210

* $\sqrt[3]{\omega^2\varepsilon}$

M = molecular weight

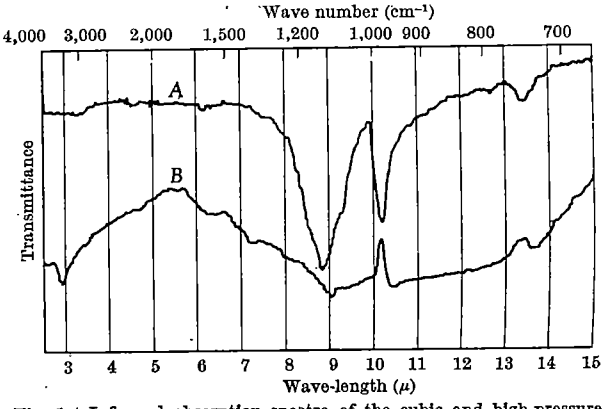

Fig. 1. Infra-red absorption spectra of the cubic and high-pressure polymorphs of ZrP_2O_7. Spectra obtained with Perkin–Elmer Infracord recording spectrophotometer using the KBr disk technique. *A*, cubic form preheated at 700° C; *B*, high-pressure form prepared from (*A*) at 55 kbars and 750° C

It persists metastably at ambient pressure, however, when heated in air at 600° C for 65 h.

Recent studies of polymorphic pairs of oxides related by re-constructive transformations of first co-ordination have shown that the effect of an increase in cation co-ordination from 4 to 6 is to decrease the molar refraction by ~12 per cent and to shift the main infra-red absorption band ~23 per cent in the direction of increasing wave-length[7–9]. Applying these principles to the polymorphs of ZrP_2O_7, it is deduced from the small difference in molar refraction and the slight displacement toward longer wave-lengths of the main infra-red absorption bands at 8·8, 10·2 and 13·4μ (cf. Table 3 and Fig. 1) that there is no difference in the primary cation co-ordination of these polymorphs and that the increase in density is due to closer packing of the co-ordination polyhedra. The two structures probably differ in secondary co-ordination and may thus be related by a reconstructive transformation of higher co-ordination[10].

There is some indication that the refractive index of the cubic form increases with pressure; reagent preheated to 400° C has $n = 1{\cdot}661 \pm 0{\cdot}002$ (Na light) whereas the cubic form pressurized at 35k bars and 750° C has $n = 1{\cdot}666 \pm 0{\cdot}002$ (Na light). The infra-red spectrum of the cubic form is in agreement with that given by Steger and Leukroth[11].

It will be interesting to subject the other known members of this isostructural group to high pressures and temperatures to determine whether a group of pressure-dependent polymorphs isostructural with the high-pressure polymorph of ZrP_2O_7 can be synthesized.

BIOCHEMISTRY

Nucleoprotein Synthesis in the New-born Mouse

The proceedings of the first World Conference on Histone Biology and Chemistry were summarized in a recent article by Bonner and Ts'o[1]. Part of the reported discussion dealt with the probable relationship between DNA replication and histone synthesis. It was pointed out that 5-fluorodeoxyuridine blocks DNA synthesis but allows the synthesis of histone to proceed in an essentially normal manner. This evidence was cited to support the view that DNA replication and histone synthesis are not necessarily coupled although they usually accompany one another. Similar conclusions have been reached by Plaut[2], who investigated the pattern of nucleoprotein synthesis in *Drosophila* polytene chromosomes by means of the pulse-labelling technique. He found that the labelling patterns resulting from brief exposures to tritiated precursors of DNA (H^3 thymidine) and protein (H^3 lysine, H^3 histidine) were distinctly different. In summary, DNA labelling was often restricted to certain sites along the chromosome, while protein labelling was found to be more or less continuous. The present report, based on the results of cytophotometric investigations, furnishes further evidence in support of the view that DNA replication and histone synthesis may not be coupled.

Table 1

	DNA–Feulgen	Histone–fast green
New-born liver	3·54 ± 0·19 (49)	1·96 ± 0·07 (52) 4·64 ± 0·17 (13)
New-born kidney	3·30 ± 0·04 (49)	1·93 ± 0·07 (34) 3·50 (6)

In the mouse, the onset of parturition appears to be accompanied by a virtual cessation of mitosis in fœtal tissues; significant restoration of mitotic activity does not occur until after suckling has begun[3]. Cytophotometric determinations of nuclear contents of DNA and histone were carried out as part of an attempt to elucidate the probable nature of this 'mitotic arrest'. Male animals were killed a few hours after birth and pieces of kidney and liver were fixed in 10 per cent neutral formalin. Following fixation and washing, the tissue samples were dehydrated, embedded, sectioned, and mounted together on the same slides (sections of liver from an adult male were used for comparative purposes). Slides were stained either by the Feulgen reaction for DNA[4], or by the alkaline fast green procedure for histone[5]. The cytophotometric procedures have been described previously[6,7]. The results are summarized in Table 1. The mean DNA–Feulgen and histone–fast green contents are given in arbitrary units (sample size is indicated in parentheses). The Feulgen data suggest the existence of only one nuclear class. The mean value is characteristic of normal diploid cells in the G_1 period of interphase. The fast green measurements, on the other hand, are indicative of a mixed population with some nuclei apparently containing the post-synthetic level of histone expected of cells in the G_2 period. From these results it may be concluded that synthesis of histone can precede DNA replication.

The results derived from three rather different analytical approaches are therefore in agreement and strongly suggest that DNA replication and histone synthesis are not invariably coupled.

Possible Cause of Electrophoretic and Chromatographic Heterogeneity of Pituitary Hormones

There is evidence that pituitary hormones can exist in more than one biologically active form. Electrophoresis[1] or chromatography[2] of thyrotrophic hormone has been found to yield a number of active fractions. Several components with corticotrophic potency were obtained from adrenocorticotrophic hormone (ACTH) from various sources[3–5], while fractionation of ovine prolactin also revealed various active forms of the hormone[6,7]. Similar results have been obtained with preparations of sheep[8,9] and human[10] interstitial cell-stimulating hormone (ICSH), as well as with alkali-treated

growth hormone from beef pituitary glands[11]. A comparative study of the electrophoretic behaviour of pituitary hormones has been published by Ferguson and Wallace[12], who reported that preparations of pituitary hormones were invariably electrophoretically impure and that more than seventy components could be detected in some crude extracts of pituitary tissue by electrophoresis on starch gel.

The appearance of more than one active form of the hormone may in some cases be due to slight differences in amide content[4,13] or in amino-acid composition and sequence between the protein molecules. There are also indications[14,15] that, due to proteolytic activity in pituitary extracts, a partial degradation of polypeptide hormones may sometimes occur, leading to the appearance of multiple components. However, the additional fractions obtained in that case are usually less active than the undegraded material[15].

It is difficult to attribute the high degree of heterogeneity of pituitary hormones, as shown by electrophoresis or chromatography, solely to differences in primary structure. Recently, indications have been found that the presence of several biologically active components in a hormone preparation was due to aggregation effects[16,17]. It was shown that the monomer of prolactin had a different electrophoretic mobility from that of aggregated forms of the hormone and that these forms were also chromatographically distinct[16].

In view of these findings we propose that association phenomena may, in general, contribute to a large extent to the charge multiplicity of pituitary hormones. We also suggest that the term 'isohormones' be used to designate the different active forms of a certain hormone.

As aggregation of prolactin occurs when solutions of the hormone are treated with alkali[17], it seemed of interest to see whether disulphide-interchange reactions were involved in the polymerization. We have therefore investigated the effect of reduction on the molecular weight of bovine prolactin[18]. Investigations in the ultracentrifuge, by gel filtration and gel electrophoresis, showed that reduction and alkylation[19] of the hormone led to polymerization, and not to depolymerization, of the protein. The finding that reduced prolactin can also exist as a polymer indicates that disulphide-interchange is not necessarily involved in the association of the protein molecules. These results will be reported more fully elsewhere.

Use of Mutants to study the Electron Transport Pathway of Nitrate Reductase

NITRATE-INDUCIBLE TPNH (reduced triphosphopyridine nucleotide) cytochrome *c* reductase is believed to participate in nitrate reduction for the following reasons: (1) Sorger[1] and Kinsky and McElroy[2] showed that it is induced and repressed simultaneously with nitrate reductase by the same specific inducers and repressors. (2) Kinsky and McElroy[2] observed that cytochrome *c* competes with nitrate in purified preparations of nitrate reductase. (3) These investigators also found that inhibitors of TPNH cytochrome *c* reductase inhibit nitrate reductase. (4) They further observed that the ratio of TPNH cytochrome *c* reductase to nitrate reductase remains constant throughout a fifty to seventy-fold purification by two procedures. (5) Sorger[1,3] and Pateman *et al.*[4] found that mutants at a single locus, lacking nitrate reductase, also lack nitrate-inducible TPNH cytochrome *c* reductase. (6) Sorger[5] noted that the ratio of TPNH cytochrome *c* reductase to nitrate reductase remains constant during heat inactivation (at 31·1° C and 42·3° C) of crude extracts made from induced mycelium.

One class of mutants, represented by *nit*-1 in *Neurospora*, and by *ni*-3 in *Aspergillus*, lacks nitrate reductase but retains nitrate-inducible TPNH cytochrome *c* reductase[1,3]. These mutants can be used in elucidating the mechanism of action and the organization of nitrate reductase because they have an incomplete enzyme, capable of carrying out only the first steps in the electron transport sequence from TPNH to nitrate. The experiments to be described are part of an attempt to elucidate the nature of the physical organization of the nitrate reductase electron transport pathway.

If TPNH cytochrome *c* reductase is an enzyme physically independent of the rest of the electron transport chain from TPNH to nitrate, one would expect *nit*-1 of *Neurospora* to have an inducible TPNH cytochrome *c* reductase identical to that of wild type. The reason for this is that *nit*-1 is blocked beyond cytochrome *c* reduction in the electron transport sequence from TPNH to nitrate; therefore, a mutation affecting an enzyme which catalyses a reaction beyond this step in the sequence should not affect TPNH cytochrome *c* reductase structurally. If, on the other hand, the entire electron transport sequence is carried out by a single protein or by an aggregate of enzymes, TPNH cytochrome *c* reductase from *nit*-1 might be expected to be qualitatively different from the corresponding enzyme of wild type. If only one enzyme is involved, a mutation would be expected to alter its properties. If an aggregate carries out nitrate reduction, a mutation affecting an enzyme in the aggregate might be expected to alter the properties of the whole aggregate.

Extracts from induced wild type and induced *nit*-1 mycelium were prepared by freezing the mycelial pads in liquid nitrogen and grinding the frozen material with chilled powdered glass in an ice-cold mortar and pestle. Enzyme in the paste was dissolved in ten volumes of 0·1 M phosphate buffer, *p*H 7·0 at 0°–4° C, and afterwards centrifuged at 20,000*g* in the cold to remove cell debris. Aliquots (0·5 ml.) of each extract were pipetted into test tubes in an ice bath and subsequently immersed in a constant-temperature bath set at 41·0° or at 30·5° C. At desired time intervals, samples were removed and stored on ice until the experiment was concluded. At this point, the samples were assayed for TPNH cytochrome *c* reductase activity by the method of Kinsky and McElroy[2].

The results in Table 1 show that *nit*-1 and wild-type TPNH cytochrome *c* reductase differ in their heat sensitivity at 41·0° and at 30·5° C.

If nitrate reductase is an aggregate, rather than a single protein, sucrose density gradient centrifugation might cause the separation of the components of the aggregate.

Table 1. Heat Inactivation of Wild Type and of *nit*-1 Nitrate-inducible TPNH Cytochrome *c* Reductase

Experiment No.	Minutes in water bath	TPNH cytochrome *c* reductase activity remaining: Wild type	*nit*-1	Wild type / *Nit*-1	$\frac{\chi^2}{(o-e)^2/e^*}$
1 (41·0 ± 0·5° C)	0	29·0	13·0	2·2	0·00/2·2
	10	7·5	2·2	3·4	1·21/2·2

	720	9	1·5	7·3	31·36/1·7
				Sum χ^2 (7 d.f.)	66·4
				P < 0·01	

*e is the initial ratio of wild type to *nit*-1 TPNH cytochrome *c* reductase activity. o is the observed ratio of these two activities.

†P is the probability that the differences between e and o are due to random variation.

One unit of TPNH cytochrome *c* reductase activity is defined as a change of 0·01 *O.D.* units per min at 550 mμ at 24° ± 2° C.

Table 2. *s* Values of TPNH Cytochrome *c* Reductase and Nitrate Reductase of Fresh and of Frozen and Thawed Preparations from Wild Type and from *nit*-1 Mycelium

Extract	Treatment	TPNH cytochrome *c* reductase Peak 1 Activity	*s*	Peak 2 Activity	*s*	Nitrate reductase Activity	*s*
Wild type	fresh	9	10·6	23	6·8	20	6·8
,, ,,	frozen and thawed	11	10·6	10	4·5	0	—
nit-1	fresh	10	10·6	34	4·5	0	—
,, ,,	frozen and thawed	11	10·6	77	4·5	0	—

For the definition of units of activity of TPNH cytochrome *c* reductase see Table 1.

One unit of nitrate reductase activity is defined as a TPNH and nitrate-dependent production of 10 mμM of nitrite in 15 min at room temperature.

s values were calculated by the method of Martin and Ames[5] using catalase as the standard enzyme:

$$\frac{s \text{ of } x}{s \text{ of reference}} = \frac{\text{Distance of } x \text{ from meniscus}}{\text{Distance of reference from meniscus}}$$

Nit-1-induced and wild-type-induced mycelia were extracted as described here and either used within 6 h of extraction or frozen in liquid nitrogen and stored for two to three weeks at −20° C before use. Sucrose gradients (5 to 20 per cent w/v) were made by the procedure of Martin and Ames[5] and centrifuged at 38,000 r.p.m. for 11 h in an *SW*39 swinging bucket head in a 'Spinco' model *L* refrigerated centrifuge. Fractions (0·16 ml.) were collected by downward displacement through a hypodermic needle; they were assayed for TPNH cytochrome *c* reductase by the method of Kinsky and McElroy[2] and for nitrate reductase by a modified version of the assay of Evans and Nason[7]. The modification was to terminate the reaction by precipitating pyridine nucleotides with barium acetate and subsequently to precipitate proteins by the addition of 95 per cent ethanol. The suspension was then centrifuged, and the clear supernatant assayed colorimetrically as usual, with sulphanilamide and N-1 naphthyl ethylene diamine. The results shown in Table 2 indicate that fresh wild-type-induced extract has a heavier TPNH cytochrome *c* reductase than frozen and thawed preparations of the same material. Also, unlike the frozen and thawed preparation, the fresh wild-type material had a nitrate reductase peak. Both frozen and thawed and fresh extracts of wild-type-induced mycelium had nitrate reductase activity before they were subjected to density gradient centrifugation.

The simplest interpretation of these data is that nitrate reductase is an aggregate of TPNH cytochrome *c* reductase and another polypeptide, and that freezing and thawing labilize this aggregation. The labilized aggregate therefore dissociates in the gradient. *Nit*-1 extracts, which have no nitrate reductase, have a TPNH cytochrome *c* reductase pattern in the gradient like that of frozen and thawed wild type. The simplest interpretation of this observation is that TPNH cytochrome *c* reductase in *nit*-1 is like that of wild type, but the aggregate with the mutationally altered protein (that would normally transport electrons from the branch point to cytochrome *c* reduction to nitrate) is unstable in the gradient. It therefore dissociates, even without freezing and thawing, into TPNH cytochrome *c* reductase and an enzymatically inactive protein. The relatively greater heat lability of the *nit*-1 TPNH cytochrome *c* reductase agrees with the above hypothesis.

This work was carried out in the Department of Biology, Yale University; details of the experiments will be published in full.

Incorporation of ^{14}C-Glucose and ^{14}C-Glucose 6-phosphate into Glycogen and CO_2 by Rat Liver Slices

It has been postulated that the hexokinase reaction is not a necessary step in glycogen synthesis. This is supported by experiments in liver slices[1,2] and in the diaphragm[3], as well as in cell-free systems[4,5]. The hexokinase reaction was assumed to occur only in the degradation pathway of glucose, and a different pathway was postulated for glycogen synthesis, circumventing the hexokinase reaction[4,5].

It seemed worthwhile, therefore, to compare radioactive glucose and radioactive glucose 6-phosphate with respect to both their production of ^{14}C-CO_2 and their incorporation into glycogen in the same liver. Liver slices obtained from male rats were used. The slices were incubated in Hastings buffer solution (medium I, ref. 6), enriched with glucose-1-^{14}C or glucose-1-^{14}C 6 phosphate. At the end of the incubation period the slices were removed to determine the radioactivity of glycogen. Glycogen was isolated with 30 per cent KOH and precipitated with ethanol, and its concentration in the slices was measured at the beginning and at the end of the incubation period by the method of Montgomery[7]. ^{14}C-labelled CO_2 was trapped with 60 per cent KOH and transformed into $Ca^{14}CO_3$ to measure its radioactivity.

It can be seen in Table 1 that glucose is a better precursor of glycogen than glucose 6-phosphate, measured by the incorporation method. The glycogen concentration of the tissue at the end of the incubation period is also greater with glucose than glucose 6-phosphate, as was shown by Niemeyer and Figueroa[1]. There is evidence that glucose 6-phosphate penetrates inside the cell since inorganic phosphate is liberated from the ester (about 10 μmoles) by the slices, and glucose 6-phosphatase does not diffuse out into the medium[8]. Glucose 6-phosphate increases oxygen uptake, while additional glucose does not when incubated with rat liver slices[1]. Additional evidence is presented in this work by the observation of the production of ^{14}C-CO_2 from radioactive glucose 6-phosphate. In fact, the results showed that consistently more ^{14}C-CO_2 is produced from ^{14}C-glucose 6-phosphate as compared with ^{14}C-glucose (Table 2).

Table 1. INCORPORATION OF ^{14}C-GLUCOSE AND ^{14}C-GLUCOSE 6-PHOSPHATE INTO GLYCOGEN BY RAT LIVER SLICES

About 100 mg of liver, in slices, was incubated in 2 ml. Hastings medium. Glucose or glucose 6-phosphate concentration was 0·03 M (100,000 c.p.m. each). 95 per cent O_2–5 per cent CO_2 was used as the gas phase. The flasks were shaken in a bath for 60 min at 37·0° C.

Exp.	Initial glycogen*	Final glycogen* Without substrate	Glucose	G-6-P	Incorporation† Glucose	G-6-P
1	71	50	182	48	1,400	143

7	134	84	448	248	2,030	796

*Glycogen is expressed as μg/100 mg of wet tissue.
†Incorporation corresponds to counts/min incorporated in 100 mg wet tissue.

Table 2. ^{14}C-CO_2 PRODUCTION FROM ^{14}C-GLUCOSE AND ^{14}C-GLUCOSE 6-PHOSPHATE BY RAT LIVER SLICES

Experiments 2–7 refer, respectively, to the animals so numbered in Table 1. Experimental conditions as in Table 1

Exp.	Glucose*	Glucose 6-phosphate*
2	376	504
3	47	378
4	122	196
6	164	202
7	261	361
8	489	635

* Figures correspond to c.p.m. incorporated into carbon dioxide by 100 mg of wet tissue.

This is in agreement with the evidence of Di Pietro *et al.*[9], who found in a rat liver homogenate a greater production of ^{14}C-CO_2 with ^{14}C-glucose 6-phosphate than with ^{14}C-glucose using uniformly labelled hexose as well as labelled in carbon 1 or 6.

Therefore, the hexokinase reaction constitutes, without doubt, a limiting step in glucose degradation. On the other hand, since glucose forms glycogen at a higher rate than glucose 6-phosphate, the hexokinase reaction does not constitute a limiting stage in glycogen synthesis. These results, as well as those of Beloff-Chain *et al.*[3], Petrova[4], Niemeyer and Figueroa[1], and Figueroa *et al.*[2,5], may be satisfactorily explained if the hexokinase reaction is not a necessary step in glycogen synthesis.

Recently, Viñuela *et al.*[10] reported the identification in rat liver of two enzymes that phosphorylate glucose. One of them, called hexokinase, has a *Km* about 10^{-5} M for glucose, and the other one, called glucokinase, has a *Km* about 10^{-2} M. Although, in the conditions of our experiments (concentration of glucose 0·03 M), hexokinase is working at maximum velocity and glucokinase is only partially saturated, the argument presented here may be applied to both hexokinase and glucokinase.

Heterogeneity of *H* Chains of Myeloma Proteins: Susceptibility to Papain and Trypsin

PROTEOLYTIC digestion of proteins has been one of the methods used in determining protein structure[1–3]. Closely allied proteins such as γ-globulins revealed after enzyme cleavage significant differences in products. It was shown that the main fragments (*S* and *F*) of normal human 7*S* γ-globulins obtained by papain digestion are heterogeneous[4–6]. These investigations were now extended to abnormal γ-globulins (7*S* and β_2A myeloma γ-globulins) in order to compare the structural make-up of the subcomponents of their *S* and *F* fragments. During the course of the investigation an *F* fragment, extremely labile to proteolytic digestions, was found in one of the 7*S* myeloma γ-globulins studied.

All the proteins were purified by starch-block electrophoresis[7] and screened for their purity and type by immuno-electrophoresis and ultracentrifugation. Group-specific antigens of both the *L* and *H* chains were typed by Dr. H. G. Kunkel. The two β_2A myeloma globulins studied were of the polymer variety. All samples were digested by papain at *p*H 7·5 for 18 h[4] and subjected to starch-gel electrophoresis in discontinuous system of buffers[8] at *p*H 8·3 room temperature, and 3–4 V/cm/h for a total of 18 h.

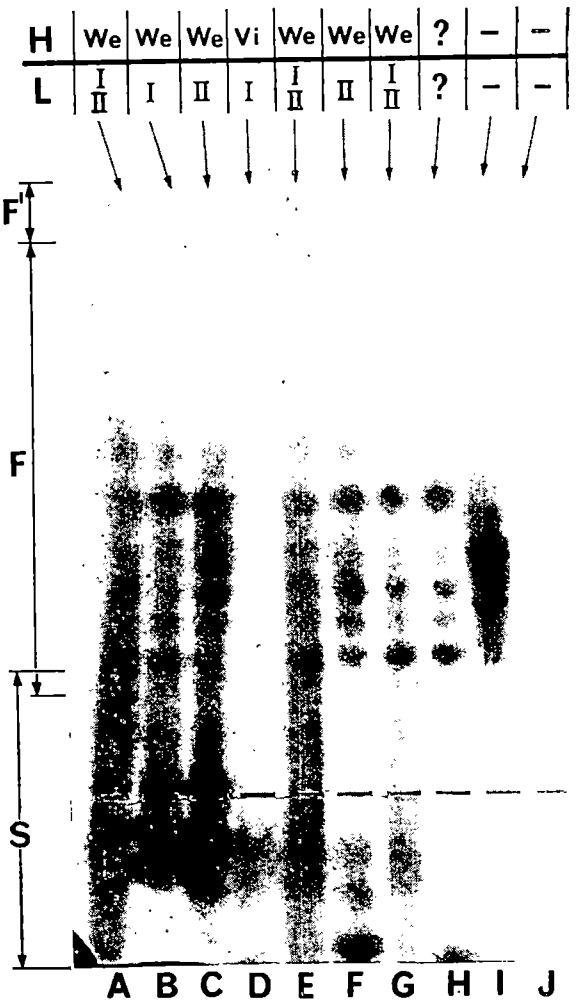

Fig. 1. Vertical starch-gel electrophoretic patterns of normal 7*S* γ-globulins, 7*S* myeloma γ-globulins and β_2A myeloma γ-globulins after papain digestion. *A*, *E*, normal 7*S* γ-globulins (Cohn Fraction II); *B*, *C*, *D*, *F*, *G* and *H*, 7*S* myeloma γ-globulins; *I*, *J*, β_2A myeloma γ-globulins, *L*, light-chain type; *H*, heavy-chain type; *F* and *F'*, fast fragments; *S*, slow fragment; (—), not typed; (?), not typable

Typical starch-gel electrophoretic patterns of normal and myeloma γ-globulins after papain digestion are shown in Fig. 1. Fig. 1*A* and *E* show typical patterns of the 7*S* γ-globulin (Cohn Fraction II). The *F* fragment is separated into 10–13 distinct sub-components. The *S* fragment of the same γ-globulin displays only a moderate heterogeneity (cf. ref. 4), in contrast to 7*S* myeloma proteins (Fig. 1*B*, *C*, *F*, *G* and *H*). Two of the myeloma proteins (Fig. 1*D* and *H*) were strikingly similar in their *S* fragment.

The patterns obtained with the β_2A myeloma globulins (Fig. 1*I* and *J*) were radically different from those of the 7*S* myeloma proteins described above. Sub-components of the *F* fragment have different mobilities and distribution with respect to those of 7*S* myelomas. In each of the β_2A myelomas tested so far, the three fast sub-components characteristic of 7*S* γ-globulin (*F'*) are missing. Although it was difficult to demonstrate the sub-components of the *S* fragment on starch-gel electrophoresis, these were shown to be present on immuno-electrophoresis.

In contrast to the multibanded nature of the *F* fragment seen in Cohn Fraction II and most myeloma proteins, a striking exception was noted with one of the 7*S* myeloma γ-globulins (Fig. 1*D*), where the *F* fragment is completely destroyed by papain. Time sequence digestion was carried out on this protein with papain[4] and trypsin[9]. Complete dissolution of the *F* fragment by papain was achieved between 2 and 4 h as shown in Fig. 2 in contrast to trypsin (Fig. 3), where digestion for 24 h was required to obtain the same result. Ultracentrifugal analysis confirmed this finding. Thus it appeared that this fragment is similar to that described recently by Takatsuki and Osserman[10]. Typing of the intact protein for the *L* and *H* chain types[11] (courtesy of Dr. Kunkel) has shown that this protein belongs to *L* chain type *I* and *H* chain type *Vi*. Grey and

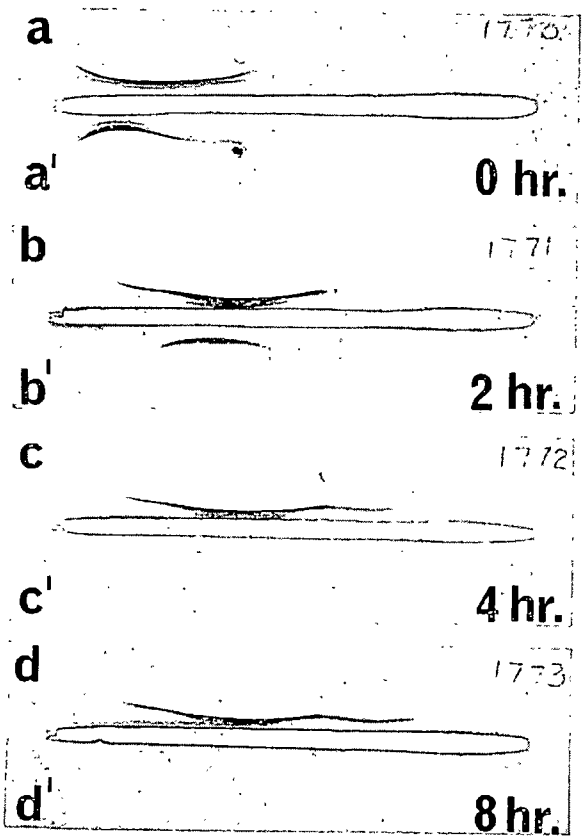

Fig. 2. Immunoelectrophoretic patterns of papain digests of 7*S* γ-globulin (Cohn Fraction II) and 7*S* myeloma γ-globulin (cf. Fig. 1*D*, Patient M. N.) carried out in time sequence. Samples removed after 0, 2, 4 and 8 h of digestion. *a*, *b*, *c*, *d*, normal 7*S* γ-globulin; a^1, b^1, c^1, d^1, myeloma protein (Patient M. N.). Specific rabbit anti-*F* antiserum was used to develop precipitin arcs

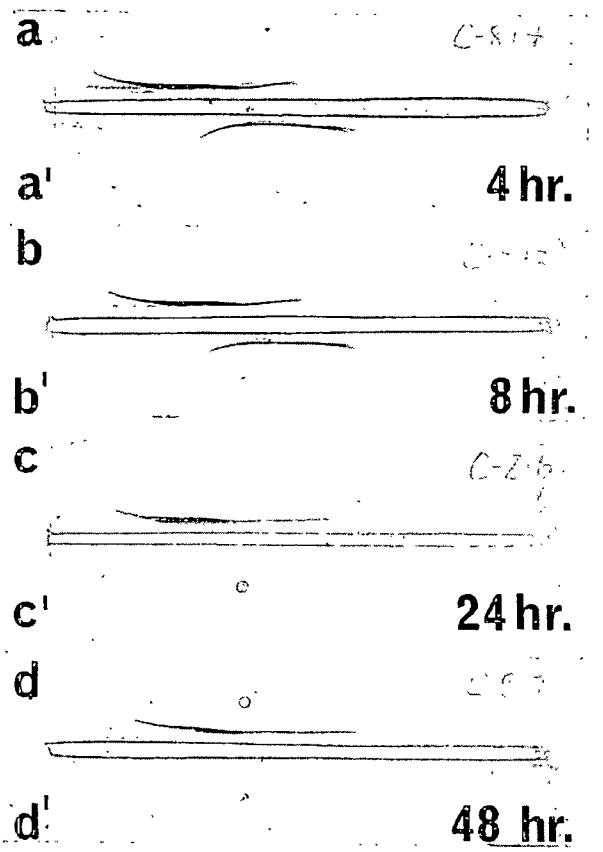

Fig. 3. Immunoelectrophoretic pattern of trypsin digests of 7*S* γ-globulin (Cohn Fraction II) and 7*S* myeloma γ-globulin (cf. Fig. 1*D*, Patient M. N.), carried out in time sequence. Samples removed after 4, 8, 24 and 48 h of digestion. *a*, *b*, *c*, *d*, normal 7*S* γ-globulin; a^1, b^1, c^1 and d^1, myeloma protein (Patient M. N.). Rabbit antiserum containing anti-*F* and anti-*S* antibodies was used to develop the precipitin arcs

Kunkel[11] have shown that the myelomas of the *Vi* type they used have papain-stable *F* fragments. Whether the availability and/or accessibility of the critical peptide bond(s) to enzyme digestion depend on the primary amino-acid sequence or on the conformation of the chains with respect to each other is under investigation. It is well known that a single amino-acid substitution may induce profound configurational changes in the protein structure. One may also anticipate an increase in the number of basic amino-acids in this protein since the intact protein migrates to the cathode in the starch gel. In contrast, the myeloma γ-globulin shown in Fig. 1*H* also migrates backwards in similar fashion, yet its *F* fragment (*H* chain) is stable to papain digestion, even though its *S* fragment appears electrophoretically to be very much the same as the *S* fragment of the papain-labile protein. It is of interest to mention here that it was impossible to classify this protein (Fig. 1*H*) according to any known immunological *H* or *L* chain type (personal communications by H. G. Kunkel).

In the light of the current reports that *H* chains of the γ-globulins appear to be markedly heterogeneous, specific antigenic determinants and properties residing on these chains now include: (*a*) *Gm* groups; (*b*) group specific *H* chain types[11–13] of which there are now four classified, *We* (γ_2b), *Vi* (γ_2c), *Ge* and γ_2a; as well as (*c*) those which are not typable; (*d*) individually specific *H* chain antigens[11]; (*e*) enzyme labile *H* chains—to papain and trypsin as shown here and to papain as demonstrated by Takatsuki and Osserman[10]. The *H* chains of both these susceptible proteins may be of the same group-specific antigenic type.

Undoubtedly new properties of the *H* chains will soon be forthcoming and permit further sub-classification of myeloma γ-globulins.

This work was supported by U.S. Public Health Service research grants *AI*-05785 and *HE*-07495 from the National Institute of Allergy and Infectious Diseases and the National Heart Institute, and in part by the Michigan Leukemia Foundation of Michigan.

Reduction and Re-oxidation of the Disulphide Bonds of Soy Bean Trypsin Inhibitor

Several examples have recently been reported of the partial or complete recovery of the native conformation and the biological activity of a protein following the reduction of all disulphide bridges under strongly denaturing conditions, such as 8 M urea or 5 M guanidine hydrochloride. The examples include insulin[1], ribonuclease[2], lysozyme[3], and pepsinogen[4]. In each case the recovery was induced by removing the reducing agent and denaturing solvent and allowing the disulphide bridges to re-form spontaneously through re-oxidation of sulphydryl groups by atmospheric oxygen.

Since the loss of the native molecular organization is generally very extensive for reduced, denatured proteins, these results are of importance as a direct test of the hypothesis that the overall configuration of proteins is primarily determined by their amino-acid sequence[5].

Investigations in this laboratory have recently demonstrated that soy bean trypsin inhibitor is likewise capable of a major degree of recovery of its native structure after treatment of this kind. The organized structure of this protein has been shown to be rather refractory to the action of 9 M urea at neutral *p*H and 25° C[6]. Exposure to alkaline *p*H or elevated temperatures in this solvent results in a time-dependent transition to a molecular state which is much more loosely organized, as judged by changes in intrinsic viscosity, optical rotation, and rotational relaxation time[6].

Soy bean trypsin inhibitor (STI) consists of a single polypeptide chain of molecular weight 21,000 which is cross-linked by 2 disulphide bridges[7]. Treatment of 1 per cent STI (Worthington) solutions in 9 M urea, 5 per cent β-mercaptoethanol for 20–30 min at 57° resulted in quantitative reduction of cystine groups to cysteine, as determined by titration with *p*-chloromercuribenzoate[8]. The product of the combined reduction and denaturation under these conditions exists in an advanced state of molecular disorganization, as indicated by the high value of intrinsic viscosity (21·2 ml. g^{-1}), and low value of rotational relaxation time ($\rho_h^{25} = 1{\cdot}6 \times 10^{-9}$), as determined by fluorescence polarization[9]. However the non-vanishing value of the latter parameter suggests that some structural restraints may survive under this condition.

Removal of urea and mercaptoethanol by passage through a 'Sephadex *G*–25' column, eluting with 0·1 M NaOAc, *p*H 5·6, yields the reduced protein in water. This material has little or no inhibiting capacity (< 2 per cent of native) for trypsin, as determined by assay with the substrate tosyl arginine methyl ester at *p*H 7·5, 25° (ref. 10).

Air oxidation of a 0·1–0·3 g/l. solution in 0·1 M phosphate, *p*H 8·0 for 48 h at 25° results in quantitative reformation of disulphide bridges to yield a re-oxidized product with 30–40 per cent of the trypsin-inhibiting capacity of the original (Table 1). Ultracentrifugal examination of the product, after re-concentration by pervaporation, shows two components of sedimentation coefficient 4·7 and 2·2 (1 per cent STI in 0·1 M potassium chloride, 0·01 M phosphate, *p*H 7). The value for the latter component is close to that for native inhibitor.

Table 1. Properties of Reoxidized STI Preparations

Preparation	Per cent reduction	Per cent activity re-oxidized material	Per cent activity monomeric fraction*
STI–*R*–1	90	42	—
STI–*R*–3	100	43	81
STI–*R*–4	100	38	85
STI–*R*–5	100		100
STI–*R*–6	93		61

Reduction was carried out in 9 M urea, 0·1 M phosphate, *p*H 7·7, for 15–20 min at 58°. Re-oxidation was carried out in 0·1 M phosphate, *p*H 8·0 for 48 h at 25°. The concentration of STI was 0·1 to 0·3 g/l.
*Obtained by 'Sephadex *G*–100' fractionation.

The two components could be separated by fractionation on a 'Sephadex *G*–100' column. The elution pattern of re-oxidized STI showed two major components and sometimes a minor (< 10 per cent) trailing component. The leading component (*F* I) and the second elution peak (*F* II) had sedimentation coefficients of 4·7 and 2·2 respectively (1 per cent STI in 0·1 M potassium chloride, 0·01 M phosphate, *p*H 7).

Almost all the inhibitory activity of the re-oxidized material was present in fraction *F* II, the specific activity of which was 80–100 per cent of the native protein. There was some indication of a slight (< 10 per cent) activity in *F* I, but the possibility of contamination with *F* II has not been rigorously excluded.

The monomeric fraction (*F* II) probably closely resembles the native material in structure, in view of its sedimentation properties and biological activity. It would, however, be premature to equate it with the original in all structural aspects. It is clear that the process, competitive with re-formation of the native molecule, involves aggregation, possibly through formation of intermolecular cystine bridges.

It may be concluded that soy bean trypsin inhibitor may be added to the list of proteins which are capable of spontaneous re-formation of a conformation resembling the native after an extensive loss of structure.

Esterase Activity of Pepsin

It is known that many proteolytic enzymes—trypsin, chymotrypsin, thrombin, papain and others—hydrolyse peptide, amide and ester bonds. Pepsin, however, is generally believed to hydrolyse the peptide bonds only, without exhibiting the esterase activity[1]. This conclusion is based on observations which suggest that pepsin does not hydrolyse the ester bonds in several esters of N-substituted amino-acids and peptides, but no special investigation of the esterase activity of pepsin has been published.

In view of the possible significance of esterase activity in the action of pepsin, we have examined its effect on some esters. The N-substituted aromatic amino-acid esters differing in the structure of the alcoholic component were chosen as substrates and the following were used: N-acetyl-L-tyrosine ethyl ester, L-phenylalanine benzyl ester (the corresponding N-substituted phenylalanine ester could not be used as it was insoluble in the experimental conditions), and N-acetyl-L-phenylalanyl-L-phenyllactic acid. Effect of pepsin on the N-acetyl-L-phenylalanyl-L-phenylalanine methyl ester, which could be expected to be hydrolysed, was investigated as well.

N-Acetyl-L-phenylalanyl-L-phenylalanine methyl ester (APPMe) and N-phenylalanyl-L-phenyllactic acid (APPL) were prepared by the method of mixed anhydrides from N-acetyl-L-phenylalanine and L-phenylalanine methyl ester and L-phenyllactic acid, respectively.

Twice-crystallized pepsin (Nutritional Biochemical Corporation) was used. Some experiments were performed with pepsin and pepsinogen purified on a DEAE-cellulose column[2].

The effect of pepsin on the ester substrates was investigated at *p*H 2–4 at 37° C during 20–48 h; the concentrations of substrate and enzyme were $2{\cdot}7\times10^{-3}$ M and $2{\cdot}7\times10^{-5}$ M, respectively. Because of limited solubility of APPL and APPMe, all the experiments were performed in the presence of 10–15 per cent of ethanol.

The cleavage of the ester bond was estimated by the hydroxamate reaction, by the method of Hestrin[3]. After 20-min treatment by hydroxylamine, HCl (about 4 N) was added, followed, after incubation for 2 min, by a 10 per cent solution of $FeCl_3{\cdot}6H_2O$ in 0·1 N HCl. Optical density at 540 mμ (spectrophotometer *SF*–4) was immediately measured in filtrates of these samples.

Table 1. Effect of Pepsin on Some Esters

Substrates	ATEE		APPMe		PBE		APPL	
*p*H	2	4	2	4	2	4	2	4
Hydrolysis: (per cent)	0	0	0	0	0	0	30	0

The data presented in Table 1 show that after incubation of pepsin with the N-acetyl-L-tyrosine ethyl ester (ATEE) and N-acetyl-L-phenylalanyl-L-phenylalanine methyl ester (APPMe) no decrease in the quantity of esters could be detected although the cleavage of the peptide bond occurred in the course of incubation of APPMe with pepsin. No cleavage of the ester bond was noted in experiments with phenylalanine benzyl ester (PBE). But after the incubation of N-acetyl-L-phenylalanyl-L-phenyllactic acid (APPL) with pepsin at *p*H 2 a decrease in the quantity of ester was observed. Table 1 shows that cleavage of APPL at *p*H 2 during 48 h is about 30 per cent. In control samples, where APPL was incubated without the enzyme or in the presence of pepsin previously inactivated by alkali, no decrease in the quantity of ester was recorded. The hydrolysis of APPL under the influence of pepsin was confirmed by silica-gel thin-layer chromatography in a methanol : ethylacetate (1: 5 v/v) system, and iodine treatment. The outline taken from the chromatogram (Fig. 1) shows, in the control sample, a single spot of APPL. In the sample incubated with pepsin during 48 h at *p*H 2 a second spot

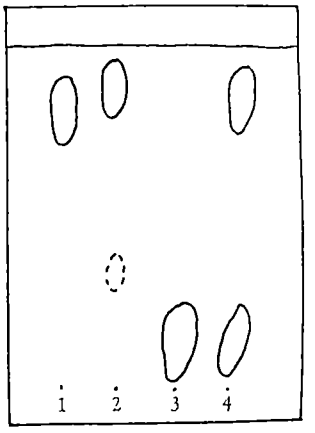

Fig. 1. Schema of silica-gel thin-layer chromatogram in methanol–ethylacetate (1 : 5, v/v) system. 1, N-acetyl-L-phenylalanine; 2, L-phenyllactic acid; 3, control sample, APPL after 48-h incubation at *p*H 2 without the enzyme; 4, experimental sample, APPL after 48-h incubation at *p*H 2 in presence of pepsin

was found. The position of this spot corresponds to N-acetyl-L-phenylalanine and L-phenyllactic acid. Neither of these compounds is resolved in the solvent system used.

Cleavage of APPL under the influence of pepsin occurs at *p*H of about 2. No hydrolysis of APPL by pepsin at *p*H > 3 could be detected (Table 1).

It could be supposed that APPL is hydrolysed by some other enzyme probably present as an impurity in the pepsin preparation used. To exclude this possibility, we have investigated the effect of various preparations of pepsin on APPL. Three preparations of pepsin purified on a DEAE-cellulose column were used. One of these preparations was free from admixtures of gelatinase. In one of the experiments, pepsinogen activated directly in the experimental samples was used. All the preparations of pepsin used hydrolysed APPL. The degree of hydrolysis of the ester was about 20–30 per cent. Hydrolysis of APPL by pepsin could also be demonstrated with several different preparations of APPL.

The data presented here show that pepsin, like many other proteolytic enzymes, possesses the ability to hydrolyse ester bonds. But the ester bond, to be hydrolysed by pepsin, has to be formed not only by a specific amino-acid residue but also by a definite alcoholic component.

The data obtained are of interest in relation to the mechanism of pepsin action. They suggest that CO-activation takes place during the action of pepsin. A similar conclusion may be drawn from the published data on the isotope exchange of oxygen in carboxyl groups of some N-substituted amino-acids occurring under the influence of pepsin in H_2O^{18} (refs. 4 and 5). On the other hand, it is known that pepsin catalyses transpeptidation of the 'amino transfer' type[6,7]. In view of these observations, it may be supposed that the cleavage of peptide bonds by pepsin includes a synchronous 'attack' on both CO- and NH-groups.

Oxidation-reduction Potentials and Capillary Activities of Humic Acids

APART from the effects which humic acids have on the physical properties of the soil, such as its structure, permeability and water retention, and through which they influence the growth of plants, it has been shown that humic acids also have a directly stimulating effect on plant growth[1–3]. In an attempt to trace the cause of this stimulation, Flaig and Otto[4] investigated the influence of quinones and other oxidation-reduction systems on the growth of plant roots, and found in many instances a favourable effect. Flaig and Beutelspacher[5] found that in an acid environment and in the presence of nitrogen the rH value (redox potential) of humic acids decreased. Proper E_0 values of humic acids, however, have not as yet been published and it was therefore considered to be of interest to study the oxidation-reduction humic acid system in greater detail.

We found that humic acids could be reduced with hydrogen in the presence of colloidal palladium, prepared as described by Gatterman[6]. After reduction of the acids and subsequent removal of the reductant, the reduced acids were titrated in a phosphate buffer at pH 7·0 in a nitrogen atmosphere, with potassium ferricyanide as oxidant. The formal oxidation-reduction potential of the humic acid system was determined from the titration curve. From Fig. 1 it follows that the redox potentials at pH 7·0 of humic acids extracted from the core samples of a tropical sphagnum peat deposit 17 m deep (for further data see Visser[7]) decrease with progressive humification of the peat samples. The mean values of the normal potentials appear to lie between +0·32 and +0·38 V. In view of these oxidation-reduction properties it also seems possible that apart from their influence on plant growth, which can probably be attributed to an influence on plant respiration, the relatively stable humic acids are playing a part in the oxidation process of soil organic matter.

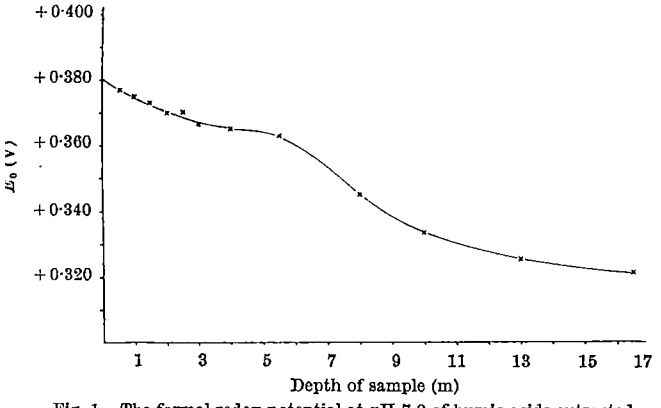

Fig. 1. The formal redox potential at pH 7·0 of humic acids extracted from a tropical sphagnum peat deposit

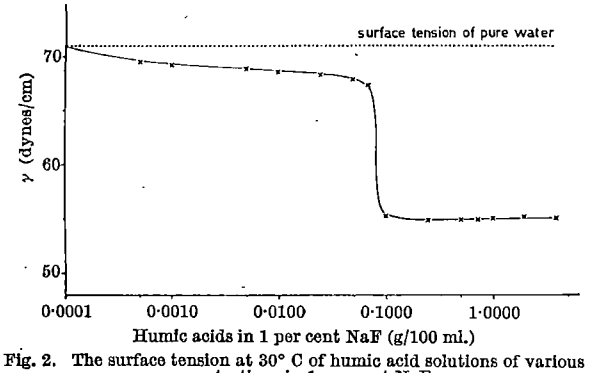

Fig. 2. The surface tension at 30° C of humic acid solutions of various concentrations in 1 per cent NaF

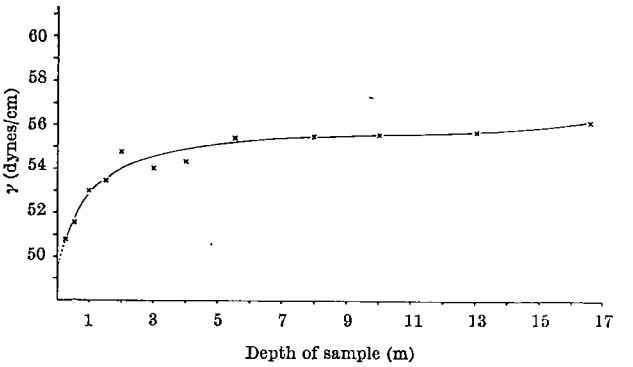

Fig. 3. The surface tension at 30° C of 0·2 per cent solutions in 1 per cent NaF of humic acids extracted from a tropical sphagnum peat deposit

Apart from their effects on plant growth, humic acids are probably also capable of raising the permeability of the cell-protoplasm, which may explain the increased ionic uptakes described by Blagowestschenski and Prosorowskoja[8] and by Chaminade and Blanchet[9]. For this reason the influence of these acids on the surface tension of water was more closely investigated.

For the measurement of the surface tension of humic acid solutions the acids were dissolved in 1 per cent neutral sodium fluoride. By using Morgan's apparatus[10] (falling drop method), kept in a thermostatically controlled bath at 30° ± 0·001° C, it was shown that humic acids behave like typical capillary active substances (Fig. 2). From Fig. 3 it can be deduced that the depression of the surface tension is markedly lower in samples nearer the deeper end of the core than in those nearer the top end, and the capillary activity of humic acids is thus shown to decrease with progressive humification.

Because of their surface-active properties, and of their abundance in soils and in some natural waters, it seems very probable that humic or pre-humic substances contribute to the foam often observed on swamp waters, and, because of their capillary properties, will contribute to the pF value of soils.

PHYSIOLOGY

A Non-dialysable, Heat-stabile, Hypertensive Substance in the Serum of Rats

INCUBATION of rat serum at 37° C, without any digestion by proteolytic enzymes or change of the pH, effects the liberation of a highly pressure-active substance. This hypertensive effect appears after an incubation of 5 h and reaches its maximum after 15 h at 37° C (Fig. 1*A*). The blood pressure of rats nephrectomized 24–48 h before or after application of a ganglionic blocking agent or infusion of hypotonic glucose is controlled. 0·25 ml. of incubated serum given intravenously causes a rise of the blood pressure of about 35 mm mercury; this equals, in terms of pressor activity, 0·05 μg of 'Hypertensin' (CIBA). Infusion of a hypertonic sodium solution diminishes the

hypertensive effect both of the incubated serum and of synthetic angiotensin (hypertensin (CIBA)). Incubation of serum during a period longer than 40 h slowly reduces the hypertensive activity of incubated serum. The hypertensive substance is not dialysable against sodium chloride. Ultrafiltration across a cellulose membrane is not possible (Fig. 1*B*). The pressure-active principle is found at 40–60 per cent saturation with ammonium sulphate. Boiling of this fraction at *p*H 1 for 10 min is sustained without any reduction in hypertensive effect; at *p*H 12 the hypertensive principle is destroyed.

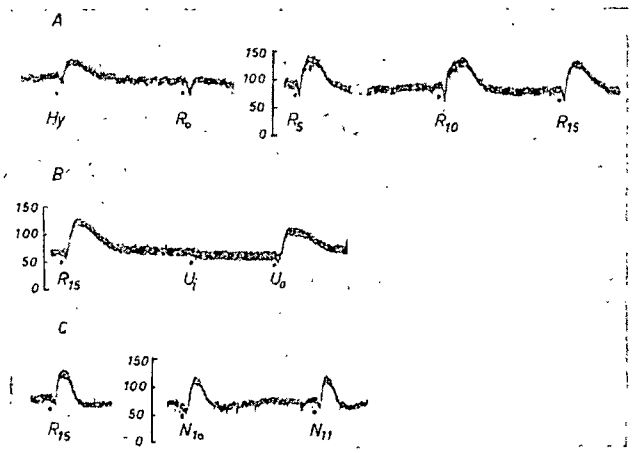

Fig. 1. *A*, Changes in arterial blood pressure. *Hy*, 0·05 μg of 'Hypertensin' (CIBA); R_0 native rat serum; R_5 rat serum, 5 h of incubation at 37° C; R_{10} rat serum, 10 h of incubation at 37° C; R_{15} rat serum, 15 h of incubation at 37° C. *B*, U_1 ultra-filtrated serum fraction of R_{15}; U_0 non-ultra-filtrable serum fraction of R_{15}. *C*, N_{10} serum of a rat 24 h after nephrectomy, incubation for 15 h at 37° C; N_{11} serum of a rat 24 h after nephrectomy, incubation for 15 h at 37° C. Volume of each single dose, 0·25 ml.; interval between injections, 5 min

In contrast to renin, which disappears from the serum within 1 h after nephrectomy[1], serum of nephrectomized rats shows the same hypertensive effect after incubation at 37° C (Fig. 1*C*).

Analysis of these results indicates that the pressure-raising activity of incubated rat serum may be caused by the action of two substances: (1) one similar to the known hypertensive polypeptides such as angiotensin, pepsitensin or anephrotensin linked to a protein or (2) a free, unknown hypertensive hormone.

We have excluded the possibility that the active principle produced by incubation at 37° C was bradykinin. This vasodepressor substance induces hypertensive reactions in certain circumstances[2], but acts as a depressor under the conditions described here.

Anephrotensin appears in rat serum after incubation at 38° C and *p*H 4 and is quickly destroyed by blood at normal *p*H. The hypertensive principle of incubated rat serum is not influenced by blood or native serum *in vitro*. Furthermore, the yield from nephrectomized rat serum is, in contrast to our results, three times greater than obtained from intact rat serum[2].

The mild treatment of native serum by incubation without any digestion or any change of the *p*H indicates that this pressure-active principle, which also exists in human and pig serum, may be involved in some physiologically important mechanism.

Achromotricia in Iron-deficient Rats

In the course of an examination of iron deficiency in rats, we noticed that the deficient animals became grey. There was variation among individuals in the time of onset and the severity of greying; but it was apparent in all test animals compared to controls (Fig. 1). Usually a change in colour of fur could be seen about four weeks after weanling animals had been placed on the deficient diet, and by eight weeks greying was pronounced.

Male weanling rats of the Long–Evans strain from the departmental colony were used; they were either all black or black-hooded. Animals were housed in individual galvanized iron cages equipped with bottles of distilled water. The iron-poor diet, fed *ad lib.*, was whole dry milk to which was added 10 mg $CuSO_4.5H_2O$, 250 mg $MnSO_4$, 1 mg KIO_3 and 1·8 g choline bitartrate per kg. The control diet contained in addition 300 mg $FeSO_4.7H_2O$ per kg and was given to both pair-fed and *ad lib.* control groups. Analysis of the mixed food indicated that the deficient diet contained 6 p.p.m. iron, compared to 66 p.p.m. in the supplemented diet. Three times weekly, the animals were given 2 ml. of a water-soluble vitamin mixture (84 mg thiamine hydrochloride, 126 mg riboflavin, 945 mg nicotinamide, 630 mg calcium pantothenate, 147 mg pyridoxine·hydrochloride, 21 mg folic acid, 21 mg biotin, 0·63 mg vitamin B_{12} and 21 mg menadione dissolved in 1,500 ml. of 5 per cent ethanol) to which was added 3 drops of an oil-soluble vitamin mixture (2 g vitamin A distillate containing 500,000 I.U./g, 250 mg irradiated ergosterol containing 400,000 I.U./g, and 5 g α-tocopherol in 1 kg of cottonseed oil).

The hair of young deficient rats was softer than that of controls, but was matted and harsh to the touch in older animals; some members of the latter group had red scaly deposits on the skin, particularly the back. The deficient animals showed the classical signs of pearly white incisor teeth, compared to brown-tinged ones in controls, and their paws were white in contrast to the pink paws of the controls. After eight weeks on the deficient diet the animals had blood hæmoglobin levels of about 3 g/100 ml. compared with about 14 g/100 ml. in controls.

The metal commonly associated with achromotricia is copper rather than iron[1]; however, a so-called 'cotton fur' effect noted in mink fed a fish diet was afterwards attributed to lack of iron[2]. A depigmentation from red to white in feathers of iron-deficient chickens has been reported[3]. We have found no reports of greying in iron-deficient rats which received adequate copper. Perhaps this is due mainly to the fact that most investigators have used albino animals.

An explanation for the greying phenomenon is not obvious. The results of a very limited number of assays

Fig. 1. Greying of fur in an iron-deficient rat. Both animals had been on the experimental diet for seven weeks. Top, iron deficient; bottom, iron supplemented

showed that there was more iron in hair from deficient animals (64 μg/g, mixed sample from two animals) than in that from controls (34, 23 and 22 μg/g, individual samples).

Ovarian Ascorbic Acid Depleting Activity in Human Brain Extracts

IT has been established that the hypothalamus controls the secretion of luteinizing hormone (LH) of the adenohypophysis through a luteinizing hormone releasing factor (LH–RF)[1,2]. This substance occurs only in the stalk median eminence of the hypothalamus[3,4] and, according to the literature, not in other brain tissue. Johnson[5] has shown that the whole brain, the hypothalamus excluded, also contains a substance displaying characteristics proper to LH–RF.

The lack of information on human material led us to carry out an investigation using extracts from different regions of human brains obtained in autopsies no more than 12 h after death. They were carefully dissected and cerebral cortex, habenular region and pineal glands were pooled apart in acetone or frozen at −10° C. Extracts were prepared by homogenizing the acetone-dried tissue with water at room temperature or with 0·25 per cent acetic acid and heating to boiling point. The soluble fraction was assayed in the ovarian ascorbic acid depletion test (OAAD) of Parlow[6,7] in normal and hypophysectomized rats. Pure LH, kindly supplied by Prof. C. H. Li, was used as a standard reference. Ascorbic acid depletion was obtained (Table 1) with most of the extracts, but great fluctuations in the yield of active material from different batches of tissues were observed.

No regional differences in activity were found.

The aqueous extracts were always more active than the acid ones or than those prepared according to Altschule[8] or obtained with glacial acetic acid and sulphuric ether precipitation.

The active material dialyses through 'Cellophane' and becomes rapidly inactive when kept in solution at ordinary temperature.

Table. 1. OVARIAN ASCORBIC ACID DEPLETION INDUCED BY DIFFERENT EXTRACTS IN PARLOW TEST

Treatment		% depletion (*S.E.*)	No. of rats	*P*
Saline		8·01 ± 4·77	17	
C. cortex–aq.ext.	(150 mg)	21·25 ± 2·96	9	< 0·02
C. cortex–aq.ext.	(8 mg)	21·67 ± 4·76	9	< 0·05
C. cortex–aq.ext.	(50 mg)	26·69 ± 1·90	5	< 0·01
C. cortex—alc.ext.	(75 mg)	21·31 ± 5·02	5	no sign
C. cortex–gl.acet.	(280 mg)	40·41 ± 2·12	4	< 0·01
Pineal–alc.ext.	(10 mg)	33·84 ± 4·80	5	< 0·01
Pineal–alc.ext.	(100 mg)	26·45 ± 3·27	5	< 0·01
Pineal–aq.ext.	(8 mg)	30·72 ± 4·12	10	< 0·01
Pineal–aq.ext.	(2 mg)	27·85 ± 4·21	9	< 0·01
Pineal–aq.ext.	(200 mg)	37·07 ± 5·75	5	< 0·01
Habenular–aq.ext.	(225 mg)	27·85 ± 4·21	9	< 0·01
Habenular–aq.ext.	(3·7 mg)	34·10 ± 3·89	5	< 0·01
Habenular–aq.ext.	(8 mg)	21·94 ± 2·91	10	< 0·02
Luteinizing hormone	0·5 μg	27·17 ± 4·16	8	< 0·01
	1·0 μg	34·75 ± 2·15	15	< 0·01
	2·0 μg	45·27 ± 4·53	19	< 0·01
	5·0 μg	55·06 ± 1·39	14	< 0·01
	10·0 μg	59·87 ± 1·06	4	< 0·01
Serotonin	10·0 μg	19·69 ± 2·31	9	< 0·02
	50·0 μg	25·27 ± 5·74	10	< 0·02
Melatonin (in propylene glycol)	10·0 μg	22·11 ± 9·02	10	no sign
	50·0 μg	17·48 ± 5·70	10	no sign
Propylene glycol	0·1 ml.	26·29 ± 6·36	10	< 0·02

Nos. in brackets, doses expressed in mg of dried tissue. Aq.ext., aqueous extract; alc.ext., alkaline extracts; gl.acet., extract prepared with glacial acetic acid and ether precipitation. *P*, related to control group treated with saline, with the exception of the group treated with 'Melatonin' which is compared to the depletion obtained with the solvent of this substance.

The same extracts were not active in hypophysectomized rats (Fig. 1) in a period when the sensitivity to LH was completely normal. This fact suggests the nature of a LH–RF and permits one to rule out the presence of LH.

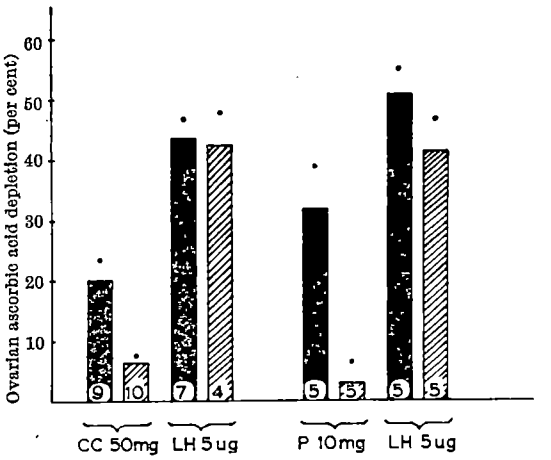

Fig. 1. Ovarian ascorbic acid depletion produced in normal and acutely hypophysectomized rats by administration of cerebral cortex and pineal extracts. The sensitivity of the rats to LH was assessed in each experiment with luteinizing hormone (LH). Dots represent the *S.E.* Numbers at the base of the bars represent the number of test animals. Black, normal; hatched, hypophysectomized; CC, cerebral cortex; LH, luteinizing hormone; P, pineal

The extracts increase the LH-like activity of the plasma of ovariectomized rats treated with œstradiol or œstradiol and progesterone[9] as shown in Fig. 2. The nature of this effect is not clear because it is not known if the intravenously injected extract remains in the blood when the plasma is taken out and assayed in the Parlow test, so the effect could be due to the injected substance and not to LH released from the animal's own pituitary.

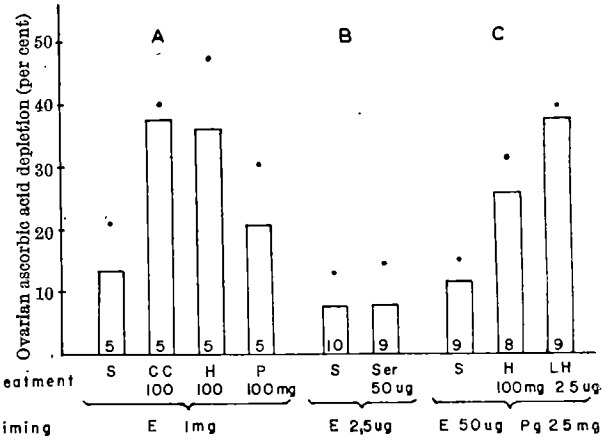

Fig. 2. Effect of different extracts, serotonin (Ser) and LH (luteinizing hormone) on plasma LH activity of ovariectomized adult rats primed with ovarian steroids. Plasma was obtained 15 min after the intravenous injection of a volume of 1 ml. of saline (S), cerebral cortex (CC), pineal (P), habenular (H) extract, serotonin or luteinizing hormone. The bars represent the ovarian ascorbic acid depletion with *S.E.*; number of recipient rats indicated at the base of each bar. The priming of the rats was with: *A*, 1 mg œstradiol benzoate (E); *B*, 2·5 μg E; *C*, 50 μg E, 25 mg progesterone (Pg) given subcutaneously 72 h previously

The daily subcutaneous injection of the extracts during 7–15 days to normal rats did not produce significant changes in the weight of the endocrine organs with doses equivalent up to 100 mg dry tissue per day. When the extracts were assayed in rats kept under constant illumination and displaying a state of constant œstrus, no change in the vaginal smear or weight of the endocrine organs was evidenced. Some experiments were performed

to establish the capacity of the extracts to induce ovulation in androgenized female rats[5] which have no spontaneous ovulation, and no effect was found with doses up to 400 mg dry tissue, which are rather low as compared with those used by Johnson. He induced ovulation with brain extracts in doses equivalent to 4–8 g of wet tissue.

The activity of the extracts on plain muscle was examined on the rat uterus *in vitro*, blood pressure of the anæsthetized rat and chicken cæcum rectale. No activity was found in these tests, so the presence of substance *P* may be discarded. Serotonin, the other substance present in brain tissue, is active in the Parlow test in high doses, which produce respiratory effects not evidenced with the active extracts (Fig. 2).

The reported results show that the whole human brain contains a substance producing depletion of the ovarian ascorbic acid, which acts through the pituitary. These results agree with those of Johnson on the brain of the sheep. The relation of this substance with that reported by McCann on the rat hypothalamus has not been examined.

Luteinizing Hormone-like Activity in Human Median Eminence Extracts

Recently, several investigators have succeeded in obtaining evidence of the presence of an LH liberating factor (LRF) in extracts prepared from the median eminence (ME) of different mammals, such as rats[1–3], cattle[2,4], sheep[3,5], rabbits[4] and monkeys[4].

The fundamental implications of this finding led us to attempt to establish a similar activity in the ME of human beings. Experiments were designed to investigate the ability of human ME extracts to elicit in the rat some of the phenomena commonly attributed to LH action such as ovulation and depletion of ovarian ascorbic acid (OAAD), and to assess whether the active substance should meet the requirements for classification as an LRF.

After resecting the pituitary stalk as completely as possible the ME was carefully removed by dissection from fresh or frozen hypothalamus obtained from cadavers of both sexes more than 10 years of age. The tissue was homogenized in 0·5 per cent acetic acid in the proportion of 1 ml./8 ME (the average weight for ME tissue was 35 mg). The homogenate was centrifuged at 2,500 r.p.m. for 20 min and the supernatant neutralized with sodium bicarbonate. Cerebral cortex (CC) extracts were prepared in the same way.

Female rats from our colony, weighing between 150 and 250 g, and with regular œstrous cycles, were used to test the ovulation-inducing ability of these extracts. The animals were kept in a room illuminated artificially from 7 a.m. until 9 p.m. by automatic control. A daily vaginal smear was taken at 9 a.m., and the rats found in pro-œstrus were injected intraperitoneally at 10.30 a.m. with 5 mg of chlorpromazine ('Largactil (R)', kindly supplied by Establecimientos Chilenos Colliere, Ltd.) per 100 g body-wt., a procedure which impedes ovulation during the following night[6]. After this the animals were anæsthetized with ether or bromethol and the extracts injected intravenously. LH dissolved in saline was also injected to check the sensitivity of the ovary under the effect of the blocking agent used (kindly supplied by Prof. C. H. Li, Berkeley, California). On the following day the Fallopian tubes were removed and the content of the ampulla examined under low illumination on the stage of a compound microscope to ascertain whether or not ovulation had occurred. The results are shown in Table 1. Eight ME and 4 CC extracts were assayed.

Seven of the nine rats which did not ovulate after ME injections were injected with the minimal dose of the respective extracts; the other two were injected with a dose greater than the minimal. LH was given at four different levels: 1, 5, 10 and 20 μg; each one to six animals. Failure to ovulate was seen in two rats at the dose of 1 μg, in one rat at the dose of 5 μg and in two rats at the 10-μg level. There was no clear relation between the number of ova shed and the quantity of LH administered at the dose-levels used.

Median eminence extracts were then assayed in hypophysectomized rats. As hypophysectomy in the chlorpromazine-treated rat causes a very high mortality the assays were performed in rats in which ovulation was blocked by hypophysectomy itself. By performing the operation at different hours in the morning of the day of pro-œstrus it was determined that the ovulatory release of LH occurs after 11.45 a.m. in our rats under the illuminating conditions described.

Ovulation was obtained in all animals hypophysectomized before 11.45 a.m. and injected with 1 or 5 μg of LH afterwards. As the rat showed, under these conditions, high responsiveness to the ovulatory stimulus, ME extracts were injected in nine hypophysectomized animals, ovulation being obtained in all of them.

The OAAD test was performed using immature female rats prepared as described by Parlow[7]. The extracts as well as the LH standard and the control solution were injected in the femoral vein. ME extracts were given also to hypophysectomized rats operated on 9 h before. The results shown in Table 2 are in keeping with those of the ovulation-inducing experiments, and both of them reveal a significant LH-like activity in the hypophysectomized animal.

This finding strongly suggests that LH may be present in ME extracts prepared from human material. This location of the hormone could be explained by the fact that the pars tuberalis covers the surface of the ME although it is generally believed that this part of the anterior lobe is devoid of hormone activity, as it is com-

Table 1. Effect of LH, Human ME and CC Extracts on Chlorpromazine-blocked Pro-œstrous Rats

No. of animals	Extract	Dose	No. which ovulated
29	None		0
39	ME	16–456 mg	30
17	CC	284–2,000 mg	0
24	LH	1–20 μg	19

Table 2. Effect of LH, Saline, Human ME and CC Extracts on OAAD of Intact and Hypophysectomized Rats

Extract	Dose	No. of rats	% depletion ± S.E.
Intact			
ME	170 mg	11	39·36 ± 2·68
CC	170 mg	7	12·02 ± 1·91
Saline	0·2 ml.	32	10·02 ± 2·44
LH	0·5 μg	8	27·17 ± 4·16
LH	1·0 μg	15	34·75 ± 2·15
LH	2·0 μg	19	45·27 ± 4·53
Hypophysectomized			
ME	170 mg	9	31·59 ± 1·65

posed mainly of chromophobe cells[8]. Despite this, ovulatory activity in the chlorpromazine-treated rat was also obtained with extracts prepared from human hypothalamus in which all possible contamination with pituitary tissue had been completely avoided by carefully excluding ME. Experiments on hypophysectomized rats will demonstrate whether the substance involved has either LH- or LRF-like activity. Since the active substance in these extracts does not dialyse, the first possibility seems more likely. The presence of LH-like activity in extracts prepared from sheep hypothalamus and ME has been reported by Guillemin *et al.*[9].

No matter how these results may be interpreted, the existence of LRF cannot be dismissed, and its occurrence in the human hypothalamus is still under investigation.

Development of Shock-inducing Factor in Canine Endotoxin Shock

DURING the course of our investigations on the mechanism of enhanced susceptibility to endotoxin after adrenalectomy in dogs, it was found that a transferable shock-inducing factor develops in the absence of glucocorticoids. The shock induced by endotoxins which have no direct cardiovascular action has been difficult to interpret. There has been debate on the indirect mechanisms[1], such as endotoxin-epinephrine synergism or histamine release. However, none could explain the effectiveness of glucocorticoids in preventing the endotoxin shock[2]. Concerning endotoxin susceptibility after adrenalectomy in rabbits, Fukuda[3,4] has pointed out that the diminution of hepatic glycogen which follows the accumulation of endotoxin in liver might have an intimate relation to the development of circulatory weakness. Prevention of the attendant hypoglycæmia and the lactacidæmic acidosis by infusions of a hypertonic glucose and sodium bicarbonate solution has been shown to be effective in the recovery of adrenalectomized rabbits even after intravenous administration of the lethal dose of endotoxin (200 μg/kg; LD_{100}).

However, in adrenalectomized dogs well maintained with DCA these procedures could have only slight ameliorating effect on the progress of profound shock, and the animals succumbed to even small doses of endotoxin such as 5 μg/kg.

As shown in Fig. 1, intravenous administration of endotoxin induced after about 30 min a progressive fall of arterial blood pressure. This type of shock could easily be prevented by glucocorticoid pretreatment. Intravenous administration of 'Decadron' (dexamethasone 21-phosphate, Merck) in a dose of 4 mg just before or within 15 min after endotoxin could also prevent the shock together with the development of hypoglycæmia due to liver glycogen depletion. Moreover, the shock was characterized by the rapid onset of intense fever accompanying shivering. As the fever induced by endotoxin has been shown to be due to the formation of endogenous pyrogen also in this species[5], it was tentatively supposed that massive formation of endogenous pyrogen in the absence of glucocorticoids might have some relation to the induction of shock.

Therefore, transfer of plasma or serum from the shocked adrenalectomized dog to another adrenalectomized dog maintained with cortisone, or to intact dogs, was tried. Thereby, an eventual combination of animals showing slight hæmagglutination with each other was avoided by cross-match blood tests. As shown in Fig. 2, a relatively small amount of serum (less than 10 c.c./kg) could induce an immediate fall in blood pressure, which was found to be due to an intense hepatosplanchnic blood pooling. Usually a prompt fever with shivering occurred. However, no correlation could be found between the fever induced and the degree of shock. Therefore, this transferable shock-inducing factor seemed to be a separate factor from the endogenous pyrogen and was shown to be heat-unstable (56° C, 30 min). From its mode of action it might act as a histamine-releaser on the liver. It developed in detectable amounts only in the blood of the shocked adrenalectomized animals. Glucocorticoids could prevent its development, but could not inhibit its action. This might well explain why glucocorticoids were not effective unless they were administered before or shortly after endotoxin.

The development of the endogenous shock-inducing factor in the absence of glucocorticoids might explain the extreme susceptibility to endotoxin in adrenalectomized dogs which could not be fully ameliorated by correcting the hypoglycæmia and acidosis. The intimate relation of its development to the almost complete depletion of liver glycogen (less than 100 mg per cent wet wt.) might suggest

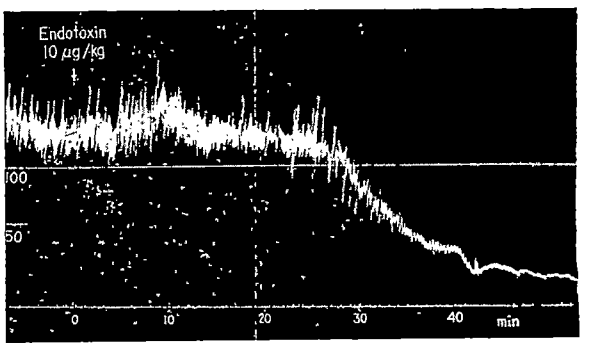

Fig. 1. Endotoxin shock in an adrenalectomized dog maintained with DCA. The blood pressure recording at femoral artery. The experiment was done 2 weeks after adrenalectomy without anæsthesia. Endotoxin dose of 10 times this amount had no effect on the blood pressure of unanæsthetized intact dogs

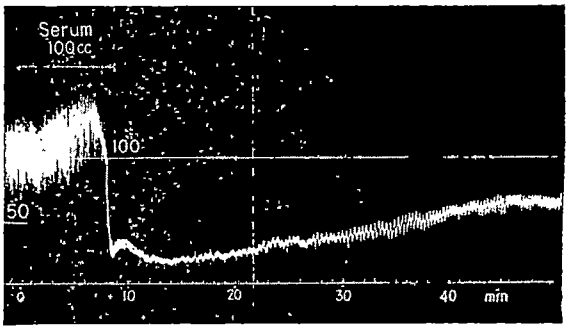

Fig. 2. Transfer of serum from an endotoxin-shocked animal to an adrenalectomized dog maintained with cortisone

its origin in the liver. Preliminary saline extraction of the factor was made by soaking liver slices (about 2 mm thick) of the shocked adrenalectomized dogs in a physiological saline solution of equal volume (4° C, 24 h). Saline washes cleared of cellular debris by centrifugation were tested, like the aforementioned serum. Only the saline extracts from the shocked animals induced an immediate fall in blood pressure, just as the serum from the shocked animals did. Thus the shock-inducing factor seemed to be liberated from the shocked liver. However, being heat-unstable it differed from VDM[6]. Thus the effectiveness of glucocorticoids in preventing endotoxin shock seems to depend on their ability to suppress the hepatic responses induced by endotoxin, such as glycogen depletion and liberation of the shock-inducing factor.

The shock in adrenalectomized dogs which could be induced even by small amounts of endotoxin differs in its mechanism from the well-documented immediate and transient falls in blood pressure observable only in this animal species with massive doses of endotoxin[7]. It seems to correspond to the late progressive shock which follows thereafter in intact dogs. It is really in this phase of shock that the effect of glucocorticoid pretreatment can be expected[2]. Whether the shock-inducing factor here demonstrated participates in endotoxin shock in other species in the absence of glucocorticoids remains to be elucidated. In rabbits, for the reasons mentioned here, the part played by this factor might be negligible. This might explain why susceptibility to endotoxin is not so much enhanced after adrenalectomy in this animal as in dogs.

Action of Enzymatic Inhibitors (Potassium Cyanide and Sodium Fluoride) on Muscle Fibre Sensitivity to Potassium Ion

The experiments reported by Carey and Conway[1] and by Conway[2] on skeletal muscle, and by Hodgkin and Keynes[3] on nerve fibre, show that ionic exchanges, especially sodium and potassium transfer, are related to aerobic metabolism in the living tissue. Therefore, metabolic inhibitors such as cyanides modify these exchanges between cell and surrounding medium by decreasing Na^+ efflux and K^+ influx.

It has been suggested that a shift of ionic exchanges when inhibitors (cyanides or fluorides) are added to the bath could consequently modify some pharmacological effects such as potassium contracture of striated and smooth muscle.

Frog rectus abdominis. We have observed that contraction of the isolated rectus abdominis of the frog produced by potassium chloride is considerably increased by addition of very low doses of potassium cyanide to the Ringer solution in which the muscle is immersed.

The rate of increase of contractions depends on the respective doses of potassium chloride and of the inhibitor. The concentration of cyanide was maintained constant at 2×10^{-4} (3 mM) and potassium chloride concentration varied from 0·5 to 2·5 × 10^{-4} (6·7–33·7 mM). For the lower concentrations of potassium chloride, increased contraction by cyanide may reach 10–20 times the initial contraction height.

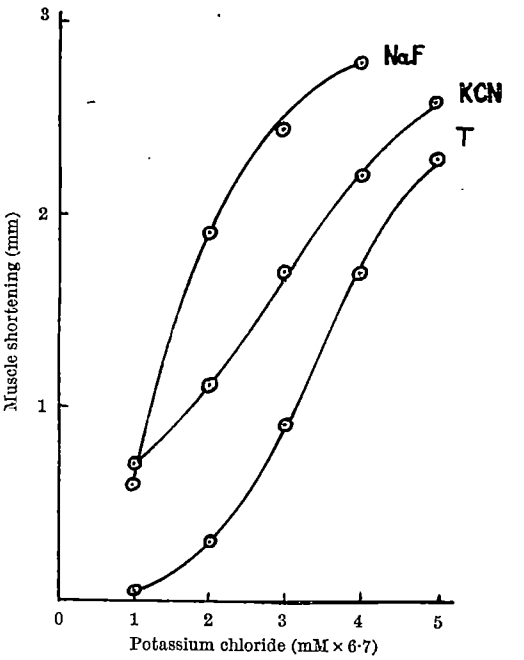

Fig. 1. Effects of sodium fluoride (4 mM) and potassium cyanide on the height of contractions produced by different doses of potassium chloride on frog rectus abdominis

Repeated experiments have shown that the degree of sensitization depends on the incubation period of potassium cyanide in the preparation. No effect has been observed for short periods of contact (15 sec), but sensitization takes place within 30 sec and reaches a maximum value for 60-sec contact. It is abolished after 5-min incubation.

Similar experiments were performed with sodium fluoride. At a concentration of 4 mM, very close to that used for potassium cyanide, sodium fluoride strongly potentiates potassium contraction of frog rectus abdominis; but the maximum potentiation can be obtained

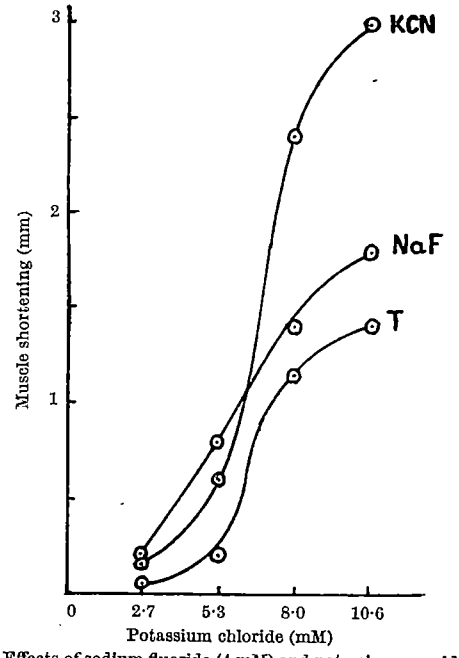

Fig. 2. Effects of sodium fluoride (4 mM) and potassium cyanide on the height of contractions produced by different doses of potassium chloride on guinea-pig ileum

only after an incubation period of 5 min. The potentiation is even stronger than that obtained with potassium cyanide. The contraction height is 3–6 times higher than the control instead of 1·9–3·7 times with cyanide, for potassium chloride concentrations ranging from 1 to 1·5 g per 1,000 (13·5–20 mM).

Fig. 1 curves describe muscle shortening (in millimetres) as a function of potassium chloride concentration in the bath, in normal conditions without any inhibitor, with cyanide and with fluoride.

Guinea-pig ileum. We observed that both enzymatic inhibitors previously used have the same influence on smooth muscle fibre potassium contracture as well as on skeletal muscle fibre.

Our experiments were performed on guinea-pig ileum, which is more sensitive than frog rectus abdominis: we obtained the same shortening with doses of potassium chloride 3–4 times weaker than in the previous experiments. Furthermore, the smooth muscle is more sensitive to the inhibitors, active doses of which did not exceed more than 1 per cent of those used on rectus abdominis. Also, it has been possible to reduce incubation period to 30 sec. So, in 0·03-mM potassium cyanide Tyrode, guinea-pig ileum shortening by potassium chloride is increased three-fold at a salt concentration less than 5·3 mM and two-fold at higher concentrations. At low potassium chloride concentrations the results are even more obvious with sodium fluoride, but at higher concentrations the potentiation is only 1·2–1·3 times.

We tried other enzymatic inhibitors with the same method: 2,4-dinitrophenol, sodium iodoacetate, sodium nitrite. No definite conclusion can be drawn from these later experiments because the results were irregular.

As a whole, the results reported here show that enzymatic inhibitors are able to sensitize smooth and striated muscle fibres to contracture produced by potassium chloride, by influencing either cellular oxidation phenomenon (cyanide) or glycolysis (fluoride).

PHARMACOLOGY

A New Antiviral Agent: 4-Bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone, M and B 7714

STIMULATED by reports of the antiviral activity of some thiosemicarbazones[1], and particularly of the activity against neurovaccinia of isatin β-thiosemicarbazone[2,3], we sought to enhance the activity of these compounds by structural modification. Thus we synthesized *N*-ethylisatin β-thiosemicarbazone independently of, but somewhat later than, Bauer and Sadler[4]. At the same time, we had been making a systematic study of the chemistry and chemotherapeutic properties of derivatives of the new monocyclic ring system, 1,2-thiazole (isothiazole), and we observed that 3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (M and B 7453) also protected mice infected intracerebrally with neurovaccinia. The relatively high toxicity of this compound (acute LD_{50} = 0·7 mg/g orally in mice) led us to examine related thiosemicarbazones, one of which, 4-bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (M and B 7714), is considerably less toxic (acute LD_{50} = 4·3 mg/g orally in mice).

4-Bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone is a yellow crystalline solid, m.p. 228°–230° (decomp.)[5]. It is less than 0·1 per cent w/v soluble in water at 37°, but dissolves as a salt in alkaline solutions.

In mice infected intracerebrally with neurovaccinia (*IHD* strain) and dosed orally once daily for four days, a marked protection was observed (Table 1).

Table 1. THERAPEUTIC ACTIVITY OF M AND B ADMINISTERED ORALLY TO MICE INFECTED INTRACEREBRALLY WITH NEUROVACCINIA

	Daily dose mg/kg (× 4)	Mean survival time (days)	Animals surviving at 10 days
Controls	Nil	4·6	0/30
M and B 7714	500	9·4	22/30
M and B 7714	250	9·0	18/29
M and B 7714	120	8·0	12/29

Table 2. EFFECT OF DELAYED DOSAGE WITH M AND B 7714 ON THE SURVIVAL OF MICE INFECTED INTRACEREBRALLY WITH NEUROVACCINIA

	Dose mg/kg	Delay before treatment (days)	No. of doses given	Median survival times	Animals surviving at 14 days
Controls	Nil	–	–	4·8	0/10
M and B 7714	1,000	0	4	12·7	8/10
M and B 7714	1,000	1	3	13·2	9/10
M and B 7714	1,000	2	2	11·1	7/10
M and B 7714	1,000	3	1	8·4	4/10

Protection was still observed when treatment was delayed (Table 2). Surviving treated animals were immune to challenge from 10^5 LD_{50} infecting doses of virus. During treatment, the circulating virus titre was below that in the infected, untreated, controls. The degree of meningo-encephalitis was less after treatment.

The compound has been tested against variola major in baby mice and found to be active[6].

M and B 7714 also shows high activity in rabbits infected intranasally with rabbit pox (Utrecht strain), but is inactive against influenza, encephalomyocarditis (Columbia *SK*), and rift valley fever viruses.

Details of a fuller laboratory investigation, including toxicological studies, and the results of an extended therapeutic and prophylactic trial will be published in due course.

Distribution of Homovanillic Acid in the Human Brain

HOMOVANILLIC acid (3-methoxy-4-hydroxyphenylacetic acid, HVA) is formed by the action of the enzymes monoamine oxidase and catechol-*O*-methyl-transferase as a final product of dopamine metabolism, and its occurrence in urine has been described[1–6]. From other investigations[7,8] it may be concluded that in experimental conditions the HVA level in the brain tissue reflects the dopamine turnover, although with a certain delay. It also seems likely that for the normal brain tissue a similar statement may be made. The actual HVA concentration in the normal brain tissue, therefore, might be a suitable index in the evaluation of the local dopamine turnover. Sharman[9] has recently demonstrated the presence of HVA in the caudate nucleus of animals of several species. This seems consistent with the high dopamine concentration in this brain area[10]. Detailed investigations have been performed on the local distribution of dopamine in the human brain[11–15]. This account describes the occurrence and local distribution of HVA in the human brain.

Human brains were selected in the autopsy room, from patients not having suffered from cerebral or mental

disease, 3–18 h after death. The brains were dissected immediately and the selected tissues were frozen and kept at −20° C until the extraction procedure took place, usually within two days. The HVA was extracted by Sharman's method[9] and the final extracts were subjected to a two-dimensional ascending paper chromatography on Whatman No. 1 paper in the following systems: isopropanol : water : concentrated ammonia solution in the proportions 40 : 9 : 1, and benzene : propionic acid : water in the proportions 100 : 70 : 4. Spots were detected by spraying the air-dried papers with freshly prepared alkaline solutions of diazotized sulphanilic acid or of diazotized *p*-nitroaniline[10]. The HVA was identified by its R_F-values and colour reactions, compared with reference spots of synthetic HVA. For the quantitative evaluation the sulphanilic acid spray only was used. The stained areas corresponding to HVA were cut out, put into test tubes, and eluted with 4 ml. of a mixture described by von Studnitz[17]. The optical density of the eluates was assayed at 500 mμ in a Beckman *DU* spectrophotometer. Standard curves were prepared from 2 to 16 μg of synthetic HVA, including the chromatographic procedure, and appropriate paper blanks were subtracted. Sufficient amounts of tissue were extracted to achieve distinct spots of HVA on the chromatogram. However, in some brain areas the tissue level of HVA was low and no colorimetric assay could be performed: in these areas the HVA concentration was estimated to be < 1·0 μg/g.

Table 1. Homovanillic Acid in Human Brain

Region	No. estimations	Homovanillic acid (μg/g tissue) Range	Mean
Caudate nucleus	3	1·3–2·4	1·8
Putamen	4	2·8–5·3	4·0
Globus pallidus	5	1·6–3·4	2·4
Substantia nigra	3	1·7–2·0	1·8
Hypothalamus	3	< 1·0	—
Thalamus	4	< 1·0	—
Nucleus amygdalae	1	< 1·0	—
Nucleus ruber	1	< 1·0	—
Floor of IVth ventricle (Formatio reticularis)	2	< 1·0	—
Cortex (Gyrus praecentralis)	2	< 1·0	—
White matter	2	< 1·0	—
Nucleus dentatus cerebelli	2	< 1·0	—

The results are summarized in Table 1. They show clearly that concentrations of HVA exceeding 1·0 μg/g were found in several regions of the human brain: the caudate nucleus (1·8 μg/g), the putamen (4·0 μg/g), the globus pallidus (2·4 μg/g) and the substantia nigra (1·8 μg/g). It is worth noting that all these areas belong to the extrapyramidal system. In the other areas investigated, namely, the thalamus, hypothalamus, nucleus ruber, nucleus amygdalae, floor of the IVth ventricle with the reticular formation, cortex (gyrus praecentralis), white matter and the dentate nucleus of the cerebellum, the HVA concentration was too low for accurate colorimetric assay and was considered to be < 1·0 μg/g.

It may be stated that in all brain areas where the HVA concentration is less than 1·0 μg/g the dopamine level is also low. Within the corpus striatum, on the other hand, the high HVA concentration (1·8 μg/g in the caudate nucleus and 4·0 μg/g in the putamen) seems to be related to the high dopamine concentration in this region. The concentration of HVA in the substantia nigra (1·8 μg/g) also seems to be consistent with a distinct dopamine accumulation in this area[15]. In contrast, no similar relation can be established for the globus pallidus, where a high HVA concentration (2·4 μg/g) was found, but where the dopamine concentration is low. This high concentration of HVA in the globus pallidus should not be disregarded, as it seems to indicate a high dopamine turnover in a place where little dopamine accumulation occurs. The significance of a high dopamine turnover in the globus pallidus cannot yet be explained, but it might be related to the fact that the major afferent fibres of the globus pallidus stem from the dopamine-rich corpus striatum.

I thank Prof. L. Haslhofer for permission to work on the autopsy material, and Mrs. Eva Kótai for assistance.

Semi-automatic Extraction using a Rotary Extractor

A simple rotary extraction procedure has been developed for the extraction of urine with chloroform. It has been found to be efficient for the extraction of unconjugated aldosterone from urine. It virtually obviates emulsion formation and has been adopted for routine use in this laboratory; it appears to be suitable for wide application in liquid–liquid extraction systems.

Two parallel, horizontal, rubber-padded metal rods are rotated by a motor through a reduction gear. A glass bottle containing urine and chloroform is laid on the rods, and partition of solute between the two liquid layers occurs as the bottle rotates on the rods (Fig. 1). In these experiments the glass bottles were of approximately 5·5 in. diameter, the rollers were 4 in. apart, and the bottles revolved 32 times per min; 10-min rotation periods were used for each extraction. At this speed the chloroform layer remains below the aqueous layer during the period of rotation and the weight of the liquid maintains the bottle in position on the rods without external support. Several bottles can be used simultaneously. The recovery of added labelled aldosterone was measured in 23 urine specimens from patients with a variety of diseases—precisely those circumstances in which the frequent occurrence of emulsions had previously occurred using separating funnels for extraction. When the daily urine volume was two or more litres, 1 l. was taken for extraction; otherwise the urine was diluted to 2 l. with water and 1 l. was used. After adjustment of the *p*H to 6·5, the urine was extracted five times with 250 c.c. re-distilled chloroform (containing 1 per cent ethanol, v/v, as stabilizer) to remove free aldosterone. The chloroform layer was withdrawn from the bottle by aspiration each time and discarded. The aqueous phase was then adjusted to *p*H 1·0 with hydrochloric acid, radiochemically pure 1,2-^{3}H aldosterone (0·1–0·2 μC) was added, and the mixture was allowed to stand at room temperature for 24 h with occasional shaking; this procedure is known to release free aldosterone from its acid-hydrolysable conjugate. After 24 h the urine was re-extracted with chloroform and the total volume of 1·25 l. chloroform was washed with small volumes of dilute sodium carbonate and water, taken to dryness and made

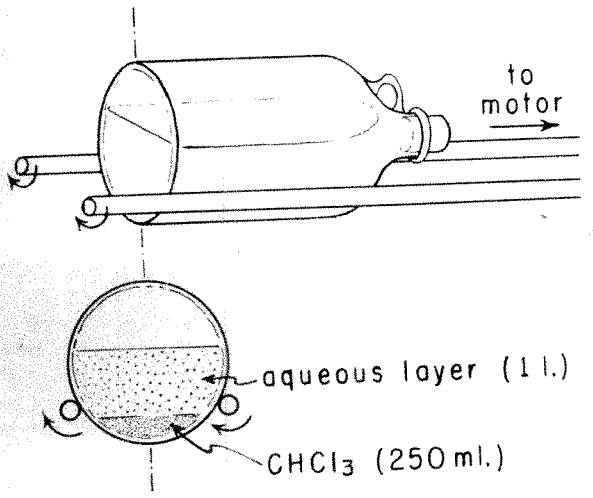

Fig. 1. Semi-automatic rotary extractor

up in methanol. A 5 per cent aliquot was taken for liquid scintillation counting. It was dried in a counting vial and 10 ml. of scintillation solution added. Each litre of scintillation fluid contained 4 g of 2,5-diphenyloxazole (PPO), 100 mg 1,4-*bis*-2-(4-methyl-5-phenyloxazolyl)-benzene (dimethyl-POPOP), 20 ml. absolute ethanol and 980 ml. of spectroquality reagent toluene (Matheson, Coleman and Bell). All values were corrected for quenching using the internal standard technique. The counting error was 1 per cent for most samples and less than 3 per cent in every case. The mean recovery of labelled aldosterone following acid hydrolysis was found to be 100 per cent with a standard deviation of ± 12 per cent.

In a few instances a very small amount of emulsion was formed, but disappeared during the washing procedure; centrifugation was not necessary. It should be emphasized that these urine samples were very 'dirty' and in several cases were from patients with serious disease, or during menstruation or significant proteinuria. Investigation of such variables as rotation-rate, volume of solvent, and duration of the extraction period is required to define the optimum conditions for extraction of aldosterone, but preliminary experience emphasizes the usefulness of this procedure, and justifies its consideration for other problems involving extraction of material contained in liquid phases.

This investigation was supported by Public Health Service research grant *AM*–06607 and training grant 2*A*–5230, National Institute of Arthritis and Metabolic Diseases, and by the Oregon Heart Association. The gift of ^{3}H-aldosterone from the Endocrinology Study Section, U.S. Public Health Service, is gratefully acknowledged. We thank Dr. W. R. Todd for advice.

HÆMATOLOGY

Hæmatopoietic Stem Cells

Normal hæmatopoiesis is initiated and maintained by hæmatopoietic stem cells. These cells perform two functions: (1) they differentiate into mature hæmic elements, and (2) they maintain and renew the population of stem cells. It is these stem cells which seed, differentiate and reproduce, thus effecting successful hæmatopoietic transplants.

Over a long period, many theories have been proposed concerning the role of the stem cell in maintaining normal hæmatopoiesis. Some of these theories have incorporated imaginative mathematical models which have been solved by sophisticated electronic computers[1], and other theories have resulted from detailed histological examination of embryonic tissues[2]. So far, with the limited techniques available for examination of stem cell kinetics, it has not been possible to accept or reject any of these proposed theories.

In 1962 we introduced a sensitive bioassay for the transplantation potential of marrow, providing a means for quantitating either the renewal capacity or the differentiating capacity of hæmatopoietic repopulating cells[3–5]. This bioassay was based on the observation made by Till and McCulloch[6], that transplanted murine hæmatopoietic tissue seeds and grows as distinct colonies in the spleens of host mice. Recently, these investigators have shown that each colony develops from a single cell[7]. Using this bioassay, we have made significant observations on hæmatopoietic repopulating cells and can show they undergo renewal and differentiation, thus indicating they are stem cells.

The technique for producing these colonies has been described in detail[3–5]. Small numbers of hæmatopoietic cells are transplanted into heavily irradiated isologous hosts. On the 9th or 10th day the spleen is removed and fixed and the colonies studied. We find that a rather constant proportion of the injected colony-forming cells seed in the spleen and proliferate rapidly with a doubling time of 10–14 h. The number of colonies formed is a function of the dose of the inoculum and the size of the colony is related to the time post-inoculation. It is our experience that colonies do not increase in number from day 5 to day 11 but merely increase in size. By the 9th day they are easily visible to the naked eye, being approximately 1–2 mm in diameter.

Renewal of repopulating units was studied using a modification of this model. At post-injection times varying from 1 day to 11 days, spleens were taken from irradiated mice which had been transfused with 45,000 isologous marrow cells. These spleens were minced and reinjected into lethally irradiated hosts. Since a rather constant proportion of repopulating cells seed in the spleen, this technique allowed us to examine the multiplication or renewal of repopulating cells within the spleens of mice which had received 45,000 marrow cells. Nine days after the injection of this donor spleen, the spleen of the second recipient was removed and the colonies counted. The mean number of colonies formed on each spleen in a second host is shown in Table 1.

It is noted that there is no increase in the number of colony-forming cells from day 1 to day 4. This is particularly significant when it is remembered that on day 4 each colony contains 200–400 immature, rapidly proliferating cells. From their appearance, we had anticipated that these cells would function as stem cells, that is, they would

Table 1. Colony-producing Potential of Spleens from Lethally Irradiated Mice following Infusion of 45,000 Isologous Marrow Cells

Day injected*	1	2	3	4	5	6	7	8	9	10	11
Mean colonies formed†	0·8	1·6		0·4	4	16	12·2	47·2	> 50‡		> 100§

* Day on which the donor spleen was minced and injected into the tally host.

† Mean number of colonies formed on five tally spleens nine days after injection of minced donor spleen.

‡ One-half of each donor spleen was injected into one tally host, and on each of the 10 tally hosts the colonies were 'too numerous to count'. As fewer than 25 colonies per spleen can always be counted, we have considered that each tally spleen contained more than 25 colonies, thus the total colonies formed from each donor spleen were scored as greater than 50.

§ One-fourth of each donor spleen was injected into one tally host, and as each of the twenty tally spleens contained colonies 'too numerous to count' we have considered the total colonies formed from each donor spleen to be greater than 100.

be capable of initiating hæmatopoiesis and would develop in host's spleens as colonies of mature hæmic elements. It is evident that they did not do so. These studies indicate that these cells which appear immature and undifferentiated using available techniques of light microscopy do not reverse their directed differentiation and do not function as stem cells effecting colony production. On day 5, there was a sharp rise in the ability of the minced spleen to form colonies and by day 11 the resulting colonies were too numerous to count, even though only one-quarter of each colony bearing spleen had been injected into the tally hosts. Thus it is apparent that, following transplantation, repopulating cells first are directed to produce differentiated hæmic elements, and later begin to replenish their own population. These data confirm observations on stem cell renewal previously reported from our laboratory[6].

The differentiation capacity of these transplanted repopulating cells was studied. Four-μ sections were cut from 260 hæmatopoietic colonies on the 9th day post-injection, mounted serially and examined. 42 per cent of these colonies contained only recognizable developing erythrocytes, 21 per cent contained only granulocytes, 21 per cent contained only megakaryocytes, and 16 per cent contained mixtures of these cell types. Some of these mixed colonies appeared to represent two colonies of pure cell type which had grown in adjacent areas and overlapped. Thus, the colony forming cells that successfully seed in the spleen of irradiated hosts grow predominantly along one of three cell lines.

The foregoing results suggest that either repopulating cells may be unipotential in their capacity for differentiation, or they may be pluripotential but are directed at the time of seeding to differentiate along one cell line. In order to obtain information bearing on these possibilities, the following investigations were carried out: Ten-day-old colonies were excised and divided into two parts. The first half was fixed in formalin and sectioned serially in order to identify the cellular composition of the colony. The second half was minced and injected into an irradiated host. Nine days later, this host's spleen was removed, fixed and sectioned, and the cellular composition of the colonies studied. The results are shown in Table 2.

Table 2. Cellular Composition of Colonies resulting from the Injection of 1/2 of a 10-day-old Colony of Erythroid Precursors

Colony No.	Ery-throid precursors	Granu-locytes	Megakary-ocytes	RBC Mega.	WBC Mega.	RBC WBC	RBC WBC Mega.	Total
1		1	1		1			3
2		2	1		1	1		5
3								0
4	2		1					3
5								0
6	1	3	4	1	3		1	13
7			2	1	2			5
8								0
9	8							8
Total	11	6	9	2	7	1	1	37

It will be noted that the cellular composition of colonies formed from the injection of half a colony containing only developing erythrocytes is similar to the cellular composition of colonies formed from the injection of normal hæmatopoietic tissue. Thus, the daughter repopulating cells resulting from the renewal of repopulating cells in a 10-day colony of erythroid precursors possess the capacity to produce colonies of granulocytes and megakaryocytes as well as erythrocytes.

The foregoing experiments indicate that the class of cells called by us 'repopulating units' or 'repopulating cells' differentiate as well as undergo renewal of their own kind. Thus they satisfy the definition of stem cells. The term 'stem cell' refers to the functional capabilities of a cell and not to its morphological characteristics. As the repopulating cells of mice possess the functions attributed to stem cells, they must be considered as such.

In conclusion, evidence has been presented that: (1) hæmatopoietic colonies which develop in the spleens of irradiated mice injected with isologous hæmatopoietic tissue are formed from cells which satisfy the definition of stem cells; (2) following transplantation and seeding, these cells first begin to differentiate into mature hæmic elements; (3) following this directed differentiation into mature hæmic elements, these cells begin to renew or increase their own numbers, thus increasing the number of cells capable of initiating hæmatopoiesis; (4) up to the ninth post-irradiation day, more than 80 per cent of these stem cells differentiate along one cell line; (5) stem cells from colonies in which the only recognizable cells are red cell precursors differentiate in a manner similar to stem cells found in normal hæmatopoietic tissue.

From these results, it also seems that hæmatopoietic stem cells are pluripotential and are directed at the time of seeding to differentiate along one cell line and that daughter stem cells produced in parallel with differentiated hæmic cells retain their pluripotential capacity for differentiation.

Erythrocytes and the Liquefying of Clotted Amphibian Blood *in vitro*

Samples of the whole blood of two amphibians (*Bufo marinus* and *Hyla caerulea*) which we have examined, after clotting *in vitro*, either naturally or by recalcification or on the addition of bovine thrombin, regularly become liquid again within a few hours. Investigation of this phenomenon, with human fibrinolysis in mind as a model, has revealed some interesting contrasts.

The clots of these amphibian bloods are jelly-like and have not the fibrous quality of mammalian fibrin. The blood contains an easily demonstrable prothrombin–thrombin conversion mechanism[1,2]. Ninhydrin-positive material, which is dialysable and is soluble in 7 per cent trichloroacetic acid (TCA), and which migrates towards the anode in acetate buffer at *p*H 4·15, is formed during clotting. Thus the thrombin–fibrinogen reaction appears to be fundamentally similar to that of a number of mammals[3].

We have been unable to show, by tyrosine assay, any further increase in TCA-soluble fragments in sera in which liquefaction of the amphibian clot has taken place, nor has electrophoresis revealed any characteristic products. This is in contrast to the human fibrinolytic system where some of the digested fibrin is eventually rendered TCA-soluble[4]. No acceleration of this amphibian clot liquefaction phenomenon by streptokinase has been demonstrable. It seems that a proteolytic plasmin-type of fibrinolysis is not involved.

The liquefaction does not occur in plasma gently centrifuged free of red cells; it returns when they are replaced in control preparations to at least one-third of their normal numbers in the whole blood. A curious finding has been that clots show little or no tendency to liquefy when prepared from whole blood which has been centrifuged briskly at speeds or for periods greater than the bare sedimentation of cells requires, and then merely resuspended. It is as though physical distortion or pressing of the cells in the centrifuge tube inhibits or counters their activity in the liquefaction of the clot. Adding tissue extracts or disrupted red cells to whole blood before clotting does not inhibit the subsequent liquefaction. Saturation of a blood sample with oxygen, or the addition of ascorbic acid or glutathione, does not alter the part played by red cells in the phenomenon. Red cell suspensions, concentrates, or extracts, placed on cell-free clotted toad plasma plates, do not affect them. It seems that natural incorporation of the cells in a clot is necessary for it to dissolve. White cells alone, both conventional phagocytes and 'thrombocytes', are not limiting factors in the process. These findings indicate that erythrocytes are involved in the resolution of blood clots in amphibians.

HISTOCHEMISTRY

Various Cell Types of the Adrenal Medulla

COUPLAND *et al.*[1] have reported that noradrenaline was synthesized in the so-called 'dark' cells, and adrenaline in the 'light' ones of the adrenal medulla. According to Coupland the 'light' or 'dark' character of these cell types depends on specific histochemical and electron-histochemical properties induced by glutaraldehyde and osmic acid treatment, enabling adrenaline- and noradrenaline-containing cells to be distinguished. Coupland's theory is supported by several other authors[2–5]; however, there are some observations, especially those of Yates, Wassermann and ourselves[6–9], which contradict it. These authors identified, by histochemical and electron-microscopical methods, cell-types containing noradrenaline (with granules of 1500–3000 Å) and adrenaline (with granules of 500–1000 Å) in the adrenal medulla of the golden hamster, and in the grass snake (*Natrix natrix*).

The purpose of this communication is to contribute, on the basis of Coupland's and our own observations, some new experimental results for the identification of adrenaline- and noradrenaline-containing cells.

Coupland[1] states that—after fixation with glutaraldehyde—the noradrenaline-containing 'dark' cells reduce osmic acid more intensively than the adrenaline-containing 'light' cells. Fig. 1 shows the reduction curve of adrenaline and noradrenaline to osmic acid obtained in *in vitro* experiments. It will be clearly seen that in *p*H 7·5 veronal buffer, adrenaline reduces osmic acid more intensively and rapidly than does noradrenaline. Even after 1 h, the extinction of osmic acid reduced by adrenaline was higher than that of osmic acid reduced by noradrenaline. It may be assumed that this is also true for the process in the tissues.

According to Coupland[1], after prefixation with formol or other chemicals, the dark cells cannot be observed. However, Fig. 2 shows that we succeeded in demonstrating the 'dark' and 'light' cells of the adrenal medulla of the rat, after prefixation with formol for 48 h. There is no essential difference between the granules of the two cell types. Otherwise the 'dark' and 'light' cell types were found in all animals examined by us—so far, the frog, grass snake, domestic fowl, rat, dog, hare, etc.

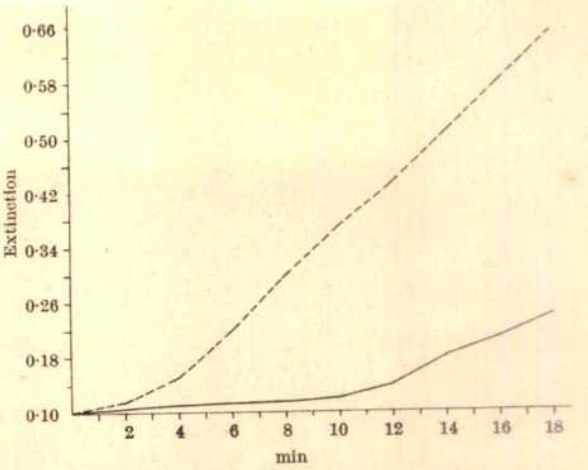

Fig. 1. Reduction curve of adrenaline (– – –) and noradrenaline (——) to osmic acid *in vitro*. In 1 ml. 1 per cent Palade's solution contained 100–100 μg adrenaline or noradrenaline

Fig. 3 shows the adrenal medulla of the domestic fowl, which is well known for its high noradrenaline level. Yet it contains 'dark' cells only here and there. The wide variety of size of some of the catecholamine granules within one and the same cell is striking. Wassermann[7]

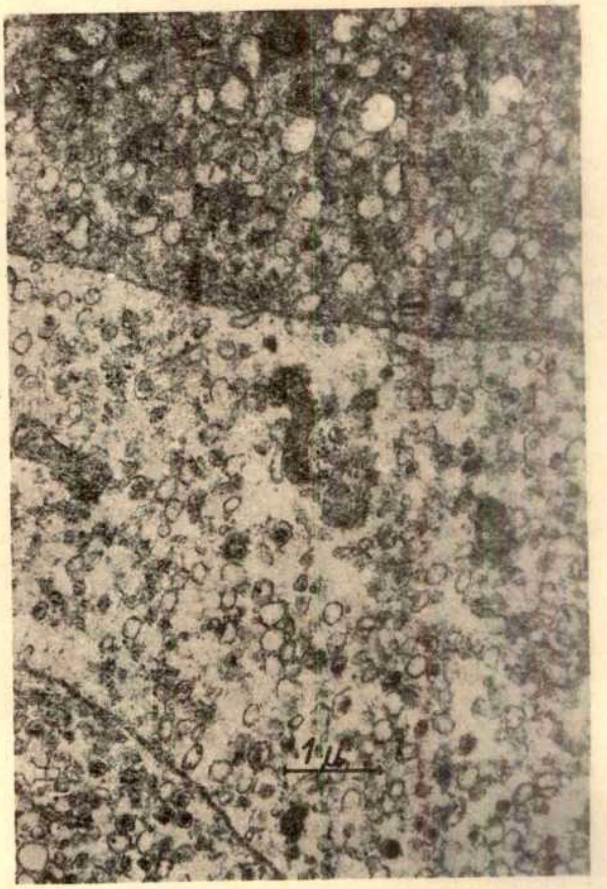

Fig. 2. 'Dark' and 'light' cells of the adrenal medulla of the rat, after prefixing with formol for 48 h (× *c.* 12,500)

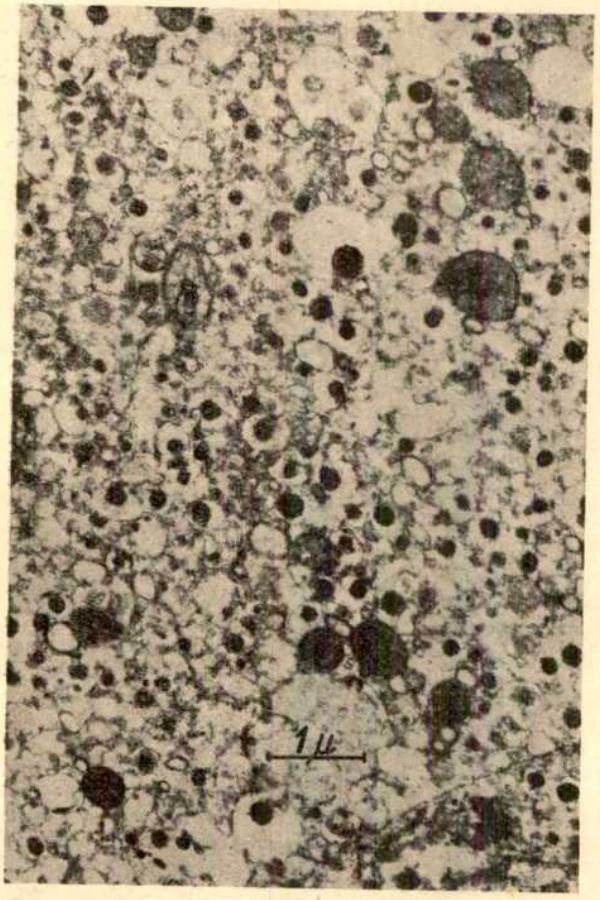

Fig. 3. 'Light' cells of the adrenal medulla of the domestic fowl. The wide variety of size of some of the catecholamine granules within one and the same cell is striking (×*c.* 12,500)

states this is characteristic of noradrenaline-containing cells.

After centrifugation of a homogenate of dog adrenal medulla at 3,000*g* the sediment was found to contain 80 per cent noradrenaline. But the fraction sedimented at 24,000*g* contained 64 per cent adrenaline. In the electron-microscopic photographs of the first fraction the catecholamine granules 2–3000 Å in size were dominant; but in the second fraction the presence of granules of 1000 Å was typical[10].

In the adrenal medulla of the grass snake we succeeded in demonstrating histochemically and electron-microscopically the presence of medullary cells containing these two types of granules[8].

On the basis of observations by Yates[6] and Wassermann[7], and all the facts described here, we are inclined to think that the 'dark' and 'light' cells which are present in the adrenal medulla of all animals (even in the rabbit, in which the noradrenaline content is very low) represent different functional and developmental stages. According to our investigations the 'dark' character of these cells is not a specific biochemical property caused only by glutaraldehyde pretreatment, for it was observed in numerous cases (dog, mouse, frog, etc.) even after prefixing with formol[9].

Our *in vitro* observation of the ability of adrenaline and noradrenaline to reduce osmic acid is at variance with the results of Coupland, and proves that the reducing capacity of adrenaline is stronger than that of noradrenaline.

Coupland's theory could not be proved even in the case of the domestic fowl, because in its adrenal medulla the 'light' cells predominate, although the adrenaline content is only 50 per cent of the noradrenaline content.

Fractionation of the granules with the ultracentrifuge, together with histochemical and electron-microscopical investigations, substantiated that noradrenaline-containing granules (2–3000 Å) and adrenaline-containing cells (1000 Å) could be found in the adrenal medulla[10].

These granules lie in separate cells (grass snake, frog) or in the same cells (dog, rat). The size of the granules mentioned here could be observed only in the 'light', 'storing' cells, while in the 'dark', 'transitional' cells, depending on the phase of synthesis, no differentiated granules with various sizes could be found.

PATHOLOGY

Toxicity of Whole Tobacco Tar

An experiment was designed to investigate the mortality pattern produced by large doses of tobacco tar in an inbred strain of mice. The object was to find the maximum dose that could evoke a definite carcinogenic response, without causing high mortality. An attempt was also made to investigate the possibility of the development of tolerance to large doses of tobacco tar, by means of varied schedules of administration.

The animals used were 4-weeks-old female inbred albino mice of an *I.C.I.* strain. Solutions of whole tobacco tar in acetone–water (9 : 1), containing the appropriate doses in standard 0·25 ml. quantities, were painted on a standard area of shaved skin on the back. All mice, except a group of untreated controls, received 3 applications per week to a total of 159. The surviving mice were killed 10–12 days after the final application, and tissues which appeared abnormal at autopsy were examined histologically.

The mice were divided into 11 groups of 24, except the untreated control group 11, with 50 mice. Each mouse in groups 1–6 respectively received 5, 10, 20, 40, 80 and 160 mg of whole tobacco tar at each application. In group 7 the initial dose was 20 mg of tar at each application for 2 weeks, increased to 40 mg for the next 2 weeks, then to 80 mg for the remaining weeks. In group 8 the dose was 20 mg at each application for 4 weeks, followed by 40 mg for the next 4 weeks and 80 mg for the remainder. In group 9 the initial dose was 10 mg for 4 weeks, then 33 mg for another 4 weeks, then 80 mg in subsequent weeks. In group 10, the mice received 0·25 ml. of the vehicle alone (acetone–water) at each painting.

The mice in group 6, and to a lesser extent the mice in group 5, showed a high incidence of mortality in the early period of painting (see Table 1). In group 6, in spite of high initial mortality, 8 mice survived until the twelfth month, suggesting the development of some tolerance to the tar. The same effect was observed in group 5. Thus it appears that the toxicity was more closely related to the amount of tar per painting than to the cumulative

Table 1

Group No.	No. mice	Dose at each application (mg)	No. dead after: 1 month	4 months	8 months	12 months	No. tumours at site of painting: Papilloma	Carcinoma
1	24	5	0	0	2	2	1	0
2	24	10	0	4	6	7	0	0
3	24	20	0	0	2	2	0	0
4	24	40	0	0	4	6	0	0
5	24	80	0	1	9	10	1	0
6	24	160	10	12	16	17	0	1
7	24	20–80	0	0	6	8	0	2
8	24	20–80	0	3	7	9	0	0
9	24	10–80	0	0	4	6	0	0
10	24	Acetone-water	0	0	4	8	0	0
11	50	Control	0	1	6	9	0	0

amount of tar received over a longer period. The pattern of mortality in the other groups did not significantly differ from that in the control groups.

Histological examination of the tissues of the mice which died early revealed widespread hæmorrhage in a variety of tissues, the liver, spleen and lymph nodes, with atrophy of the lymphoid elements in the latter. There were benign and malignant tumours of the skin at the site of painting and there was an increase in the invasive character of these tumours as the total dose of tar at each application was increased.

The results therefore show that a dose of whole tobacco tar of up to 40 mg, though capable of inducing neoplastic response at the site of application, has no immediately toxic effect on this strain of mice. Toxic effect could be discerned at a dosage level of 80 mg per application and at 160 mg the mortality reached a level of about 50 per cent within the first months. The animals that survived the early months proved to be reasonably viable during the remainder of the experiment.

I thank the Tobacco Research Council for financial support and for the supply of tobacco tar, and Dr. T. Ghose for help with the histological work.

Absence of Kynurenine in Hair of Patients with Scleroderma

ONE of the diseases in which there may be a defect of tryptophane metabolism is scleroderma. This belief is based on such experimental evidence as the increased excretion of the intermediate metabolites of tryptophane after oral administration of large doses of trytophane[1]. One of these metabolites, kynurenine, has been identified in water extracts of rat hair[2]. It seemed of interest, therefore, to determine whether or not kynurenine could be found in the hair of patients with scleroderma. Kynurenine has not been reported in previous analyses of normal human hair[3,4].

Hair clippings were obtained from five patients with scleroderma of the progressive systemic sclerosis type. Hair clippings were also obtained from three normal subjects. All the specimens were handled identically. The hair was pulverized in a jar mill with stainless steel balls, and the resulting powder was then defatted by refluxing with ether for five hours. The powder was then extracte with distilled water at 50° C overnight, evaporated *in cuo* to concentrate the extract, and then spotted on 'W atman No. 1' chromatograph paper.

De ending chromatograms were run, using commercially obtained kynurenine as well as rat hair extracts as controls. The solvent used consisted of *n*-butanol, methanol, benzene and water in proportions of 2 : 4 : 2 : 2 (ref. 2). Kynurenine was detected by fluorescence under long-wave ultra-violet light, by ultra-violet absorption spectra after elution from the paper, and by spectrophotofluorometry after elution.

No kynurenine could be detected in normal human hair or in the hair from patients with scleroderma, although it was found that amounts as low as 0·05 γ of pure kynurenine could be detected on chromatograms by visible fluorescence.

It appears, therefore, that patients with scleroderma, in spite of an apparent metabolic defect which may result in the presence of increased amounts of kynurenine in the urine, do not deposit this amino-acid in the hair.

Cell Differentiation and the Primary Lesion in Mouse Mammary Carcinogenesis

IN high cancer strains of mice carrying the milk agent[1], the formation of hyperplastic alveolar nodules, the preneoplastic nature of which was demonstrated by De Ome *et al.*[2], is at present considered as the earliest sign of carcinogenesis. These nodules appear in adult mice, usually after one or several pregnancies, and therefore much later than the initial malignant transformation of the original mammary cell. Experimental data gathered from tissue culture tests now appear to locate this initial lesion in some of the alveolar cells which differentiate from the elementary duct system of the virgin mouse.

When mouse mammary fragments are explanted as organ cultures on a nutritive medium, the morphology and to some extent the functional activity of the glandular tissues can be maintained only in the presence of very specific hormones[3,4]. These hormones normally control mammary differentiation in the animal and their combination varies according to the stage of pregnancy[5]. In early pregnancy, the prevailing hormones are ovarian (œstradiol; progesterone) and hypophyseal (growth hormone; prolactin). In late pregnancy and lactation, prolactin and adreno-cortical hormones are principally involved. Whereas the first combination induces lobulo-alveolar differentiation and active cell replication, the second mostly stimulates the secretory function[6,7].

When attempts are made *in vitro* to reverse the physiology of the mammary cell, for example, by placing lactating explants in the presence of hormones which stimulate growth, extensive necrosis of the glandular tissues occurs. If, however, explants of early pregnancy are exposed to adrenal hormones and prolactin, cell multiplication stops and vesicular structures are formed[8]. In other words, the death of the mammary tissues which results from attempts to return the cells to an earlier stage of differentiation does not necessarily occur when the differentiation process is accelerated rather than reversed. These findings suggest a physiological irreversibility in the gradual differentiation of the mammary cell towards maturity and functional activity.

Evidence for this hypothesis of irreversibility was recently obtained from monolayer cultures of normal mouse mammary epithelium. As opposed to the organotypic cultures mentioned in the preceding paragraphs, where fragments of organs explanted *in vitro* as a whole grew in an organized fashion, the monolayer cultures were derived from a total enzymatic dissociation of the pooled glands from one mouse. The glands were minced in a solution of collagenase (1 mg/ml. of balanced salt solution) and dissociated at 37° C in about 45 min with moderate agitation. A mild centrifugation then eliminated most of

the adipose tissue, which remained with the supernatant. The epithelial and stromal cells collected in the pellet were re-suspended in the culture medium (Eagle's basal medium, 10 per cent calf serum and 0·5 per cent lact-albumin hydrolysate). A final suspension of 15–20 × 10^4 cells per ml. was then distributed in 10 ml. aliquots into *T*60 flasks. The free cells grew at random on the glass surface with seldom any evidence of tissue organization. Small, isolated colonies began to form after 24 h.

The results of 45 attempts to grow the mammary tissues from 3 agent-free strains of mice (*C57BL*, *ZBC*, *Ax*) and one high-cancer strain, *R*111, are summarized in Table 1.

Table 1. Comparative Cultivation Time of Mouse Mammary Tissues in Monolayer Cultures

Physiological stage	Agent-positive *R*111		*C*57		Agent-free *ZBC*		*Ax*	
	Weeks	No. exp.	Weeks	No. exp.	Weeks	No. exp.	Weeks	No. exp.
Virgin	—	—	10	3	4–5	2	10	3
Early pregnancy*	3	1	4–5	8	4–6	3	—	—
Late pregnancy	2	2	2–3	2	2–3	11	—	—
Lactation	1	1	1	1	1	6	—	—
Resting	—	—	—	—	5	2	—	—

* In early pregnancy the cultures underwent 2–4 transfers in a 1 : 2 ratio. Up to 6 transfers could be made with mammary tissues from virgin *C*57 and *Ax* mice.

It can be seen that when taken in lactation or at the end of pregnancy the mammary cells are extremely labile and cannot be maintained for periods longer than one week if lactating, or a maximum of two weeks if prelactating. They do not multiply, but necrose and autolyse. At these stages, the bulk of the explanted cells come from the alveolar epithelium; other cell types, although present, can scarcely be found in the cultures.

For cells from early pregnancy the maintenance period is extended to 4 or 5 weeks. Most of the epithelial cells are still of alveolar origin, but fibroblasts, hystiocytes and lymphoid cells account for roughly one-fourth of the total volume. All cells replicate actively and transfers are necessary. After the fourth transfer, however, the mitotic activity subsides; foci of necrosis appear and the same autolytic phenomena as observed in the former series occur. These observations are comparable in all the strains of mice observed.

The longest sub-cultivation (10 weeks) was obtained in the mammary cells from 3 month-old virgin mice. The cultures then present a mixed population of epithelial cells and fibroblasts, all replicating actively. The stroma cells are the most numerous, but the epithelium, easily detected as circular patches of cells, is carried throughout the successive passages.

These results, consistently reproducible, show that the mammary cell gradually loses its replicating properties while progressing towards functional activity and complete differentiation. Even though the culture medium used in the foregoing experiments is poor in specific hormones, it is unlikely that early autolysis of the most differentiated cells expresses a state of hormone dependency. In two instances, one with mammary tissues from early pregnancy, the other from late, adding the proper hormones to the medium did not increase the length of the cultivation period but rather shortened it by at least two days. Recently data have been compiled by Hayflick[9] to indicate that somatic cell strains in general have a limited life *in vitro*, unless they undergo substantial alteration. For human diploid strains from a variety of tissue sources the doubling potential *in vitro* appears to be finite, and to centre around 50. It might be expected that tissues like the mammary epithelium, which normally undergo a cyclic differentiation from stem cells, would exhibit a greatly shortened life-span and reduced doubling potential proportionate to the length of their cycle. This expectation appears to be borne out by the mouse mammary epithelium in our cultures, the *in vitro* life-span of which is even related to its position in the cycle at time of explantation.

It is now possible to interpret the results from earlier experiments with organ cultures: it has been observed that when mammary fragments from agent-positive *R*111 mice early in their first pregnancy are stimulated *in vitro* by ovarian and hypophyseal hormones, foci of alveolar hyperplasia eventually develop. Such foci have been found to maintain some mitotic activity even when exposed to the antagonistic action of adrenal hormones and have therefore acquired hormone independency[8]. They are also a site of viral particle (*B* type) production as evidenced by electron microscopy[10]. Alveolar hyperplasia and presence of particles are the basic characteristics of the preneoplastic lesion of De Ome. However, whereas the nodules are observed *in vivo* only in 4–5-month-old mice, the tissue culture technique shows that they really are initiated as early as the first pregnancy.

The only cells which in this first pregnancy can originate foci of hyperplasia are those which have acquired the MTA during the suckling period. Under the initial stimulation of the specific hormones they enter a phase of active replication most favourable to virus production. The agent-free cells normally proceed in their differentiation to functional activity; however, even though such cells can later become infected and be a site of virus multiplication, they will not originate a new centre of hyperplasia because they already have differentiated beyond their capacity to replicate. In conclusion, it is only in the early beginnings of pregnancy that the actively dividing mammary cells can be modified by the MTA and build up the preneoplastic lesion.

ANATOMY

A Hadal Fish (*Bassogigas profundissimus*) with a Functional Swimbladder

During the Danish Galathea Expedition (1950–52) a specimen of the brotulid fish, *Bassogigas profundissimus* (Roule, 1913), was caught in the Sunda trench (Station No. 466, depth 7,160 m); it measured 157 mm in standard length. The gear used was a herring otter trawl, which was operated at the bottom for a period of 2 h. The bottom material consisted of bluish mud, and the bottom temperature was 1·5° C. The uphaul of the trawl took 4 h.

Unfortunately, it is not known for certain whether the present specimen was actually caught at the bottom or at a pelagic depth, as the gear could not be opened and closed again at any specific depth. Fifteen genera of fish, known to be pelagic, were also represented in the trawl. On the other hand, reasons have been put forward for considering the specimen benthic[1]. In summary: (1) The bottom material and benthic invertebrates in the trawl showed that the trawl did work at the bottom. (2) The stomach contained specimens of the Isopod genus *Eurycope*, of

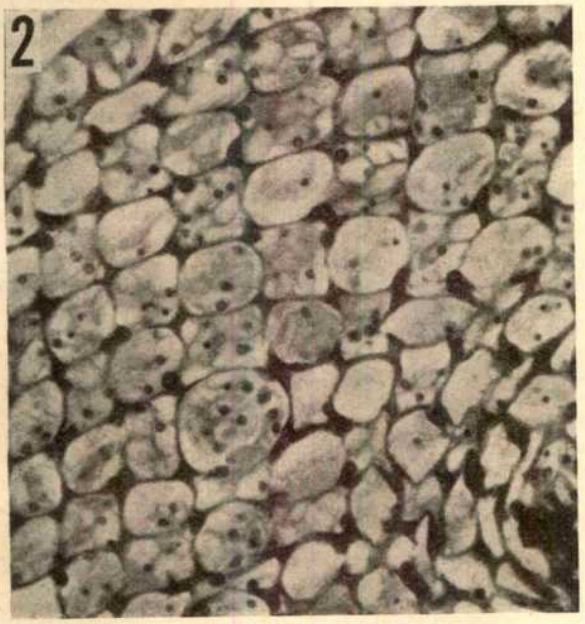

Fig. 1. Section (8μ) through resorbent area in swimbladder wall. *c*, resorbent capillary; *l*, lumen of swimbladder; *t*, tunica externa of swimbladder wall. (Hæmatoxylin and eosin, × *c.* 390)

Fig. 2. Section (8μ) through part of rete mirabile. (Hæmatoxylin and eosin, × *c.* 390)

which almost all species are benthic. (3) The present species is now known in four specimens, three from the Atlantic and one from the Indian Ocean, from stations varying in depth from 5,610 m to 7,160 m. On all four occasions it was proved that the trawl had reached the bottom. The fact that *B. profundissimus* was never caught in the many abysso-pelagic and hado-pelagic hauls also indicates that it lives on the bottom. It should perhaps be mentioned that from the Galathea Expedition alone, about 20 pelagic hauls were made at depths between 5,000 and 7,000 m.

On dissecting this specimen, it was found to contain a closed swimbladder, 15 mm long, and situated in the usual position. (It was not ruptured or forced out into the œsophagus and mouth, which is often the case with other fish.) In the ventral wall of the swimbladder was found the gas gland, the long winding rete mirabile, and the gas gland ganglion. The well-developed gas gland lies in the submucosa (terminology according to Fänge, 1953, ref. 2), in the central part of the ventral wall. It appears to consist of medium-sized cells[3] with intercellular capillaries, but owing to its brittle consistency it was badly damaged during cutting.

The gas gland ganglion is situated in the ventral wall, slightly behind the gas gland. The single unipolar rete is situated in the submucosa of the ventral wall; owing to its winding course, the length of the rete is approximately equal to that of the swimbladder. The capillaries of the rete form a typical chequer-board pattern[4] (Fig. 2). There are approximately 220 capillaries. An area with resorbent capillaries is found in the dorso-caudal part of the swimbladder wall (Fig. 1). There is no histological evidence of regression, and since the swimbladder appears perfectly normal as regards morphology it is, possibly, also functional.

In pelagic deep-sea fishes living below 1,000 m the swimbladder is either missing or regressed, but in at least half of the benthic deep-sea fishes living below a depth of 2,000 m, normal swimbladders with very long retia mirabilia are found[3]. The deepest-living species with a well-developed swimbladder known hitherto is the brotulid *Bassozetus taenia*, which has a known depth range of 4,575–5,610 m. The depth range of *Bassogigas profundissimus* may now be regarded as 5,610–7,160 m (ref. 1). The length of the rete mirabile in *Bassozetus taenia* is 25 mm, while that of the present species is 15 mm; this means that when the number of capillaries is about 220, the total length is 3·3 m.

The major constituent of the gas in the swimbladder of deep-sea fishes is oxygen, which forms 80–90 per cent of the volume[5–7]. At a depth of 5,000 m the density of oxygen is about 7/10ths that of sea-water, while at 7,200 m its density is equal to that of sea-water[3]. Thus, the swimbladder of *B. profundissimus* can scarcely be considered to have any significance as a hydrostatic organ. However, as the oxygen content decreases rapidly at the last few metres near the bottom[8], the swimbladder might function as an oxygen store, as proposed by Jones[9] and Fänge[2].

IMMUNOLOGY

Rabbit Gamma-globulin Allotypes

ALLOTYPIC specificity of rabbit γ-globulins, differentiating individuals of the same species, was first described by Oudin[1]. This kind of specificity is defined by means of reactions between rabbit iso-precipitating sera and the serum of individuals of the same species. The iso-precipitating rabbit sera used for differentiating rabbit γ-globulins were obtained in two ways: (1) by injecting rabbits with immune complexes composed of heterologous antigen (human, equine, sheep and hen erythrocytes) and their corresponding rabbit immune antibodies; (2) by injecting rabbits with suspensions of rabbit globulins obtained by precipitation with aluminium potassium sulphate. In both cases it was necessary to take into account differences in γ-globulin characteristics between the rabbit donor of hetero-agglutinins or globulins and the rabbit donor of iso-precipitins.

By means of iso-precipitating sera obtained in this way, five allotypes of rabbit γ-globulins, designated *a*, *d*, *e*, *f*, *g*, were distinguished. Further investigation showed that these allotypes are hereditary, and that the types *a*, *f* and *g* form an independent genetic system controlled by three autosomal allelomorphic genes.

This conclusion was based on the examination of 1,250 rabbit sera with 15 iso-precipitating sera containing antibodies against the allotypic characteristics *a*, *d*, *e*, *f* and *g*, and statistical analysis of the frequency with which the

genes governing the appearance of these characteristics occurred in the rabbit populations concerned. Their hereditary transmission was also investigated.

The material consisted of sera from four rabbit populations, in which different frequencies of characteristics *a*, *f* and *g* were found, depending on the choice of animals used for breeding. The largest 'mixed' group, consisting of rabbits purchased randomly from different suppliers, was therefore considered to be the most representative. The frequency distribution of characteristics *a*, *f* and *g* within the four populations is shown in Table 1.

Table 1. Frequency of the Allotypic Characteristics *a*, *f* and *g*

Source	No. rabbits	Allotypic characteristics of γ-globulins *a*	*f*	*g*
Mixed	842	0·156	0·985	0·058
Albinos	210	0·094	0·994	—
Path. dept.	68	0·583	0·655	0·148
Own stock	130	0·422	0·883	0·015

As can be seen in Table 1, the albino population, which was composed of rabbits from three different farms, is more homogeneous than the remaining populations, in which the frequency of the characteristics *a*, *f* and *g* varies considerably.

On the basis of the frequencies of characteristics *a*, *f* and *g*, the expected frequency of allotypes in the *afg* system was calculated for the mixed rabbit population, in accordance with the theory of Bernstein. The observed and expected data are compared in Table 2.

Table 2. Frequency of Allotypes of the *afg* System in a Mixed Population of Rabbits compared with Expected Values

Values	Allotypes of the *afg* system *aa*	*af*	*ag*	*ff*	*fg*	*gg*
Expected	0·007	0·144	0·005	0·789	0·052	0·001
Observed	0·0067	0·146	0·0052	0·783	0·056	0·001

Assessed by means of the χ^2 criterion, the difference between the observed and expected frequencies of allotypes of the *afg* system is not statistically significant.

Hereditary transmission of the allotypes of the *afg* system was investigated in 130 young rabbits, offspring of 29 rabbit pairs with known allotypic characteristics. The results demonstrated the hereditary character of the rabbit allotypic γ-globulins and confirmed the existence of an independent *afg* genetic system controlled by three autosomal allelomorphic genes.

Comparison with earlier findings[2] indicates that characteristics *a*, *f* and *g* correspond to characteristics *A*4, *A*5 and *A*6 determined by three allelomorphic genes, described earlier[3].

In Table 3 the frequency of occurrence of rabbit γ-globulin allotypes is summarized, using both the present nomenclature and that proposed by others.

Table 3. Frequencies of Rabbit γ-Globulin Allotypes

Nomenclature according to: Oudin	Dray	Dubiski	Grodecka	Dray, Dubiski, Kelus, Lennox and Oudin
a − 0·97	II − 0·952	*F* − unknown	*f* − 0·985	*A*4
g − 0·10	I − 0·246	*A* − 0·111	*a* − 0·156	*A*5
f − 0·12	—	*C* − 0·087	*g* − 0·058	*A*6

These observations, which show that the differentiation of rabbit serum γ-globulins is genetically conditioned, may serve as the basis of a method for assessing the purity of breeds of experimental animals. Moreover, the results confirm the fact of the differentiation of serum proteins, hitherto only assumed as a possible cause of some cases of post-transfusion shock in human beings.

RADIOBIOLOGY

Relationship between Nuclear Volume and Radiosensitivity of Different Cell Types in Gemmæ of *Marchantia polymorpha* L.

The radiosensitivity of various species of plants has been investigated for many years[1,2]. Much recent work has been concerned with attempts to discover if there is some common cellular feature which might serve as an index of radiosensitivity. In general, the nucleus (or its components) has been considered as the primary object determining radiosensitivity[3–7]. One method of investigation has been to irradiate a number of different species and then to correlate the responses of the irradiated plants with inherent particular nuclear parameters of apical meristem cells of unirradiated control plants. In general, plants with the smaller nuclei have been found to be more resistant to radiation than those plants with the larger nuclei. Indeed, where the species being compared differed in chromosome number, Sparrow *et al.*[8] have shown that the quotient of the nuclear volume divided by the chromosome number (the interphase chromosome volume) is a more accurate index of radiosensitivity than nuclear volume alone. Thus chromosome number is important in determining radiosensitivity where variation in numbers exists.

The gemmæ of *Marchantia polymorpha*, a bryophyte, are convenient well-defined organs with features which make it possible to examine the radiosensitivity of particular cells within the structure. Normally, one of the two apical cells at each end of the gemma produces the new thallus; but in the absence of a functional apex other cells in the gemma are capable of producing new thalli. Thus it is possible to examine the radiosensitivity of the particular cells of this multicellular vegetative structure by noting the position of the vegetative outgrowths produced by the gemmæ.

Gemmæ were collected from stock plants and prepared for aseptic culture according to the procedures previously published[9]. Some of the gemmæ were exposed in plastic containers with a wall thickness of 1 mm to various amounts of cobalt-60 γ-rays and all gemmæ were allowed to grow aseptically for two weeks on inorganic agar medium. The light intensity at the level of the Petri plates was 1,000 ± 250 ft.-candles, the photoperiod was 18 h, and the temperature was 78° ± 2° F. At the end of the first week of growth the original shapes of the gemmæ were still discernible and the gemmalings were scored for apical and/or non-apical survival. At the end of the second week the entire gemmæ were scored as 'survivors' or 'non-survivors' since a non-apical outgrowth is often not discernible until this time. The 0 per cent survival point was determined for the apical and vegetative cells from the exposures at which no survival of each type was observed. Nuclear volumes of 20 apical and 80 non-apical vegetative cells were obtained according to the previously published method[8]. The energies absorbed by the two types of nuclei at the lethal exposure were then calculated and compared (Table 1).

The average nuclear volume of the apical cells was 98·9 ± 4·9 μ^3; the average nuclear volume of the non-apical vegetative cells was 54·7 ± 3·3 μ^3. The 0 per cent survival

Table 1. Summary of Nuclear Volumes for Vegetative Cells of a Gemma and Calculated Amounts of Energy Absorption at the Lethal Exposure

Cell type	Nuclear volume (μ^3)	Lethal exposure (kr.)	Energy absorbed per nucleus at lethal exposure (× 10^6 eV)*
Apical	98·9 ± 4·9	29	164·9 ± 8·2
Non-apical†	54·7 ± 3·3	55	173·0 ± 14·8

* Based on an average value of 32·5 eV per ion pair and 1·77 ionizations per cubic micron of wet tissue per roentgen (Table 2, ref. 11) multiplied by the exposure in r.
† Rhizoid initial cells are excluded since they are not capable of producing a new thallus.

exposure was 29 kr. for the apical cells and 55 kr. for the vegetative cells. It is apparent that those cells with the larger nuclei are more sensitive to radiation[5,8]. In fact, the nuclei of the apical cells, which are about twice the volume of the nuclei of the vegetative cells, are about twice as sensitive as the vegetative cells to the radiation when the exposure is expressed in kr. The calculated energy absorbed at the 0 per cent survival point for each type of cells was $164{\cdot}9 \pm 8{\cdot}2 \times 10^6$ eV for the apical nuclei and $173{\cdot}0 \pm 14{\cdot}8 \times 10^6$ eV for the nuclei of the vegetative cells; there is no statistical difference between these two values. Thus the apparent difference in tolerance disappears when energy absorption in the nuclei at the 0 per cent survival exposure is used as a measure of radiosensitivity; this observation for the radiosensitivity of cells within a plant organ is consistent with previous findings for the comparative radiosensitivity of a number of different higher plants at the lethal exposure[8,10]. The fact that the energies absorbed at the lethal exposure by the apical and vegetative cells are not significantly different from each other is evidence for the idea that it is not the relative number of deleterious events which leads to the same end point but rather the absolute number[8]. The nature of these deleterious events remains to be determined, however. Further work on the radiosensitivity of gemmæ of *Marchantia* is in progress and will be reported in detail elsewhere.

Relationship between Chemical Structure and the Extent of Protection against Ionizing Radiation given by Alcohols to *Salmonella typhimurium LT2*

Burnett *et al.*[1] concluded that methanol, 2-propanol, 1-butanol, 2-methyl-1-propanol, 2-methyl-2-propanol, 1,2,3-propanetriol, 1,2-propanediol and 1,2-ethylenedioxydiol are about as effective as ethanol in affording protection against radiation. The results given here permit more definite conclusions to be made.

The radiation source was electrons from an 8-MeV linear accelerator in most of the experiments; but in some cases a Solus–Schall constant potential X-ray unit operating at 250 kV was used.

Pre-irradiation culture procedures. The bacteria were cultured overnight on a nutrient agar slope (Oxoid medium) at 37° C. A further culture was then made on a slope for approximately 2 h at 37° C prior to collecting, first in 0·1 M phosphate buffer *p*H 7·0, followed by one washing and re-suspension in *tris* buffer *p*H 8·0 (6 g of sodium hydroxide dissolved in 70 ml. of 1 M *tris*-hydroxymethylaminomethane, *p*H adjusted to 8·0 with conc. hydrochloric acid and made up to 1 l.). The density of the suspension was gauged by means of a nephelometer. A suitable aliquot was re-suspended in *tris* buffer to act as control, while another aliquot was re-suspended in *tris* buffer containing the alcohol under test at 0·8 M concentration.

Irradiation. The irradiation of the liquid suspension was carried out under fully oxygenated conditions in vessels permitting the passage of a generous stream of air. (For a description of these vessels, see Howard-Flanders and Alper[2].)

Post-irradiation culture procedures. Following irradiation, suitably dense suspensions were plated out on to nutrient agar (Difco medium) by means of a platinum tipped dropper delivering 0·002 ml. per drop, and cultured overnight at 37° C. The resulting colonies were then counted (three plates each for control and test at each dose level) giving counts of the order of 100 colonies per plate. Irradiation was carried out over six intervals covering the range 0–50 krads.

The alcohols tested were pentane-1,5-diol, butane-1,4-diol, butane-1,3-diol, glycerol, propane-1,2-diol, propane-1,3-diol, erythritol, ethanediol, methanol, ethanol, isopropanol, mannitol and *n*-propanol. In addition to these, primary, secondary and tertiary butanol, isobutanol, amyl and tertiary amyl alcohol, allyl alcohol and propargyl alcohol were investigated, but proved too toxic to be included in the radiation trials.

For control and test, respectively, the logarithm of the survival fraction was plotted against the radiation dose for each alcohol examined. The protection factor was then evaluated from these curves by comparing the radiation dose giving a specific survival fraction in the presence of the alcohol, with the dose giving numerically the same survival fraction in the control. This is essentially the method used by Kelner[3].

In the case of pentane-1,5-diol, erythritol and mannitol, which were tested on the same batch of organism, no control curves were available. The protection factor for these three compounds was obtained by using a control curve derived from the mean of 16 control curves obtained in the other experiments in this series.

Fig. 1 shows the results of plotting the protection factor found for each alcohol against carbon chain-length.

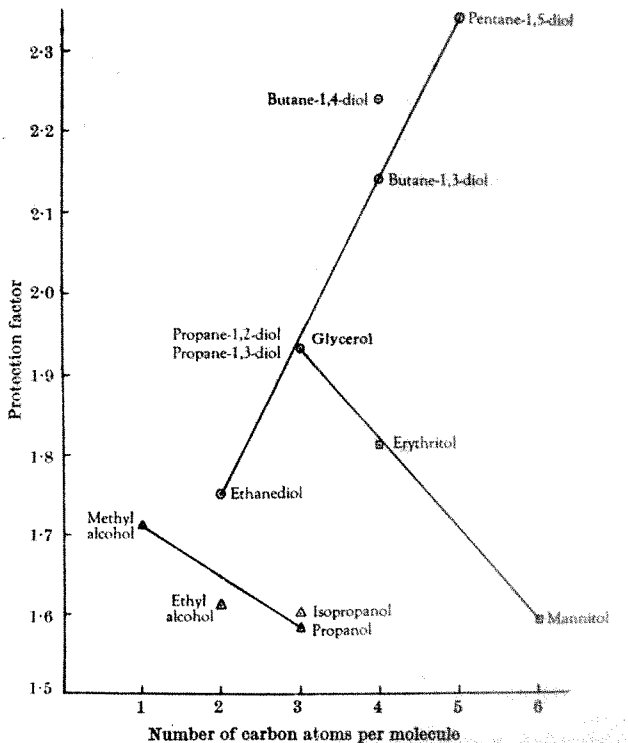

Fig. 1. The protection factor for each compound, plotted against the number of carbon atoms per molecule

The following points emerge from Fig. 1: (1) There is a regular increase of protection with increasing chain-length in the case of the diols. (2) With the polyhydric and monohydric alcohols, the tendency is for a decrease in protection with increasing chain-length. (3) The diols are a better class of protector than either the polyhydric or the monohydric alcohols.

It could be inferred from this that a balance must be struck between the hydrophilic and the lipophilic features of the molecule in order to achieve optimum protection, and that such a balance is achieved in the case of the diols. This in turn may be a reflexion of a favourable partitioning of these compounds between aqueous and lipoid systems in the organism whereby oxygen is excluded or reduced. This would lead to diminished oxygen-dependent radiosensitivity of the organisms.

Ebert and Hornsey[4], investigating the effect of a number of gases on the irradiation of bean root (*Vicia faba*), were able to show a parallel between lipid–water partition coefficients and the effectiveness of these gases in reducing radiosensitivity. In order to explain their observations, they offered the oxygen displacement principle referred to here.

The small range of values for the protection factors in the case of the monohydric alcohols accords with the results obtained by Burnett *et al.*[1].

Recovery from Sub-lethal X-ray Damage of Mammalian Cells during Inhibition of Synthesis of Deoxyribonucleic Acid

The ability of mammalian cells to recover from sub-lethal X-ray damage was first demonstrated by Elkind *et al.*[1], who found that the effect of two doses separated by an interval of time was less than the effect of the same total dose given as a single exposure. This recovery phenomenon has been confirmed *in vitro* and *in vivo* in a wide variety of mammalian cell types[2–5]. These investigations characterized the dependence of radiation sensitivity on the interval between divided doses as having an initial increase to a maximum followed by a minimum and a subsequent new maximum plateau. The nature of the recovery curve between the fractionated doses suggested that the curve may be the result of two opposing reactions and that one reaction at least may be dependent on the metabolic state of the cell. Hence, the recovery curve may be subject to alteration when a major metabolic process is inhibited. We recently reported that the repair processes were operative under conditions in which DNA thymine was partially replaced by 5-bromouracil[5]. Reported here are the results of experiments designed to test whether the recovery phenomenon requires uninterrupted DNA synthesis during the interval between fractionated doses. In these experiments 5-fluorodeoxyuridine (FUDR) was used as an inhibitor of DNA synthesis.

HeLa *S*–3 cells (obtained from Dr. P. I. Marcus, Albert Einstein Medical College, New York) were grown in monolayers on a flat glass surface in French square bottles using Eagle's medium supplemented with 10 per cent calf serum. Four–six-day stock cultures were trypsinized and plated in 60-mm plastic Petri dishes (Falcon Plastics) in 4 ml. of medium containing FUDR (4×10^{-7} M). After about 14 h of incubation, cultures were irradiated for inactivation studies. The dose rate was 170 rads per min (200 kVp., 15 m.amp, half-value layer 0·8 mm copper). All irradiations were performed at room temperature. FUDR was kept in the medium for 22 h and replaced with the medium containing thymidine[6] (4×10^{-5} M). Cell plating efficiencies were generally 0·6–0·7 for control cells (no FUDR) and 0·3–0·4 for cells exposed to FUDR. The extent of incorporation of deoxycytidine-^{3}H into DNA was considered a measure of DNA synthesis. The DNA was isolated for liquid scintillation counting by a modification of the procedure of McIntire and Sproull[7].

Exposure of bacterial and mammalian cells to FUDR inhibits the synthesis of DNA[6,8,9]. This inhibition was tested for HeLa *S*–3 cells under our cell culture conditions in two ways. As shown in Fig. 1, FUDR (4×10^{-7} M) inhibited rapidly and almost completely the utilization of tritiated deoxycytidine for DNA synthesis. Inhibition of DNA synthesis by FUDR was also demonstrated by the autoradiographic studies summarized in Fig. 2. The percentage of cells able to utilize tritiated thymidine (15 min pulse) for DNA synthesis increases with the time interval of exposure to FUDR (Fig. 2). The results shown in Fig. 2 were interpreted in terms of the mitotic cycle of the untreated or control cells. FUDR inhibited DNA synthesis in cells which were in the *S* period and prevented other cells from entering the *S* period. After the periods of *G*–2 plus *M* plus *G*–1, almost all the cells should be ready to enter the *S* period when thymidine is supplied. The time for this maximum labelling was about 14 h (Fig. 2).

In order to test whether or not the repair process requires uninterrupted DNA synthesis, the fraction of clones surviving a 558-rad dose administered in two equal doses was plotted as a function of the interval between doses. The recovery pattern for cells not exposed to

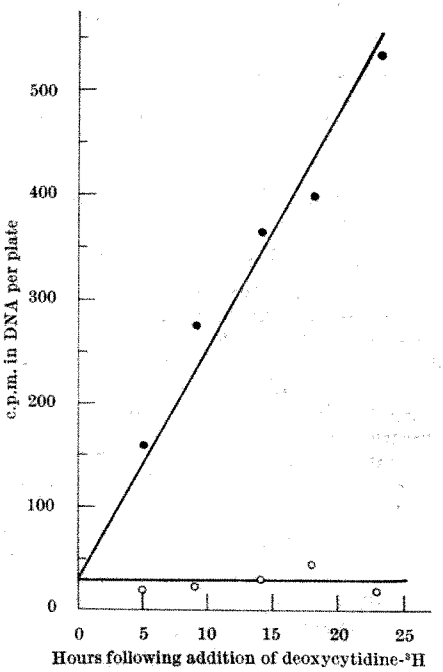

Fig. 1. Incorporation of tritiated deoxycytidine into DNA of HeLa *S*–3 cells. HeLa *S*–3 cells (approximately 5×10^5) were incubated in media containing and lacking FUDR (4×10^{-7} M) and supplemented with tritiated deoxycytidine (0·05 μc./ml.). After various intervals the DNA was isolated from the cells and its radioactivity determined. ●, Control cells; ○, cells treated with 5-fluorodeoxyuridine

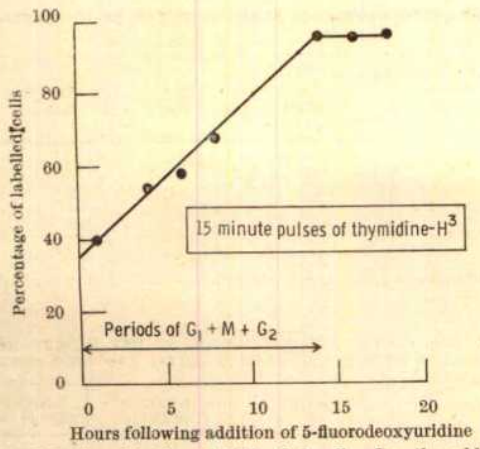

Fig. 2. Labelling kinetics of HeLa *S*-3 cells after the addition of FUDR (4×10^{-7} M). The number of labelled cells was determined at various times after the addition of FUDR by 15-min pulse labelling of tritiated thymidine (0·05 μc./ml.). Autoradiographs were made and the number of labelled cells scored

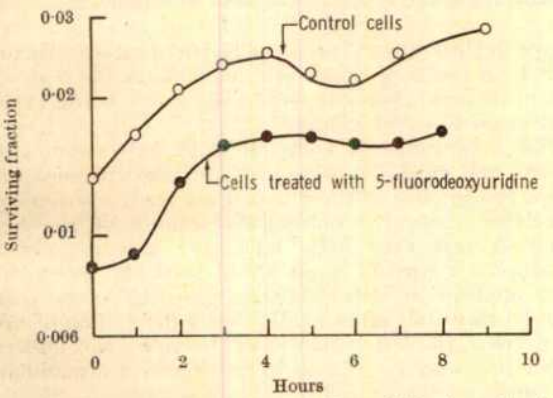

Fig. 3. Fraction of clones surviving a total dose of 558 rads as a function of time-interval between two equal doses.[1] Lower curve (solid circles) refers to the cells treated with FUDR during the fractionation studies. Cells were exposed to FUDR (4×10^{-7} M) for 14 h before the first radiation dose of 279 rads. The FUDR-containing medium was replaced by medium containing thymidine (4×10^{-5} M) 8 h after the first radiation dose

FUDR is shown in the upper curve (Fig. 3). The curve has a maximum at about 4 h, followed by a minimum at about 6 h. Below (filled circles) is the recovery curve for cells treated with FUDR for 14 h before X-irradiation. After this radiation exposure the cell population should be at the end of *G*–1 period or immediately before the *S* period with the exception of those cells which were in the *S* period at the start of exposure to FUDR. Thus, during the interval between doses about 60 per cent of the cell population was arrested at the end of *G*–1 or early part of the *S* period. A comparison of the curves in Fig. 3 demonstrates that the principal features of the recovery pattern are similar. Consequently, these experiments demonstrate that the mechanism of the repair process does not require uninterrupted DNA synthesis. The well-defined structure of the initial maximum in the recovery curve was demonstrated under conditions in which DNA synthesis was almost completely inhibited.

Cells exposed to FUDR under the conditions used in Fig. 3 appear to be more radiosensitive since the recovery curve for these cells lies below the control curve. This may suggest enhanced radiosensitivity in the late *G*–1 stage, and this point will be explored more thoroughly.

Alteration of the initial recovery peak by temperature changes and the use of actinomycin *D*[10,11] suggest a dependence of the recovery curve on the metabolic state of the cell. We are at present attempting to elucidate mechanisms underlying repair by experiments using inhibitors of nucleic acid and protein synthesis and studies using a population of synchronized cells.

BIOLOGY

Boron Toxicity in *Hevea brasiliensis*

It has recently been found in Malaya that the rubber tree, *Hevea brasiliensis*, when growing on certain soils, can accumulate sufficient boron to cause the appearance of boron toxicity symptoms on the leaves. The soils on which evidence of boron toxicity has been found are the recently deposited alluvial clay soils on the west coast of Malaya, on which approximately 20 per cent of the rubber in Malaya is grown, and certain coarse sandy loams derived *in situ* from a very acid granite where only a shallow layer of top soil overlies the decomposing parent material. The main leaf symptoms of boron toxicity on rubber, common to many plants, are the development of necrotic spots in the interveinal areas, particularly around the leaf margin, and of a tip and marginal necrosis which may take the form of a narrow regular band or may result in a large area of the leaf, at the distal end, becoming necrotic (Fig. 1).

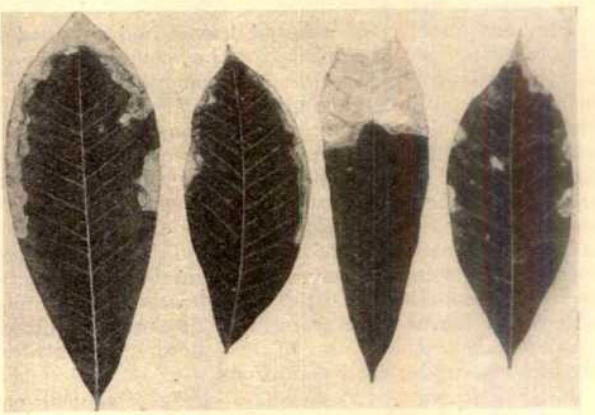

Fig. 1. Boron toxicity symptoms shown by two leaflets from clone *PB* 86 (left) and clone *G* 1 (right); trees growing on coastal alluvial clay soil

Sand culture experiments. A simple experiment involving the daily application of six levels of boron (applied as H_3BO_3) to established rubber seedlings, eight months old, was carried out to determine the effects of excess boron supply on leaf development and the leaf concentration of boron associated with toxicity symptoms. The first symptoms were observed three weeks after

Table 1. Effect of Different Levels of Boron, supplied as H_3BO_3, to Rubber Seedlings growing in Sand Culture on the Concentration of Boron in the Leaves

Boron treatment (p.p.m.)	Top whorl*		Second whorl*		Top whorl † entire lamina
	Green, central part of lamina	Necrotic edge of lamina	Green, central part of lamina	Necrotic edge of lamina	
0·36	41	No sample	65	No sample	20
0·72	142	152	217	241	36
1·80	253	216	337	477	70
3·61	290	459	491	609	104
7·21	385	365	329	924	137
14·43	560	1,416	711	1,251	221

Leaves were sampled from top and second whorls 31 weeks* after first application of boron, and top whorls again after 52 weeks†. Boron concentrations expressed as p.p.m. on a dry weight basis.

commencement of treatment with 14·4 p.p.m. boron; the concentrations of boron in the leaves are shown in Table 1. Leaves from the top and second whorl on the unbranched main stem were sampled separately after 31 weeks: at the second sampling after 52 weeks it was only possible to collect leaves from the top whorl since much defoliation of the older leaves, including the leaves on the second whorl, had taken place. Some branching from axiliary meristems on the main stem occurred particularly on plants treated with the highest level of boron; on these plants the apical meristem appeared to become dormant but was not killed.

Tip and marginal necrosis of the leaf occurred when the leaf boron concentration was approximately 140–150 p.p.m. The accumulation of boron in the necrotic extremities of the leaf which were analysed separately from the central portion of the lamina, and the greater accumulation in the older second whorl leaves, are in accord with previous findings[1].

In another experiment excessive accumulation of boron and development of marginal and tip necrosis in older leaves on the fourth whorl of approximately one-year-old seedlings were observed following the continuous daily application of 0·24 p.p.m. boron: concentrations of boron in the central green portion of the lamina of 40–60 p.p.m., and of 160–240 p.p.m. in the marginal necrotic portion of the leaves, were recorded.

Field studies: coastal clay soils. Leaf symptoms of tip and marginal necrosis, particularly on leaves which are older than approximately six months, are frequently observed on rubber growing on coastal alluvial clay soils reclaimed from mangrove[2]: these soils are poorly drained and the symptoms are generally thought to be associated with water-logged conditions.

Previous analysis of affected leaves had revealed no abnormalities with respect to the concentrations of nitrogen, phosphorus, potassium, magnesium, calcium, manganese, sodium and chloride in the leaves. Following identification of the symptoms of boron toxicity, affected leaves were collected from different locations situated on coastal alluvial clay soils on the west coast of Malaya and analysed for boron. Without exception all leaves contained abnormally high concentrations of boron, particularly in the necrotic leaf margin and tip. The boron concentrations in the leaves shown in Fig. 1 are given in Table 2, together with the concentrations in a limited selection of leaves taken from different clones of different ages, to show the range of leaf boron concentration encountered under field conditions.

It is reasonable to expect, from geochemical considerations, a high concentration of boron in the coastal alluvial deposits in Malaya, and work is in progress to determine the amounts of boron in soils derived from such deposits.

Boron toxicity on sedentary soil derived from granite. Symptoms similar to those illustrated in Fig. 1 have recently been found on rubber growing on eroded hill-tops on soils derived from an acid granite. The boron concentrations, averaged over seven samples, in the central portion of the lamina and in the necrotic leaf margin and tip were 86 p.p.m. and 257 p.p.m. respectively. As no

Analysis carried out on bulk samples collected from thirty trees.

borax fertilizers have been applied it must be concluded that high levels of boron are available in the soil. The extent of such granite-derived soils where boron toxicity may occur is as yet unknown.

The importance of boron toxicity in restricting tree growth and yield is not known but in one instance where borax was applied at the rate of 1 oz. per tree to one-year-old trees, extensive marginal scorching of the leaves occurred and very little apical or axillary meristem development was observed for at least eighteen months after application. Rubber trees growing on the coastal alluvial clay soils often exhibit early defoliation of upper branches in the latter months of the year: this abnormal defoliation may be related to an excessive accumulation of boron.

Isotopic Investigations of Nitrogen Fixation in Non-legume Root Nodules

Investigations involving the use of nitrogen-15 and previously reported have been continued as suitable plant material became available. It was shown earlier[1] that when 10 per cent of nitrogen is present in the supplied atmosphere (total pressure 1 atm.), fixation in detached nodules of *Alnus*, *Casuarina*, *Myrica* and *Hippophaë* is depressed if the proportion of oxygen exceeds 20 per cent (mean for the different genera). In a further experiment, with *Casuarina* nodules, the extent of this oxygen-inhibition in the presence of a higher level of gaseous nitrogen was examined, with the results shown in Fig. 1. In order to reduce the number of nitrogen-15 assays required, the digests from the triplicate samples of nodules at each gas mixture were pooled prior to assay; thus statistical treatment cannot be applied, but previous data[1] show that this nodule material replicates satisfactorily and indicate for the mean of three samples a standard deviation of the order of 10 per cent of the value of the mean. The results when 10 per cent of nitrogen was provided are similar to those previously reported. Some irregularity is shown in the results at 30 per cent nitrogen; but it is clear that the inhibitory effect of increasing oxygen tension is now considerably mitigated. This could be explained by a competition between oxygen

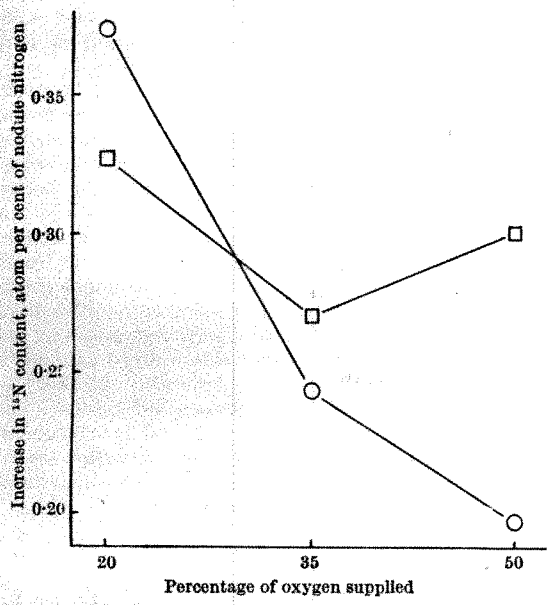

Fig. 1. Effect of increasing oxygen supply on fixation in *Casuarina* nodules at two levels of gaseous nitrogen. Samples of 1-g nodules from second-year plants of *C. cunninghamiana* were placed in 28-ml. containers charged with gas mixtures comprising the stated proportions of nitrogen (with 36 atom per cent excess nitrogen-15) and oxygen, and argon to 1 atm. Exposure was for 5·5 h. The experiment was carried out in August. ○, Ten per cent nitrogen; □, 30 per cent nitrogen

and nitrogen at some stage in the fixation process, evidence for which has been adduced by other authors in respect of *Azotobacter*[2] and legume nodules[3]. The suggestion in Fig. 1 that at 20 per cent oxygen fixation was greater with 10 per cent nitrogen than with 30 per cent could also be explained in this way.

Again in respect of nodules detached from the plant, it was reported earlier[1] that the excision of the rootlets which in *Myrica* and *Casuarina* grow from the nodule lobes resulted in a substantial reduction in the fixation shown by the nodules. This finding has been confirmed in further tests, though the explanation remains uncertain. No evidence of fixation was obtained when samples of the rootlets alone were exposed to labelled nitrogen.

Tests have been made to determine whether a capacity for fixation survives in homogenized nodules. Preparations made by grinding nodules of *Alnus*, *Myrica* and *Casuarina* in water (1–4 parts by weight) showed a scarcely significant maximum enrichment of 0·007 atom per cent of the whole nodule nitrogen after exposure for 4 h to a gas mixture comprising 10 per cent nitrogen (with 36 atom per cent nitrogen-15), 20 per cent oxygen and argon to 1 atm. In further tests with *Casuarina* nodules in which only the fraction of nodule nitrogen extracted by 3N hydrochloric acid was assayed, an enrichment of 0·012 was shown, and was not increased when sucrose or ketoglutarate was added initially. The fixation indicated, though far feebler than in the intact nodules, warrants further investigation.

A final aspect concerns the path of translocation of fixed nitrogen in the nodulated plant. Previously[4] it was shown that in *Alnus* the removal over a short zone at the base of the shoot of the tissues external to the xylem resulted in a marked reduction of fixation in the nodules, but did not prevent an upward movement into the shoot of such nitrogen as was fixed. It was concluded that this movement can, and probably does, normally occur through the xylem. The results of a similar test with *Hippophaë* are presented in Table 1, and permit the same conclusion.

Table 1. Effect of Stem-Ringing on Translocation of Fixed Nitrogen in *Hippophaë*

Plant number	Treatment	Enrichment shown in nitrogen-15, atom per cent of total nitrogen: Roots and nodules	Shoot
1	Not ringed	0·342	0·150
2	Not ringed	0·426	0·078
3	Not ringed	0·260	0·025
4	Ringed	0·045	0·020
5	Ringed	0·159	0·088

The root systems of first-year plants of *Hippophaë rhamnoides* were sealed into 100-ml. jars containing culture solution and a gas space charged with 15 per cent nitrogen (36 atom per cent excess nitrogen-15), 20 per cent oxygen and argon to 1 atm. The plants were left set up for 96 h under greenhouse conditions (in August).

I thank the staff of the National Institute for Medical Research, London, and Dr. R. H. Burris, University of Wisconsin, for the nitrogen-15 assays.

Root Formation on Cuttings of *Camellia reticulata* var. 'Capt. Rawes'

Most camellias will form roots readily on cuttings, but the *C. reticulata* cultivar, 'Capt. Rawes', is a notable exception. Failure to induce roots in cuttings of this camellia, despite the use of modern techniques such as growth regulators, etc., has led to the belief that it is unable to form roots, and several reasons have been put forward to account for this. It may be due to anatomical features, such as fibre, creating mechanical resistance[1] or the presence of inhibitors which prevent root formation[2] or the absence of some internal factor which is essential for root formation. Went[3] first postulated the presence of such a factor which he termed 'rhizocaline', but the presence of a single substance of this nature has never been demonstrated. Hess[4] has shown, however, that certain substances which are present in the juvenile form of *Hedera helix*, but absent in the mature form, could account for the failure of the mature form to initiate roots on cuttings. He has described these substances as 'co-factors of rooting'.

Camellia reticulata, var. 'Capt. Rawes', has been compared with *Camellia japonica*, var. 'Emperor', which roots readily from cuttings, to determine which, if any, of these reasons could explain its failure to form roots. The cuttings were taken in November, after the new season's shoots had become firm. Microscopic examination of sections of the base of cuttings showed no anatomical differences between *C. reticulata* and *C. japonica* that could account for the failure of the former to form roots.

Leaves taken from the cuttings of each variety were examined for the presence of growth promoters or inhibitors, using the mung bean bioassay described by Hess[4]. The results are shown in Fig. 1. These show that

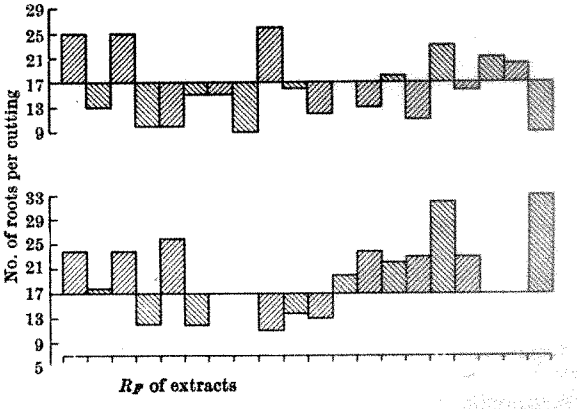

Fig. 1. Roots formed per mung bean cutting (average of 20 replicates) in the presence of extracts of *Camellia* leaves. Above, *C. reticulata*; below, *C. japonica*

Table 1. No. of Each Cutting/Scion Combination forming Roots

Combination	Cutting	Scion	No. forming roots
1	*C. japonica*	*C. japonica*	17
2	*C. japonica*	*C. reticulata*	18
3	*C. japonica*	—	17
4	*C. reticulata*	*C. reticulata*	0
5	*C. reticulata*	*C. japonica*	10
6	*C. reticulata*	—	0

C. reticulata did in fact contain a number of inhibitors of root formation which did not occur in *C. japonica*, whereas *C. japonica* contained a prominent group of growth-promoting substances which were absent in *C. reticulata*.

To elucidate this further, a cutting/grafting experiment was laid down. Cuttings of *C. reticulata* were grafted with either *C. reticulata* or *C. japonica* scions, and cuttings of *C. japonica* were grafted with *C. japonica* or *C. reticulata* scions. Ungrafted cuttings of each variety were also included. The cuttings were all treated with indolyl butyric acid, 0·8 per cent in talc, and planted in pumice in a propagating frame at 70° F. Twenty cuttings were used in each treatment. The results are shown in Table 1, and it is obvious that grafting a scion on to a cutting of the same *Camellia* species does not affect its potential to form roots. When *C. reticulata* scions are grafted on to *C. japonica* cuttings, any inhibitor in the scion is not effective in preventing root formation in the cutting, which casts doubt on whether the inhibitors present in *C. reticulata* are really effective in preventing root formation.

When *C. japonica* scions are grafted on to *C. reticulata* cuttings, however, there is a stimulation of root formation, from which one can postulate that some substance is conducted across the graft union, and is effective in promoting root formation. The nature of this substance has not yet been determined.

Kinins in the Embryo and Endosperm of *Prunus persica*

It is increasingly evident that endogenous kinins are involved in cell division in plants. Van Overbeek[1] reviewed in 1962 their possible role in fruit development. Several investigators have demonstrated their presence in a number of fruits including the peach[2–6]. In studies of peach fruit development we have found that alcoholic extracts of endosperm and embryo tissues show pronounced kinin activity.

Endosperm was removed from ovules of developing fruits of peach (*Prunus persica* cv. 'Halehaven') on July 14, 1960, when endosperm dry weight was still increasing, and on July 28 after its dry weight had started to decline because of digestion by the embryo. Embryo samples were taken on July 21, just after the beginning of rapid embryo development, on August 4 when it was well under way, and on August 18 when embryo growth was still progressing, but nearing the end of the period of rapid development, as measured by dry-weight increases. The tissues were immediately frozen with dry ice, and later lyophilized. Extractions were made with 75 per cent methyl alcohol. The alcohol was evaporated and the residue partitioned between water and *n*-butyl alcohol to attempt some purification. Both the aqueous and alcohol fractions were then serially diluted and assayed by means of the tobacco pith explant test[7]. At the end of three months, when growth had almost stopped, the callus was cut from the explants. Both callus and explant were weighed and the callus yield calculated as a percentage of the explant weight.

Appreciable kinin activity, as measured by growth of the callus, was detected in all samples of both the aqueous and butyl alcohol fractions. There were no clear-cut differences in activity between the butyl alcohol and aqueous fractions of a particular sample, nor between similar samples taken on different dates. There was only a suggestion that the endosperm was a richer source of kinins than the embryo. The data for the aqueous fraction of the July 14 endosperm sample and the aqueous fraction of the July 21 embryo sample are summarized in Fig. 1. At all concentrations of the endosperm extract, and at all but the highest concentration of the embryo extract, the growth of the explants was considerably greater than could be accounted for by endogenous indolylacetic acid. In one case it was equal to that caused by the coconut milk. Further comparisons of kinin concentration between the various samples are not valid since the distribution of inhibitors of the bioassay is unknown.

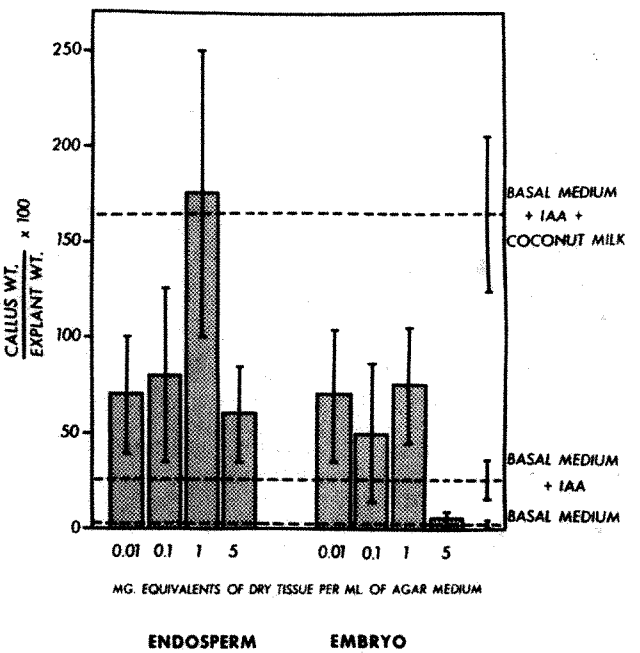

Fig. 1. Kinin activity in the aqueous fraction of extracts of endosperm (July 14) and embryo (July 21) from seeds of developing peach fruits. Tobacco pith explants were grown on 1·9 per cent agar containing basal medium (consisting of modified White's salts, sucrose, vitamins, and iron), indolylacetic acid (IAA), 2 p.p.m., and endosperm or embryo extract at the concentrations indicated. Control explants were grown on (1) basal medium only; (2) basal medium plus indolylacetic acid; and (3) basal medium plus indolylacetic acid plus 10 per cent coconut milk. Standard deviations from the mean are indicated

It has been suggested[1,8] that kinins may play a part in fruit development during the early stages of this process, since it is at this time that cell division in the pericarp may be occurring. In the peach pericarp cell division is said to continue for three to four weeks after fertilization[9]. Mitoses have been observed in an embryo 12 weeks after bloom (unpublished data), and are obviously required for the growth of the endosperm and embryo. The present data show that kinins exist in immature peach seeds for at least three months after fertilization. It seems likely that kinins are necessary for the normal development of the ovule, and thus must play a vital, if indirect, part in the middle as well as the early stages of peach fruit development, since the development of the pericarp is dependent on the ovule well into the middle period of fruit development of this species[10].

This work was performed while the senior author was a member of the Department of Pomology, New York State Agricultural Experiment Station, Cornell University, Geneva. We acknowledge the advice of Dr. F. G. Dennis in the performance of the bioassay, and the assistance of Mr. Bock Chan in securing the endosperm and embryo samples.

Bimodality of Laying–Hatching Times in *Testudo elegans* Schoepff (Chelonia)

A FEMALE and three male Indian starred tortoises (*Testudo elegans* Schoepff)[1] have been kept since August 1962 in Bhubaneswar in a yard which is only partially paved. All the tortoises were obtained from dealers in Calcutta.

The eggs and young observed are listed in Table 1. 62I and 63I were resting on grass. 62I was put on damp blotting paper in a glass jar. It was discarded after it had cracked and become malodorous. The eight eggs 63I and 64I–VII were also put individually in glass jars and buried 6–8 cm deep in soil which was not moistened afterwards.

Table 1

No.	Laid	Where	Size (cm)	Hatched	Incubation period	Hatching weight (g)
62I	17/10/62	Surface	5·1 × 3·7			
63I	26/3/63	Surface		15/7/63	111	13·87
64V	18/4/64	Buried	4·25 × 3·5	4/6/64	47	16·13
II	18/4/64	Buried	4·35 × 3·55	4/6/64	47	18·94
VI	18/4/64	Buried	4·4 × 3·55	11/6/64	54	21·53
I	18/4/64	Buried	4·05 × 3·15	18/8/64	122	14·43
III	18/4/64	Buried	3·95 × 3·1	22/8/64	126	11·93
VII	18/4/64	Buried	4·4 × 3·3	29/8/64	133	13·77
IV	18/4/64	Buried	4·65 × 3·4	12/9/64	147	15·22
				Found		Weight when found
VIII				26/6/64		20·66
IX, X, XI		One at least buried with XII		3/7/64, 3/7/64, 3/7/64		19·14, 19·07, 20·74
XII		Buried		Died near term		

On April 18, 1964, at about 6 p.m., the female was found digging with her hind feet. About 1 h later, she was seen sitting quietly with her hind parts in the pit thus made. At midnight, she was more than 8 m away from this place, which was marked and excavated next morning. The soil was swarming with ants and had to be flooded before it could be handled. The eggs were buried 5–15 cm deep, each touching at least another. The numbers given to them unfortunately do not record the order in which they were taken from the pit. Though we extended this pit for at least 10 cm in all directions from this group of eggs, we found no more.

The female has not since had mud on her hind parts as she had after burying these eggs. However, four other baby tortoises have been found in the yard. The three young, 64IX–XI, were found virtually simultaneously and within a few metres of the previous egg pit. Very near the site of our previous excavation, we found a freshly opened cylindrical hole, about the diameter of a young tortoise, descending vertically. This contained fragments of egg-shell and an egg containing a putrid embryo very near term. As such a hole would have been quickly washed away in the rain then falling, and as the three young were so near to it, we have little doubt that we found them within a few minutes of their leaving the soil.

The laying to hatching periods of the 1964 eggs given in Table 1 show the young falling into two groups, the quick developers and the slow developers, and that the hatching weights of the former are greater than those of the latter. Their weights confirm that the four young found after hatching are plausibly quick developers, and that 63I is a slow developer.

It is known that the period between laying and hatching of reptile eggs is very variable within a species. This is attributed to their dependence on external temperatures, which vary from season to season and in different parts of the species range[2]. A range of laying–hatching times differing by a factor of 3 (which is, incidentally, larger than any listed by Goin and Goin[2]), together with its bimodality, suggests that the differences observed among the littermates 64I–VII kept in apparently identical conditions are genetically determined. The two groups may represent the sexes.

Here we are somewhat isolated from the literature and would be grateful to learn of any comparable variation in laying–hatching time in any other vertebrate. Like variation in time needed to reach sexual maturity, it may be characteristic of long-lived, and correspondingly infertile species. Wynne-Edwards[3] discusses the adaptive value of such patterns of development.

'Metarchon': a New Term for a Class of Non-toxic Pest Control Agents

CONCERN over the contamination of the environment by pesticide residues is directing attention to the possibility of combating insect pests by means of chemical or other influences which, without being toxic, are able to affect an organism adversely by inducing deviations from the normal behaviour. Insect repellents and insect attractants (both chemical and optical) are familiar examples, but they do not exhaust the possibilities. For example, a sex-attractant scent could be distributed broadcast in order to confuse or attenuate the male response, and other olfactory signals might be used to induce a female to oviposit at the wrong time or place. Other possibilities no doubt remain to be discovered.

Since no single term denotes agents using this principle, I suggest that behaviour-modifying influences purposefully applied as a means of pest control be given a special name, 'metarchon', from the Greek meta, a prefix indicating change (as in metamorphosis), and archon, ruler or controller (as in monarchy or anarchy).

'Metarchons' are defined as external stimuli artificially introduced into the environment of an organism for the

purpose of modifying its behaviour, by eliciting an inappropriate response or inhibiting an appropriate one.

The term 'pheromone' has been coined to denote chemical signals which emanate from one individual and evoke a behavioural or developmental response in a second individual of the same species[1]. A pheromone might, therefore, be used as a metarchon, but the latter term also embraces food attractants and multi-component odours, as well as such physical agents as lights or sounds.

I thank Dr. Malcolm F. McGregor for his advice.

Paralogy, a Concept Complementary to Homology and Analogy

In the application in practice of the concept of homology it is necessary to keep taxonomical considerations constantly in mind if false homologies are not to be drawn[1].

It would seem that there is also some need to consider the concepts of homology and of analogy and to delimit a third and complementary concept, which might be termed 'paralogy'[2].

For meaningful discussion to be possible it is essential that there should be strict uniformity of usage in regard to the important concepts of homology and analogy, but, as was pointed out by Boyden[3], strict usage has by no means always been the rule. When working some years ago in the Department of Anatomy of the University of Sydney this point was forcibly brought home to me. Indeed, even in books devoted to comparative anatomy, it is possible to find examples of looseness of usage of both the term 'homology' and the term 'analogy', or their related parts of speech.

For the meaning of these concepts we can do no better than to go back to Richard Owen, who first clearly defined them in the glossary to his *Lectures on the Comparative Anatomy and Physiology of the Invertebrate Animals*, delivered at the Royal College of Surgeons of England, and published in 1843: "Analogue. A part or organ in one animal which has the same function as another part or organ in a different animal" and "Homologue. The same organ in different animals under every variety of form and function."

While these definitions are, perhaps, not perfect as such, the nature of the concepts is clearly indicated. The confusion in the usage of terms relating to these concepts, and in their practical application, appears to have been in part engendered by the lack of explicit definition of the complementary concept of purely anatomical or structural resemblance, for which the term 'paralogy' is suggested. Following Owen, its meaning may be indicated thus: 'Paralogue'—a part or organ in one animal similar in anatomical or microanatomical structure to a part or organ in a different animal.

Paralogy, then, refers only to anatomical similarity and has no phylogenetic or functional implications. Although lacking the comparative anatomical importance of true morphological correspondence (homology) and the comparative physiological significance of functional resemblance (analogy), a term which may help in limiting the drawing of false homologies on the basis of superficial resemblance in structure appears to be amply justified.

VIROLOGY

Transfer of Lily Curl Stripe by a Leaf Union Method Applicable to Monocotyledonous Plants

Curl-stripe disease has seriously affected certain plantings of *Lilium longiflorum* Thunb. in Oregon and California. Control approaches have been uncertain because occurrence patterns and symptomology were equally indicative of nutritional imbalance or virus ætiology and because we had been unable to transmit the disease[1]. Early-season symptoms, central striping of young leaves due to retardation of plastid formation, followed by curling and twisting of leaves, are striking. Such symptoms may continue or, more usually, later formed foliage may be normal. Bulbs from such plants may or may not produce visibly diseased plants the following year. Such symptom variability is atypical of virus infections of bulb plants.

Initially, the presence of a soil-borne virus, probably tobacco rattle, was suspected. Tests by us and by Dr. R. G. Grogan, of the University of California, proved that while rattle virus is occasionally present in Easter lilies, it is certainly not the cause of curl-stripe. Numerous inoculations over a 5-year period failed to isolate a probable virus from typically diseased plants or to effect a transfer from lily to lily. Probable virus ætiology was indicated, however, by electron microscopy and by the development of an antiserum which gave a positive Ouchterlony agar double-diffusion reaction to sap from typically diseased plants. Virus ætiology has now been verified by infecting 20 of 22 lilies by leaf union inoculation. The procedure should be applicable to similar problems in tropical diseases of coconut and maize.

The objective is to fasten the distal half of an infected leaf to the basal half of a leaf on a test plant in such fashion that the cut ends of the parallel veins will be joined and union will occur. The equipment needed is two razor blades, strips of paper masking tape approximately 20 mm × 40 mm and a spectacle-type magnifier which can be worn. Two operators are required so the union can be made and sealed in 30 sec or less. A leaf on the test plant is cut in two with a razor blade and a piece of tape attached to the lower surface so it extends out about 10 mm beyond the cut end of the leaf (Fig. 1). Then the distal half of the leaf cut from the infected plant is fitted to the basal half of the test plant leaf so the ends of the veins meet. Slight magnification is needed to ensure adequate joining of the veins. The sticky tape extending beyond the cut end of the test plant leaf enables one to hold both cut ends in position until an assistant can fit a second piece of tape above them to form a waterproof sandwich.

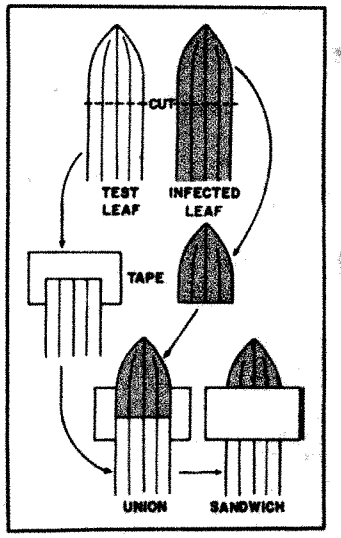

Fig. 1

The critical points in the technique are: (1) the grafting must be performed rapidly while the veins are still 'bleeding'; (2) a suitable easily handled paper tape must be used. The very sticky, easily curled 'Cellophane' tapes used for sealing purposes are unsuitable.

Initial trials of this technique on lilies growing outdoors, without recourse to humid chambers considered necessary for difficult grafts, showed that lily leaves so united usually remained green and turgid for at least 30 days; occasional leaves for more than two months. It is not claimed that a true graft union developed; but exchange of vascular fluids did occur as witnessed by long life of the attached leaf part and significant transfer of a hitherto 'non-transmissible virus'.

GENETICS

Effect of Supernumerary Chromosomes on Sex Ratio in *Calligrapha philadelphica* L. (Coleoptera: Chrysomelidae)

Supernumerary chromosomes occur sporadically in plants and animals. In the animal kingdom, they have been observed in at least 50 insects and two turbellarians, and they may be present or absent in different populations of the same species[1]. They are generally considered to be inert as they are usually heterochromatic and their carriers are not distinguishable morphologically. The chromosomal polymorphism that they confer on some populations suggests that they play an adaptive part in the success of the population[1,2]. In plants supernumerary chromosomes have a harmful effect on vigour and fertility, and the effect becomes more pronounced as their number increases[3]. The work of Lewis[4] and Frost[5] has suggested that their presence may be an adaptation to arid regions[3].

This report concerns *Calligrapha philadelphica* L., one of 17 species of the genus that I have examined cytologically. Most of the species, including *C. philadelphica*, are bisexual, but six are obligatorily parthenogenetic. The adults hibernate in the ground in winter and emerge in the spring to mate (if bisexual) and lay eggs. There is a single generation each year. The bisexual species have a basic chromosome formula of $n = 11 + XO$ ($2n = 23$♂, 24♀), which in some species is modified by the presence or absence of supernumerary chromosomes in colonies from different localities. The parthenogenetic species are ameiotic tetraploids ($4n = 48$). Bisexual *C. philadelphica* was found in 1961 to contain 5–8 univalent supernumerary chromosomes per individual in a colony at Berthierville, Quebec, and none in a colony at Ottawa, Ontario. Accordingly, it was clear that a cross might provide some interesting hybrids.

In two years of collecting and rearing, the sex ratio from each colony was virtually 50 : 50. In 1963, chromosome samples indicated that the colonies had not changed with regard to the presence or absence of supernumerary chromosomes. Because of technical limitations only a one-way cross, that is, males from Berthierville with females from Ottawa, has been attempted this year. Two lots, *A* and *B*, containing two males and three females, and three males and two females, respectively, were bred and reared separately. Lot *A* yielded 18 adult progeny, lot *B* 14, from a total of 43 young larvæ. All the progeny were female. At the same time 39 Berthierville control females were allowed to mate in lots of two to five individuals, and these yielded 218 female and 199 male progeny, derived from 900 young larvæ. In other words, the number of females per female parent was 6·4 in the test cross and 5·5 in the control, so that the yield of female progeny in the two samples was not very different. However, the figure 5·5 actually represents 52·5 per cent of the total progeny whereas 6·4 represents 100 per cent, that is to say, the test cross gave only females. The survival-rate from young larva to adult was 46 per cent in the control and 74 per cent in the test cross, and as this certainly does not indicate an excessive mortality in the larval stage of the test group it is suggested that the male component was lost at fertilization or in the egg stage.

Thus the male sex in *C. philadelphica* is not represented in the adult progeny of a cross between females from the Ottawa colony and the males from Berthierville, and the most probable explanation is that this result depends on the addition of supernumerary chromosomes originating from the Berthierville colony. Further experiments with the surviving 32 female adults of the test cross as well as adults from laboratory-reared stock from both localities are in progress.

PSYCHOLOGY

Effect of Pentobarbital Sodium on Sleep Latency and Length of Sleep in the Rat

The effects of repeated dosages of pentobarbital sodium on two sleep responses in the rat have been investigated. The responses observed were sleep latency (the time between drug injection and an observed sleep response) and sleep length (the time between the observed sleep response and arousal). The dosage used was purposely designed to obtain a significant delay between injection and the sleep response. The study was an outgrowth of an attempt to produce, in a minimally distracting environment, a low variability but delayed sleep latency which would be susceptible to systematically introduced environmental sleep distractors. The investigations are a part of a larger programme directed toward determining the environmental antecedents of sleep.

The experimental observations were carried out in a sound-deadened room maintained at 70° F and kept dimly lighted during the experiment.

Injections were given intraperitoneally in a dose of 20 mg pentobarbital sodium/100 g body-wt. A solution containing 16·7 mg/c.c. of pentobarbital sodium was freshly prepared each day.

All animals were adult males of the Long-Evans hooded variety. The four animals in the first experiment were 140 days old at the beginning of the experiment. The six animals of the second experiment were 190 days old at the beginning of the experiment. These animals had free access to food and water except for the period in which they were in experimental cages.

After injection, the animals were placed in individual observation cages which were 10 in. × 7 in. × 7 in. made of meshed galvanized wire. The time of sleep onset was measured to the nearest second. Sleep onset was determined by observational means. The animal was considered asleep when it lay down, body flaccid, respiration shallow, no gross movements occurring, and would not respond to an object waved in front of its eyes. Total length of sleep was measured to the nearest minute starting with the first appearance of the sleep response until arousal. The animal was considered awake when it responded to

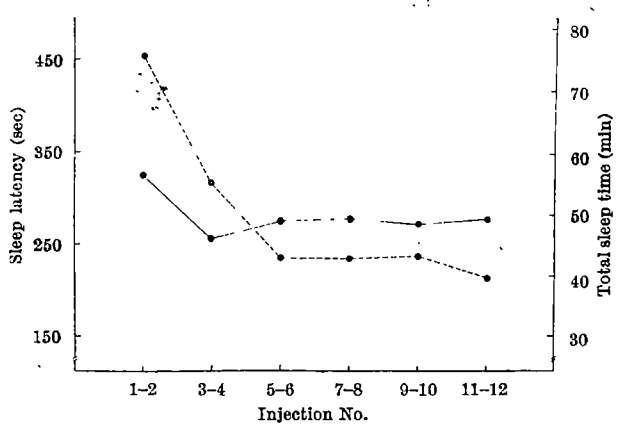

Fig. 1. ———, Sleep latency; - - - -, total sleep time

an object waved in front of its eyes and moved about the cage.

There was a 48-h interval between each drug administration.

In the first experiment four animals were given a series of 42 injections of pentobarbital sodium and sleep latency was determined. The average sleep latencies in seconds in blocks of six injections for the four animals were as follows: 404, 318, 383, 379, 405, and 411. An analysis of variance of these six unit blocks of *S*s was performed. The between-blocks variance (in this case tolerance effect) was not significant. There was a significant difference between *S*'s in the effect of pentobarbital sodium on sleep latency time ($P = 0{\cdot}01$). A 43rd placebo injection (distilled water) was given after 48 h. No animal slept within a 30-min observation period, indicating no conditioning of the sleep response with the delay latency obtained in this experimental design.

In a second experiment six animals were given a series of 12 injections of pentobarbital sodium and both sleep latency and sleep length were measured. The results are shown in Fig. 1. A highly significant tolerance effect was present in the case of length of sleep. This effect was demonstrated within the first three trials. Four injections produced more than 50 per cent of the reduction in time of sleep. The length of sleep variable appears to become asymptotic after 5 injections. An analysis of variance of the latency data using blocks of three trials yielded no significant tolerance, *S*, or interaction effect; an analysis of variance of the sleep length data yielded significant *S* and tolerance variances, but no interaction effect ($P = 0{\cdot}01$ and $0{\cdot}001$, respectively).

This work was supported by grant *NIH–MH*–03881–03 from the U.S. National Institutes of Health.

Lateral Preferences in the Monkey

There is general agreement that the majority of monkeys show lateral preferences on a particular task[1–6], about as many animals showing a strong preference for the left hand as for the right. However, Ettlinger[5] reported that significantly more monkeys preferred to use the left hand than the right on their first discrimination task (irrespective of the task being visual or tactile). Seventeen of the 42 monkeys showed a strong preference for the left hand, six for the right and 19 animals showed weak or ambiguous preferences. Brookshire and Warren[6], as a result of their more comprehensive investigation of lateral preferences under a variety of test conditions, wrote: "Four monkeys were judged to have had a predominantly right-hand preference, nine were judged left-handed, and six were considered either ambidextrous or without definite preference". It is not yet known what factors are associated with the preferential use of a particular hand (left or right) on a given task[6]. If a significant asymmetry in the incidence of lateral preferences in favour of the left (or right) hand can be established it will be important to seek for neural or other correlates in a species which is generally considered to lack cerebral dominance.

Hand preferences have now been recorded for 27 unoperated immature rhesus monkeys, all receiving their first training on a simple tactile discrimination task. These animals were all housed and examined under constant conditions during the period 1962–64. Training, under standard conditions (40 daily trials, non-correction), was begun in the light but quickly (after 1–4 sessions) transferred to the dark. Two test-objects, a cylinder and a sphere, were made available on each trial. At first the animals were able to see these objects; afterwards they were only able to palpate them in the dark. Choice of the one object (cylinder), whether to left or right, was rewarded. The animals indicated their choice by pushing one test-object and thereby opening the lid of one food box. Following correct choice the animals were able to pick up a food reward (peanut) from the food box which was uncovered. Records were taken of the hand used to push the test-object (and, therefore, the lid of the box) on all trials; and also of the hand used to bring the food to the mouth on all rewarded trials. Responses made during initial trials in the light have been excluded from analysis. Separate tabulations were made for: (1) all the trials (totalling 3,585) in the dark during the stage of training before the animals reached a standard level of performance (90 per cent correct responses in 200 consecutive trials); (2) for trials 71–100 of the stage of training in the dark when the animals had reached the standard level of performance (a total of 810 trials). In addition, animals were individually graded as showing a left or right lateral preference if 90 per cent or more of their responses during either stage of training were made with a single hand.

Table 1. Number of trials on which response to the test-object (and also to the food reward on rewarded trials) was made with the left or right hand at two stages of training on a tactile discrimination task; and number of animals using the left or right hand for the test-object (and also the food reward on rewarded trials) in 90 per cent or more of trials, at two stages of training on the same task

Hand used:	Left	Right		Left	Right	
Trials	1,925	1,422	$\chi^2 = 75{\cdot}6$ $P < 0{\cdot}001$ Binomial	448	270	$\chi^2 = 44{\cdot}2$ $P < 0{\cdot}001$ Binomial
Animals	7	4	*N.S.*	12	7	*N.S.*
	During stage of training before performance is 90 per cent correct			During stage of training when performance is 90 per cent correct		

Trials on which animals used both hands to push the test-object, and rewarded trials on which different hands were used for the test-object and food reward, have been excluded from the table. Similarly, animals not using the same hand in 90 per cent of trials have been excluded from the analysis related to individual animals.

The results are shown in Table 1. At both stages of training there were significantly more trials on which the left hand was used in preference to the right hand. However, the number of animals showing left-hand preferences does not significantly exceed the number of right-handed animals. Nevertheless, it is noteworthy that a trend towards a greater incidence of left than right lateral preferences has been reported in two recent investigations[5,6] and also in this communication.

We thank Prof. G. D. Dawson and Prof. P. M. Daniel for facilities, and the Medical Research Council for financial support.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 9

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Submarine Telephone Cables—Protection, Damage and Repairs" opened by Mr. R. J. Halsey and Mr. N. E. Holmblad.

PHARMACIA (GREAT BRITAIN), LTD. (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 6 p.m.—Dr. J. Killander (Sweden): "Fractionation of Serum Proteins by Gel Filtration". (To be repeated at the Molecular Biology Laboratories, Hills Road, Cambridge, on November 10 at 2.30 p.m.)

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. G. Ekman (Stockholm): "Psychological Scaling. II: On the Psychological Function and Related Problems".*

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Capt. J. M. Loyd: "Across the Wahiba Sands".

Tuesday, November 10

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. Ursula Mittwoch: "Sex Chromosomes and Sex Chromatin".*

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

UNIVERSITY OF LONDON (in the Assembly Hall, Institute of Education, Malet Street, London, W.C.1), at 5.15 p.m.—Mr. Victor Clark: "Local Education Authorities versus Bingo". (Fifth of a series of lectures on "Leisure and Education—Challenge and Response".)*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. W. J. Leaman and Mr. R. K. Postlethwaite: "Oil Jetties at the Port of Hull".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. A. Weaver: "Computer Aided Study of Character Recognition".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine, 26 Portland Place, London, W.1), at 5.30 p.m. —Mr. S. M. Ardley: "The Use of Resins in Rubber Reinforcement". 7 p.m. —Mr. G. J. Lake: "The Roles of Ozone and Flexing in the Failure of Rubber".

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. G. Ekman (Stockholm): "Psychological Scaling. III: Applications of Scaling Techniques in the Study of Psychological Mechanisms".*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.30 p.m.—Mr. G. L. Wilde and Mr. F. J. Allen: "Supercharging the 1½-litre V-16 B.R.M. Racing Engine".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at Norwood Technical College, Knight's Hill, West Norwood, London, S.E.27), at 7 p.m.—Film Show.

Wednesday, November 11

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Prof. C. J. O. Morris: "Recent Advances in the Fractionation of Protein Mixtures".*

UNIVERSITY OF LONDON (at Bedford College, Regent's Park, London, N.W.1), at 5.15 p.m.—Prof. W. J. G. Beynon: "International Co-operation in Science".*

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Dr. M. Borner and Mr. A. Russen: "Electro-Mechanical Filters".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. A. H. Strickland: "Pest Control and Productivity in British Agriculture".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. A. T. S. Babb: "A Recording Instrument for the Rapid Evaluation of the Compressibility of Bakery Goods"; Dr. D. G. Land: "The Off-Flavour of Dehydrated Carrot Exposed to Oxygen"; Dr. H. Fore and Mr. R. Walker: "A Problem Associated with Food Colouring Matters".

Thursday, November 12

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 11 a.m.—Discussion Meeting on "International Indian Ocean Expedition. The Geology and Geophysics of the North West Indian Ocean" organized by Dr. M. N. Hill, F.R.S.

UNIVERSITY OF LONDON (in the Recital Room, Goldsmiths' College, New Cross, London, S.E.14), at 4.45 p.m.—Mr. T. K. Rees: "Modern Views on the Mechanism of Evolution".*

GLACIOLOGICAL SOCIETY (in the Geology Department, The University, Edgbaston, Birmingham), at 5 p.m.—Mr. Albert Bauer: "Antarctic Traverse".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. K. Preece, Mr. P. Lundberg, Mr. P. Selway and Dr. V. G. Tull: "Pressure Sensitive Effects in Semiconductors".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Current Balance Earth-Leakage Circuit-Breakers—Design Features and Future Employment" opened by Mr. E. J. Sutton.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. T. Eayrs: "Thyroid and Nervous System". (Seventh of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. P. G. Foote: "The Saga of the Faroe Islanders" (Inaugural Lecture).*

ROYAL AERONAUTICAL SOCIETY (at 4 Hamilton Place, London, W.1), at 6 p.m.—Discussion Meeting on "Is the Aeronautical Industry Making the Best Use of Its Graduates?" opened by Mr. S. L. Bragg and Mr. R. L. Lickley.

OIL AND COLOUR CHEMISTS ASSOCIATION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. P. Whiteley: "Mould Resistance of Paints in the Tropics".

RADAR AND ELECTRONICS ASSOCIATION (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7 p.m.—Mr. L. F. Mathews: "Televising the Tokyo Olympics".

ROYAL INSTITUTE OF CHEMISTRY (at Croydon Technical College, Fairfield, Croydon, Surrey), at 7.30 p.m.—Mr. R. A. Hudson: "The Physical Chemistry of Detergency".

Friday, November 13

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. J. D. N. Nabarro: "Steroid Therapy".*

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. S. A. Nasar: "Electromagnetic Theory of Electrical Machines".

ROYAL AERONAUTICAL SOCIETY, TEST PILOTS GROUP (at 4 Hamilton Place, London, W.1), at 6 p.m.—Mr. E. B. Trubshaw: "Low Speed Handling with special reference to Super Stall".

OCCAM SOCIETY (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. H. L. Jolley: "Causality".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Cambridge University Chemical Society and the East Anglia Section, at the Cambridge University Chemical Laboratory, Lensfield Road, Cambridge), at 8.30 p.m.—Prof. John Yudkin: "Needs and Wants—The Dilemma of Civilization and the Role of the Chemist".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. A. H. Ewen: "'The Friend of Mankind'—a Portrait of Count Rumford".

Saturday, November 14

GLACIOLOGICAL SOCIETY (joint meeting with the Scott Polar Research Institute, at the Scott Polar Research Institute, Cambridge), at 8.30 p.m.—Mr. Albert Bauer: "Antarctic Traverse".

Monday, November 16

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Lieut. Comm. J. B. Dixon, R.N.: "Hydrographic Surveying in the Antarctic".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. R. C. Brian: "Electrons and the Mode of Action of Certain Herbicides".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. P. M. S. Blackett, F.R.S.: "Britain and India's Development Plans" (Rickman Godlee Lecture).*

Monday, November 16—Thursday, November 19

INSTITUTION OF MINING AND METALLURGY, in co-operation with the Institution of Mining Engineers and the Institute of Quarrying (at Caxton Hall, Westminster, London, S.W.1)—Symposium on "Opencast Mining, Quarrying and Alluvial Mining".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

UNIVERSITY LECTURER (with a special interest in genetics including microbial genetics) IN BOTANY—The Administrator, Department of Botany, The University, South Parks Road, Oxford (November 10).

ASSISTANT LECTURER OR LECTURER (preferably qualified in the fields of biophysics, biochemistry, ecology, genetics, microbiology or physiology) IN THE SCHOOL OF BIOLOGICAL SCIENCES—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (November 20).

LECTURER OR ASSISTANT LECTURER IN THEORETICAL PHYSICS—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (November 20).

RESEARCH FELLOW for mainly experimental work in the hovercraft field—The Secretary and Registrar, Room 9, The University, Highfield, Southampton (November 20).

TUTORIAL RESEARCH STUDENT IN MATHEMATICS (Pure or Applied)—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (November 20).

LECTURER and an ASSISTANT LECTURER IN PURE MATHEMATICS—The Secretary, The University, Aberdeen (November 21).

LECTURER (medically qualified or non-medically qualified) IN THE DEPARTMENT OF PHARMACOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/344 (November 21).

LECTURER OR ASSISTANT LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Sheffield (November 28).

CHAIR OF MECHANICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea (November 30).

EXPERIMENTAL OFFICER (chemist or biochemist with at least H.N.C. or L.R.I.C., with some research experience) to assist with research into drug metabolism in the horse—Head of Forensic Laboratory, Equine Research Station, The Animal Health Trust, Newmarket, Suffolk (November 30).

JUNIOR LECTURER IN MATHEMATICS; and a LECTURER/SENIOR LECTURER IN PSYCHOLOGY at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, November 30).

JUNIOR LECTURER IN ZOOLOGY; and a JUNIOR LECTURER IN BOTANY at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, November 30).

LECTURER (with a science degree with special qualifications (and preferably postgraduate experience) in entomology or helminthology) IN ZOOLOGY—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (December 1).

BIOCHEMIST, Basic Grade (with an honours degree in chemistry or biochemistry, or A.R.I.C.)—The Group Secretary, Southmead Hospital, Westbury on Trym, Bristol (December 5).

SENIOR LECTURER OR LECTURER IN PURE MATHEMATICS at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 7).

SIR WILLIAM DUNN CHAIR OF PATHOLOGY at Guy's Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 10).

CHAIR OF PHARMACOLOGY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, December 15).

RESEARCH ASSISTANT (with a good honours degree in engineering or metallurgy) in a group working on the strength properties of materials under dynamic loading—Dr. J. D. Campbell, Engineering Laboratory, The University, Parks Road, Oxford (December 31).

SECOND CHAIR IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University of Essex, Wivenhoe Park, Colchester, Essex (January 5).

BIOCHEMIST OR MICROBIOLOGIST (with a Ph.D. degree) to work on factors controlling the biosynthesis of enzymes in bacteria—The Director, National Institute for Medical Research, Medical Research Council, Mill Hill, London, N.W.7.

BIOLOGIST (between 24 and 35 years of age, with an honours degree in zoology and postgraduate experience in animal ecology) in Tanganyika, to carry out investigations concerned with the management of wild life and to advise the Chief Game Warden—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 275/173/01.

LECTURER IN MATHEMATICS—The Principal, The Training College, Bognor Regis, Sussex.

MASTER TO TEACH CHEMISTRY (large share in sixth form work)—The Headmaster, Epsom College, Epsom, Surrey.

PHYSIOLOGIST or PATHOLOGIST (preferably with postdoctorate or other experience) to carry out a research programme concerned with the physiology and pathology of fish—Dr. D. R. Idler, Director, Fisheries Research Board of Canada, Technological Research Laboratory, P.O. Box 429, Halifax, Nova Scotia, Canada.

RESEARCH ASSISTANT (with a good honours degree in animal physiology or zoology or an equivalent qualification, and preferably an interest in biochemistry) IN THE PHYSIOLOGY DEPARTMENT, for investigation of blood levels of oxytocin in relation to reproduction and lactation—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. 64/16.

RESEARCH ASSISTANT (with an honours degree in physics) IN THE DEPARTMENT OF PHYSICS, to undertake research work in nuclear physics—The Registrar, Bradford Institute of Technology, Bradford, 7.

SENIOR PHARMACIST (full- or part-time)—The Physician Superintendent, Oakwood Hospital, Maidstone, Kent.

SCIENTIFIC MAN-POWER AND THE NEXT TEN YEARS

THE science resources planning study, *Sustaining Academic Science*, 1965–75, prepared by W. V. Consolazio, of the National Science Foundation, deals primarily with the question of what resources the United States will require to train adequately all those who will seek higher education in science, mathematics and engineering during this decade. It does not discuss the related questions of the adequacy of the economy or the adaptability of the social and cultural *milieu* to utilize this man-power fully. Dr. Consolazio predicts that during this decade man-power in academic science and engineering will approximately double at both the trainer and the trainee level and that a full-time faculty of 173,000, including 93,000 with doctorates, will be needed for an output estimated in terms of 2,600,000 bachelor's degrees, 480,000 master's degrees and 130,000 doctorates.

The instructional costs in science and engineering at colleges and universities are estimated at some 28,000 million dollars, with a further 15,000 million dollars for research, 9,000–10,000 million dollars for plant, 7,000 million dollars for assistance to fellows and scholars, 2,500 million dollars for information services and a similar amount for improving the teaching of science and mathematics in the schools. Dr. Consolazio regards the total cost of 65,000 million dollars as a conservative figure, but, while he assumes that the nation possesses the necessary resources, only some 37,000 million dollars is expected to be available from non-Federal resources, and he is doubtful whether the Federal Government will, in fact, assume the responsibility for the difference of some 28,000 million dollars. He shows clearly enough what is likely to be involved if the United States attempts to provide the supply of scientific and technical man-power that he postulates, but he does not attempt to consider whether the provision of these resources is justified, still less to examine whether in fact such trained man-power would be wisely and effectively used.

Nevertheless, this paper, now reprinted from the Spring 1964 issue of *The Educational Record*, published by the American Council on Education, makes an interesting complement to Dr. C. F. Carter's address, "The Economics of Higher Education", before Section F (Education) at the British Association meeting in Southampton on August 27. Moreover, it complements the Manpower Study, *The Pattern of the Future**, issued by the Ministry of Labour at almost the same time, and the long-term building programme of £83 million for universities and colleges of advanced technology between 1966 and 1969 announced on September 2 by the then Secretary of State for Education and Science, Mr. Q. Hogg. Of this amount 3 million was proposed for the first year, but the figures of £25 million for each of the subsequent two years were provisional, pending more precise advice from the University Grants Committee on the capital position as it will be when the existing building schemes have been completed. They provide for the colleges of advanced technology and two Scottish central institutions, the Heriot Watt College, Edinburgh, and the Glasgow College of Commerce, which is to be combined with the University of Strathclyde. These figures were related only to building costs and did not include the cost of sites, professional fees or equipment.

Dr. Carter's paper went much nearer to asking the vital questions that should be considered before we determine the magnitude of the expansion in higher education that our resources allow, still more the means by which the desirable expansion should be achieved. He was critical of the Robbins Report on some points, and his paper was a stimulus to clear thinking. He was not content to show that the cheapest place to expand is probably an existing institution with access to a large cheap site, or to question whether any more new institutions are needed, in addition to the seven recently-founded universities, if the plans for resiting and expanding the present colleges of advanced technology are carried out. He provoked, deliberately, some realistic thinking about student life and halls of residence and the like.

As Dr. Carter rightly stated, before we ask for great additions to the substantial support which the State already gives to higher education, we owe the community some clear thinking about the results that we are trying to achieve, and the necessity of the expenditure proposed as a means of achieving those results. He quoted with approval questions asked by Prof. B. R. Williams in an article on "Capacity and Output of Universities", published in May 1963 in *The Manchester School*. Dr. Carter himself was manifestly prepared to consider the possibility of a longer teaching year if work is programmed to give members of staff uninterrupted periods of research. Quite apart from any possibilities which research into teaching methods may indicate, he was also open-minded on the length of the academic day and believes that there may be educational advantage in devising a teaching day in which formal teaching, private study, social contacts and recreation are well mixed, with no long periods allocated to any single activity.

Dr. Carter is too wise to overstrain the argument for economic efficiency but he and Prof. Williams believe that it is possible, without detriment to academic autonomy or quality, to give a university some direct incentive to think of ways of using its buildings and equipment most efficiently. Higher education cannot be considered in complete isolation from the economic life and position of the nation, and that in itself is sufficient reason for looking at university expansion in the light of the first of a series of investigations coming from the Ministry of Labour's Man-power Research Unit. This examination surveys Britain's future man-power resources, describing the expected changes in the size and structure of the working population, and then attempts to forecast future employ-

* Ministry of Labour, Manpower Studies No. 1: *The Pattern of the Future*. Pp. 52. (London: H.M.S.O., 1964.) 4*s*. 6*d*. net.

ment trends in the different groups of industry and the distribution of man-power between broad sectors of the economy, before finally considering the main implications for policy. It is essentially concerned with the national level and does not deal with regional employment problems, providing, however, the national setting within which examination of regional employment problems may be made.

First, the Study points out that, while between 1958 and 1963, in spite of unusually large numbers of school-leavers and immigrants, addition to the working population barely kept pace with the rising numbers of those outside it, in the next five years it is expected that they will fall short by a considerable margin, and after that the gap will widen. In the decade 1963–73 the estimated increase among those at work will be only one-third of the increase in the remaining population. Accordingly, the growing volume of goods and services needed to maintain and raise our general standard of living must come from relatively few extra people at work. This not only implies that productivity must increase at a faster rate even if it is to maintain the present rate of improvement in standards of living, but it implies also a two-sided challenge to all institutions of higher education, to teachers and students alike. To use man-power—or woman-power—efficiently is as imperative as to provide more efficient and highly trained man-power and woman-power in the first instance. The note of responsibility is unmistakable and unavoidable.

Of the detailed examinations of the manufacturing or services sectors of the economy set forth in the survey it should suffice here to note that employment in chemicals and in iron and steel, which has tended to rise over the past decade, may tend to level off. Moreover, in several other expanding sections—food, drink, tobacco, the large engineering groups and the paper and printing industries—the rate of growth may be slower. The decline in the textiles and clothing group is expected to moderate, and in many other industries no major changes of trend are foreseen. In services, the largest increases are expected in health and education services and in distribution, though with some retardation of the rate of growth for the last-mentioned. In financial services, the rapid growth of business is expected over the next five years to outweigh the effect of introducing computers and an increase is also expected in employment in public administration. One detail to be noted in the present context is that employment in educational services increased by 44 per cent, about half this being in the last four years of the decade, and in these services the proportionate increase for men was slightly larger than that for women.

The four remaining groups—agriculture, forestry and fishing; mining and quarrying; the construction industries; and the public utilities—have little in common and show widely different trends. For the first group a continuing decline in employment over the next few years is forecast, and a similar continuing decline is expected in the coal industry, as well as in the mining and quarrying group as a whole. In the construction industries, employment is expected to continue at least at its present level, but some increase in the labour force may well be required even allowing for substantial rises in productivity. Employment is expected to increase, but more slowly, in the electrical industry, but the gas industry is expected to meet increasing demand with a somewhat smaller labour force.

A feature of the forecast is the stability expected in the share of employment represented by manufacturing industry, which over the next five years is expected to stay at about the level of 1963, or just more than 9 million in 1968, when more than 11·5 million are forecast in the services sector and about 3 million in the rest of the economy. The increased percentage share of the services sector is likely to be mainly at the expense of the rest of the non-manufacturing sector. Since between 1963 and 1968 the working population is expected to be growing at a rather slower rate than hitherto, it is probable that, taking account of technological changes already operative or known to be in prospect, the needs of an expanding economy will at least provide the sufficient number of jobs for the foreseen increase in the number of workers.

Accordingly, the Study concludes that total man-power resources are unlikely to be more than adequate during the period and the efficient and flexible use of man-power will continue to be of the greatest importance. At times of peak demand labour shortages comparable with those of recent years may well occur unless active steps are taken to prevent them. Further, while opportunities of employment for women may expand slightly more rapidly then those for men, the distribution of the labour force as between the sexes is likely to remain unchanged. The only major alteration expected in its structure is a fall in the number of single women and girls, matched by a corresponding increase in the number of married women. Pressure on female labour resources may be particularly strong, and the increasing proportion of the labour force over 45 years of age will necessitate greater readiness to retain or engage older workers.

It was outside the scope of this Study to consider the implications for education and training of these changes or of the continuing rise in the proportion of 'white-collar' workers in manufacturing industry, but no responsible administrator in education at any level can disregard those implications, whether in respect of the courses and education to be given or the demand for services made on the economy. Efficient utilization of man-power, the report reiterates, will become even more essential if the task of maintaining and raising the general standard of living is to be achieved with a labour force which will be smaller in proportion to the total population. Not only will the development of automation and of any other means of increasing productivity assume increasing importance and, even be stimulated by the shortage of labour, but also other factors, such as the decrease in the number of young people entering the labour market, will call for adjustments, while simultaneously tending to make the labour force less adaptable and flexible. The continuing rise in the number of married women employed will enhance the need for mobility among the rest of the working population.

These are all factors or trends of which due account must be taken in the shaping of educational policy and in the allocation of resources for education, nor is this picture of tightly stretched man-power resources likely to change significantly after 1968. Indeed, up to 1973 it is more likely to be intensified, and although, admittedly, at this range forecasts of employment are hazardous, the very slow increase in the labour force during this period suggests that overall shortage is much more likely than a surplus, and man-power resources may well be more severely strained after than before 1968. For that reason alone the expansion of education should be planned with prudence and with regard not merely to the imperative

need to equip the rising generation more effectively to cope with the problem of living in a technological and rapidly changing world but also to the resources which can in practice be made available for that task.

This is not to deny the responsibility of the State for the education of its young—or older—citizens. It is to assert that that responsibility must be discharged realistically, with an imaginative understanding of what is required, as well as with a keen appreciation of the nation's resources for the task and of the opportunities which will be available for those it educates and trains at particular levels. It means that educational policy must provide a firm basis in the schools which equips the young citizen with some understanding of the world in which he lives, encourages responsibility and adaptability and provides an appropriate starting point for particular technical or professional training later. It must also ensure that the provision of training for technicians, craftsmen and others is not only appropriate but also on a scale sufficient to permit the most efficient use of the more highly trained technologists, scientists or other professional workers when they will be called on to assist, and equally that the facilities for such higher education are both adapted to their purpose and on a scale commensurate with the resources and the needs of society. The quantitative aspect should never be entirely disregarded in a realistic educational policy, for to do so is indeed a grave disservice to the interests of the individual himself. Both Mr. Consolazio and Dr. Carter have given timely warnings of the danger of an unlimited and idealistic expansion of higher education which pays insufficient attention either to the resources available, to the capacity of the student or to opportunities open to him or her when trained.

BRITISH BUSINESS SCHOOLS

THE report on *British Business Schools* made by Lord Franks* last November (see *Nature*, 201, 1252; 1964) has been followed by one from a Working Party†, set up towards the end of December 1963 with Lord Normanbrook as chairman, by the Federation of British Industries. The object was to establish the acceptance by the universities concerned, by the University Grants Committee, and by industry and commerce, of the principles of partnership recommended by Lord Franks. The Working Party was to work out a capital budget, as well as an operating budget, and, on this basis, to chart out the financial requirements for each school, and establish a recommended basis of sharing the provision of funds. Lord Franks's recommendation that each of the two business schools should provide a one-year course for 200 postgraduate students and two post-experience courses annually, each for 100 students, giving a maximum of 300 students at any one time at each school, was accepted by the Working Party, together with the assumption that these post-experience courses should last 20 weeks. Without challenging Lord Franks's assumption that the courses would be most valuable if wholly residential, it was concluded that it would be unrealistic to plan on the basis that all students would be in residence, and the Working Party has assumed instead that only 50 per cent would be residential. Further, while the School at Manchester would, from the outset, be an integral part of the University, in London certain constitutional complications might be avoided by establishing the School in the first instance as an independent institution, although it would be sponsored by the London School of Economics and the Imperial College of Science and Technology, and would draw on their resources.

The capital cost of establishing a business school is estimated at £935,000 apart from the site. In Manchester the total capital expenditure is unlikely to exceed £1 million, but in London the cost of acquiring and clearing a suitable site may bring that figure to between £1·18 and £1·43 million. The recurrent expenditure is estimated as rising from £118,500 in the first year to £300,000 when the school is at full capacity in the eighth year, by which time the income of £134,000 should bring the recurrent cost to £166,000. The Working Party did not consider the detailed curriculum, but discussions on the purpose of the instruction to be given and the general content of the curriculum showed no substantial differences of view, on either methods or purposes, between the two Universities and the business interests represented on the Working Party.

The Working Party is in full agreement with Lord Franks's general description of the purpose and function of the business schools, to promote business and industrial efficiency by ensuring a larger supply of managers and potential managers familiar with the new techniques and tools of management, and trained to foresee and decide well in swiftly changing situations. It suggests, however, that emphasis should be given in the curriculum to the importance of acquiring a thorough knowledge and understanding of financial controls in a business organization, and it also hopes that the courses will be designed to inculcate a strong sense of cost-consciousness, which in the Working Party's view is needed in non-profit-making as well as in profit-making organizations. Further, while endorsing the proposals that the courses should aim to attract students between 28 and 35 years of age, it hopes that the average will be nearer the younger than the older end of the range, and it is believed that a course of this kind would be of most value to a man who has spent about ten years in industry. The schools may well decide later to offer other kinds of courses for older and more experienced people, and the Working Party observes that the facilities available must be capable of adjustment to meet such changes in demand.

The Working Party has thus not accepted the assumptions of Lord Franks's report uncritically or without constructive suggestions. It should be noted also that, as Mr. Stephen Aris has pointed out, in describing an enquiry into the present state of management education in Britain which he recently broadcast in the B.B.C. Third Programme (see *The Listener*, 982; June 18, 1964), while both industry and Government have officially accepted Lord Franks's broad proposals, some of his detailed suggestions and even some of his basic principles are being strongly challenged among business men and

* British Institute of Management. *British Business Schools:* Report by the Rt. Hon. Lord Franks, P.C., G.C.M.G., K.C.B., C.B.E. Pp. 20. (London: British Institute of Management, 1964.) 5s.

among management teachers at the universities and elsewhere. Further, while repeated emphasis is placed on the importance of efficient management from many points of view both in industry, for example, by Lord Bowden, and in Government, as in Prof. G. Devons's broadcast talk, "Economic Management in Whitehall", the subject is attracting attention in many different places. A sentence about university training in Mr. S. P. Chambers's Chuter Ede Lecture on education and industry (*Nature*, 203, 227; 1964) was widely quoted out of its context, and one of the most interesting passages in the fifth report of the Estimates Committee, *Treasury Control of Establishments* (*Nature*, 203, 797; 1964), is that containing Sir Ronald Holroyd's evidence on the recruitment and training of staff by Imperial Chemical Industries, Ltd. It is also not without significance that, in launching a new *Business Supplement* on September 27, the *Sunday Times* included a long article on recent changes in the organization and administration of that firm, the trend of which is strikingly in line with the emphasis of Lord Normanbrook's Working Party on financial control and cost-consciousness.

Mr. Aris points out that while it is to-day widely recognized that there is urgent need for the manager to acquire a professional approach to his job, most British managers have only a sketchy idea of the tools available to them, and as yet have made singularly little effort to find out. Nevertheless, there are still those in industry who stoutly maintain that management is unteachable, that it is an art, not a science. Obviously, the answer depends on what you mean by management, and the academic approach has its limitations, as Dr. R. W. Revans, professor of industrial administration at the Manchester College of Science and Technology, admits. When the techniques have been learned, the problem is to apply them in a factory. Dr. T. Lupton, of the Department of Industrial Administration, Birmingham College of Advanced Technology, thinks that management teachers try too hard to persuade business that they can solve its problems, whereas what they have to offer is something which business men can use in solving their problems themselves. Moreover, industry is entitled to be concerned over the close linking of the two business schools with universities unless its teachers have some degree of practical business experience.

The need is for teachers with both the necessary intellectual skills and the practical experience, and in Britain we are now paying for the long years of neglect in which quite unnecessary obstacles were created to the movement of men between industry and the universities and colleges of technology. Dr. Lupton does not regard the problem as insoluble though it will not be solved by the offer of high salaries alone. More may well depend on how far the universities are able to undertake research in this field, and the co-operation of industry is essential if teachers are to gain the necessary experience.

Apart from a reference to the desirability of efforts, parallel to the establishment of the two business schools, to establish management studies as part of the accepted structure of teaching and research in a number of universities, Lord Franks ignored this aspect of research, and Mr. Aris notes that it is primarily the members of the newer universities and the colleges of advanced technology who recognize that industry offers a legitimate field for intellectual enquiry. Some of them, however, have reservations as to the effect on their own institutions of an attempt at this juncture to build up two new schools almost from ground level, and would prefer to develop existing resources as the more economical policy. Here again it is a matter of man-power resources and of the limitations imposed by earlier neglect and lack of foresight.

Apart from these wider issues, it is clearly important for both industry and the universities, as both Mr. Aris and Dr. Lupton suggest, to consider even more closely the precise nature of the contribution which the schools can and should make. In addition to hard constructive thinking about the content of courses, industry must also take the development of management much more seriously. Some firms like Pilkington's, the glass manufacturers, already recognize that responsibility for training managers does not begin and end by selecting suitable men and sending them to a business school. Steps must be taken also to broaden the general outlook of the trainees, and here management courses at technical colleges and in the economics departments of universities and colleges of technology, as well as management consultants, may have something to offer. Part of the whole process is the selection and internal movement practised by Imperial Chemical Industries, Ltd., which Sir Ronald Holroyd described to the Estimates Committee.

With all this must go clear ideas as to the type of manager for which particular courses are designed, and it may well be necessary to take a fresh look at the functions of such an institution as the Administrative Staff College at Henley. Moreover, Mr. Aris made a sound point in emphasizing the need for an attempt to ensure that even the middle ranks of management are fully aware of the implications of new skills and developments, socially as well as technologically: much unrest in industry is the result of ignorance rather than of ill-will. Lord Bowden made rather a similar point in emphasizing the importance of research into the problems of society, though in his enthusiasm for vocational education he tended to suggest that an appropriate expansion of technological education is all that is needed. Certainly, Prof. Devons did not suggest that, whether in Government or in industry, techniques alone are sufficient, and, without being dogmatic as to the precise structure required, he was emphatic that much more attention should be paid in Whitehall to the selection and training of managers.

Mr. Chambers's lecture, "Education and Industry", is particularly significant against just this background, for he was concerned neither with academic education nor with vocational training but with the development of character, especially of all those elements which enable a man to work effectively and harmoniously with his colleagues. He recognized that the inculcation of moral values was also important, though he was not concerned specifically with this or with the equally important acquisition of knowledge, the development of the power of thinking and reasoning, or with specialized vocational training. He was concerned primarily with such characteristics as the capacity to evaluate factors and reach firm decisions; to control other men fairly and firmly and win their confidence; to delegate responsibility and to tolerate errors of judgment in subordinates within reason and without inquests; and to take firm action, however unpleasant, where the standard of performance has fallen below the tolerable limit.

Mr. Chambers pointed out that training in the principles of management at a later stage would not convert a timid man into a man of decision. It was in this context that he remarked that life at a university, with its intel-

lectual and inconclusive discussions at the postgraduate level was, on the whole, a bad training for the real world, and only men of very strong character could overcome this handicap. He was not attacking university education but directing attention to certain shortcomings which are often ignored—for example, in the 1963 Reith Lectures—and to which little attention is directed in planning the expansion of higher education. If, as Mr. Chambers reminds us, brilliant academic achievement is frequently linked with poor judgment, indecisiveness and incapacity to delegate work or control men, while the positive characteristics are frequently found in men with second- or third-class degrees, are we wise to attempt to channel so much talent into university institutions to the neglect of colleges of technology and other institutions of further education ?

Mr. Chambers's lecture is important for the questions which it raises and on which the Robbins Report scarcely touches, and these questions have a significance which is far from being limited to training for management. It has implications for the universities themselves, and although the Robbins Committee, like the University Grants Committee, recognized the importance of character training, little attempt is apparent in working out the implications. Certainly it would be hard to find in Dr. Sloman's Reith Lectures any satisfactory discussion of either the development of character or of the related problem of discipline.

Mr. Chambers's lecture was thoroughly realistic on both these issues and he showed just where we are heading if we fail to devote a good deal more attention to problems which are often highly unpopular. Besides this emphasis and its call for hard constructive thinking, as in his reference to the importance of education for management, his remarks on applied science deserve to be widely read. Mr. Chambers has no use for the arrogance which regards pure science as of a higher order of intelligence than applied science. The combination of powers of intellect and judgment required for applied scientific work by brilliant scientists struggling with a specific objective may not be possessed by the pure scientist who looks down on them, nor will that scientist understand how much harder is the task of working successfully in a team than the individual attack on abstract problems, just as he will also fail to appreciate the importance of problems of management or team-work generally.

This spirited defence of applied science is important and timely, and while it includes a plea for greater respect for efficient management in the context of management generally, the importance of Mr. Chambers's address lies in its reminder that if the new business schools are to be assured of a continuous supply of suitable students, we must see that the foundations are firmly laid in our educational system as a whole. Whatever changes in the staffing or methods of our universities may be desirable, we cannot wait until the student enters the university or the college of technology before coming to grips with the related problems of discipline and the development of character. A start must be made in the schools, which must share the responsibility with the universities and the other institutions of higher education. Unless, indeed, this responsibility for the training of character is fully and speedily recognized and appropriate measures taken with real determination, neither the institution of business schools nor the expansion of higher education is likely to provide Britain with the managers, the men or the sense of purpose that is needed.

EXPERIMENTAL AND THEORETICAL TWINNING OF CRYSTALS

Mechanical Twinning of Crystals

By M. V. Klassen-Neklyudova. Authorized translation from the Russian by Dr. J. E. S. Bradley. Pp. xiv+213. (New York: Consultants Bureau, 1964.) 19.50 dollars.

MECHANICAL Twinning of Crystals provides a good comprehensive review of experimental and theoretical work on the twinning of crystals. As with other publications of this kind, its particular advantage lies in its up-to-date survey of Russian work in this field.

The ground covered by the book is more extensive than the title at first suggests. In addition to a full treatment of the fundamentals of mechanical twinning there are interesting chapters dealing with martensitic transitions, recrystallization twins, and lattice re-orientation in inhomogeneous deformation (kink bands, deformation bands, etc.).

The book is divided into three parts. The first part deals with experimental data on mechanical twinning from the point of view of twin geometry and crystallography. A clear and detailed exposition of the geometrical laws and the methods for determining the twinning elements in the different crystal systems is given. Methods of producing mechanical twins in crystals are dealt with and there is an interesting account of elastic twinning in crystals. Short chapters deal with twinning without change of form in quartz and with the role of mechanical twinning in plastic deformation and fracture. The latter is very brief and confined mainly to Russian work on this subject. The second part of the monograph considers effects related to mechanical twinning such as recrystallization and martensitic changes. In this section, too, there is a good account of large-angle re-orientations accompanying inhomogeneous deformation. The final part of the book deals with the theory of twinning and has a chapter on twin growth considered in terms of the macroscopic theory of elasticity, and a chapter on atomic and dislocation models of twinning.

Appendixes contain tables of twin elements for metals, alloys and non-metallic crystals. There is also a short review prepared by V. I. Startsev for the English edition of selective dislocation-etch methods for examining the twinning mechanism in calcite.

The monograph is primarily a review and as such it is a good one. It is concise, possibly too concise in parts; on the other hand, the field dealt with is large and it is better in a work of this kind to provide references (there are more than 500) than to repeat the arguments in full. The book is intended for research people already working in the field. Someone new to the subject would benefit, however, from the introductory chapters dealing with the fundamentals of twinning.

The book is well produced and illustrated and the translation reads smoothly. Its publication in English is to be welcomed, but it is a pity that it should be so expensive.

J. H. BRUNTON

TUMOURS OF THE HUMAN ENDOCRINE GLANDS

Human Tumours Secreting Catecholamines

Clinical and Physiopathological Study of the Pheochromocytomas. By Prof. Henri Hermann and Prof. René Mornex. Translated by Dr. R. Crawford. (International Series of Monographs on Pure and Applied Biology, Vol. 23.) Pp. xiii+207. (London and New York: Pergamon Press, 1964.) 60*s*. net.

TUMOURS of the human endocrine glands that are not easily detectable by clinical means usually secrete abnormal quantities of their characteristic hormone, and

are thus open to detection by chemical or biological tests. Interest in these tumours is consequently shared by physiologists and clinicians. *Human Tumours Secreting Catecholamines* deals with the phæochromocytomas; the adrenaline and noradrenaline secreted in more than normal amounts produce effects in the human body which are familiar to the physiologist from his animal experiments, and which assist the clinician in diagnosis. It is thus appropriate that this investigation should be the result of collaboration of a physiologist and a physician. It represents about 30 years of investigation of the subject in the School of Medicine at Lyons. The authors have collected details of more than 500 published cases, and the various aspects discussed are illustrated by reference to appropriate patients.

The most obvious manifestations of these tumours are cardiovascular, with paroxysmal or sustained hypertension, as might be expected from the hypertensive action of adrenaline and noradrenaline. Hypertension is such a common symptom that the difficulty is to detect the relatively small number of cases in which it is due to a tumour of chromaffin cells. There are excellent chapters dealing with the various manifestations, cardiovascular, metabolic, and endocrine; and unusual clinical forms, for example, asymptomatic cases in which the adrenomedullary tumour may remain latent throughout life, only to be discovered at operation or autopsy. These tumours of chromaffin tissue may be single or multiple, confined to the adrenal medulla or ectopic (developing from embryonal rests); all these are well described in the chapter on anatomical forms. The most important chapter is that on diagnosis, an aspect which is often difficult because of the diverse symptoms produced by the tumour.

Profs. Hermann and Mornex stress the importance of interrogation and clinical examination. But from their experience of a large number of urinary catechol estimations, they are struck by the number of cases in which the clinical diagnosis of a tumour has to be rejected on the laboratory evidence. This is a general experience of those carrying out tests. The authors point out that no single technique is sufficient for complete investigation; they favour the estimation of urinary catecholamines, first by a biological method using dogs, followed by chemical methods for vanillyl mandelic acid or other methoxylated derivatives, and for the most accurate estimations the fluorimetric (trihydroxyindole) method.

Pathological anatomy, biological investigations, and physiopathology are dealt with in the concluding chapters. One would like to have seen more mention of the neuroblastomas, the other human tumours that secrete catecholamines. The 500 cases are listed in a table, with references, and all statements are supported by references to the literature contained in a bibliography of 800 papers. By contrast, the subject index is so brief as to be of little value. The translation reads well. This book is a most excellent and comprehensive treatment of the subject.

A. B. Anderson

VITAMINS AND COENZYMES

Vitamins and Coenzymes

By Dr. Arthur F. Wagner and Dr. Karl Folkers. Pp. xvi+532. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1964.) 132*s*.

THIS volume, which derives from the extension of a chapter on vitamins in the second edition of *Medicinal Chemistry* (Burger, 1960), is introduced by a discussion of the evolution of the vitamin theory—appropriately headed by Sir Frederick Gowland Hopkins's comment: "No general or widespread belief in the view that an adequate diet must contain indispensable constituents other than adequate calories, a minimum of protein, and a proper mineral supply, could be said to exist until the years 1911–12". After the historical introduction, the known activities and the nomenclature of vitamins are outlined before the main thesis of coenzyme connexions is explored. The earliest recognition of coenzymes related to vitamins was in the investigation of thiamine metabolism and of cocarboxylase. The consideration of coenzyme activity is preceded in the chapter on thiamine, as in succeeding chapters, by an account of the isolation, chemical identification and synthesis or biosynthesis of the vitamin. Nutritional and therapeutic investigations in animals and man are included as a final section for every chapter.

Within the framework thus designed, a useful and comprehensive account is given of many highly diverse biological systems. The vitamins of the B complex participate in many enzyme groupings and work in the field of B vitamins has been the main source of the expanding knowledge of coenzyme structures and activities. The original naming of diphosphopyridine nucleotide and triphosphopyridine nucleotide as coenzyme I and coenzyme II is an example of the basic importance of B vitamins in the coenzyme field. With the recognition of the role of pantothenic acid as an integral part of the universally important coenzyme A, a further wide field of metabolic investigation was opened in physiology, medicine, nutrition and microbiology. With pyridoxine and codecarboxylase, another step was taken towards the elucidation of the biochemical mechanisms essential to life from the cellular level up to the higher organisms. Biotin, which for many years was mainly investigated in relation to so-called "egg white injury" and then as a bacterial growth factor, has now emerged as an essential part of the "activated carbon dioxide" in the acetyl coenzyme A carboxylase system.

Folic acid and its array of derived pteroylglutamic compounds is another important field and so is cyanocobalamine with cobamide coenzymes related to vitamin B_{12}. The chapter on lipoic acid is very useful since it is not easy to find a full and satisfactory account of this recently discovered factor elsewhere in the literature.

For the fat soluble vitamins there were few clear coenzyme connexions known until the discovery of coenzyme Q or ubiquinone related to vitamin A. The review of the ubiquinone group provides a good final chapter to round off a valuable contribution to the biochemistry bookshelf. Though the emphasis of the material is essentially biochemical, the nutritional and therapeutic roles of vitamins and coenzymes are discussed so that *Vitamins and Coenzymes* serves as a reference source for many disciplines.

The way in which chemical and structural formulæ are presented is very good. The book can be recommended for advanced biochemical teaching though it is probably too chemical for medical students. For biochemical and nutritional research it is invaluable, since it covers most recent literature and presents a balanced review of the vitamin field. As the authors state in their preface, omission of material inevitably occurs, deliberately or inadvertently, but the whole picture is undoubtedly well conveyed.

A. M. Copping

THEORY AND PRACTICAL IMPLICATIONS OF QUANTITATIVE INHERITANCE

Quantitative Genetik

Von Gunnar Eilert Hiorth. Pp. viii+467. (Berlin: Springer-Verlag, 1963.) 86 D.M.

QUANTITATIVE Genetik covers the theory and practical implications of quantitative inheritance, and students with a moderate knowledge of German will

find that it is a useful introductory text in this field. The greater part of the illustrative material used in the book is taken from research work on crop plants and, unlike most other modern books on the subject, the author's approach is non-mathematical.

The treatment is a description of the biological basis and practical utilization of quantitative variation rather than a statistical interpretation of the genetical basis of quantitative inheritance. Indeed, anyone interested in the latter approach would find the volume particularly disappointing. For example, the absence of a serious discussion of Mather's contributions to biometrical genetics and of his theory of polygenic inheritance is to be regretted in a book of this kind. Furthermore, the lack of treatment in depth of the basic tools and concepts of quantitative genetics, such as variance analysis, heritability, the variance analysis of diallel crosses and the coefficient of inbreeding, is an unfortunate omission in a specialist text-book on quantitative genetics. Advanced students of genetics will therefore find the treatment incomplete, but for non-specialists in biology and agriculture, the numerous examples and detailed description of methods supply a thorough basic understanding of the characteristics of quantitatively inherited variation.

The first three chapters are devoted to a historical introduction, to elementary statistics and to the basis and general nature of quantitative variation. Chapter 4 is a valuable assembly of detailed summaries of the behaviour of some of the best-known examples of quantitatively inherited characters in plants. The eight chapters which follow present the genetic basis of quantitative variation including: gene conversion, cytoplasmic and environmental effects, gene interaction, heterozygosis, allelic frequencies, gene mutation, correlated characters, the effect of competition on quantitative characters in populations of inbreeding and outbreeding species, the effects of inbreeding and the genetic basis of inbreeding depression. Regrettably, however, neither additive gene action nor directional dominance is discussed in connexion with the latter. Three chapters are devoted to selection where the emphasis is on description of methods of selection, particularly those used in plant breeding. There is also some discussion here of the principles underlying selection of quantitative characters such as heritability, the response to selection and correlated response (*nebeneffekte der Selektion*), but, in general, the treatment is rather brief and sketchy.

Heterosis is discussed at length in three chapters, one of which describes the methods used for the isolation and testing of inbred lines for superior combining ability in hybrids. Chapter 19 is a miscellany of breeding methods additional to those covered in previous chapters, including gamete selection, polycross testing, synthetic varieties and the utilization of male sterility. Finally, a very short chapter is devoted to "The System of Variability", and a concluding chapter recapitulates some of the main themes. There is a useful bibliography appended to each chapter, and the text is well supported by numerous tables and figures, and by author and subject indexes.

WATKIN WILLIAMS

DEVELOPMENT OF A BIOLOGICAL THEORY

Heat and Life

The Development of the Theory of Animal Heat. By Everett Mendelsohn. Pp. x+208. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1964.) 36*s*.

AT the present time, when the volume of scientific literature is increasing at an overwhelming rate, less and less attention is paid to material and ideas published before the turn of the century. It is therefore very refreshing to trace the history of an important biological problem to that point in time when most modern developments take root. The choice of animal heat as a subject has been made carefully in order to provide a biological problem which has occupied the minds of philosophers and scientists since the earliest times and also one where the development of theory has been linked with advances in physics and chemistry. The problem of the origin of body heat is ideal for this purpose and, using it, the author sets out to investigate how far the reduction of a biological phenomenon to a physical analogue has been useful in biology.

The history begins with the Ancient Greeks who believed in a vital heat which burned in the heart. Even at this early stage, long before the experimental approach was used, a connexion between body heat and true fire was postulated, the breath serving both to cool the fire and fan the flame while food provided the fuel. No attempt was made, however, to put forward a physical or mechanical explanation for the warmth of the body, innate heat being regarded as mysterious and in some way akin to the heat of the Sun.

These, and similar views, were held until the seventeenth century and the beginnings of modern science. At this time Harvey, while still keeping the idea of an innate heat, suggested that the blood served to transport this heat about the body. In his later works the concept of innate heat lost for Harvey a little of its mystery and he tended to regard it simply as a property of blood. Descartes also held ideas about animal heat and he advanced a theory of the heart's motion based on the expansion of the blood as it entered the heart which was, he believed, extremely hot. In these notions Mr. Mendelsohn sees the first willingness on the part of man to explain the action of the body in mechanical terms, and he traces the development of theory through Willis, van Helmont, Hook and Boyle. As he points out, the changes in biological theory at this time were related not so much to new information as to a new approach to the problem.

The next phase of development, in the later seventeenth century, consisted in further attempts to relate combustion and animal heat, and in the beginnings of the experimental approach. During this period Borelli was at least able to show that there was no burning heat in the heart. The emphasis then shifted in the early eighteenth century towards a mechanical explanation based on the heat of friction generated as the blood passed through the blood vessels. In spite of several attempts at measurement and calculation this period produced a great confusion of thought which, in Mr. Mendelsohn's opinion, stemmed partly from the lack of instruments and techniques but mainly from the primitive state of chemical and physical theory. The principal difficulty lay in the confusion of temperature with quantity of heat.

The step which was needed to form the basis of modern theory was made by such men as Black, Crawford and Lavoisier, who finally established the connexion between combustion and metabolism and recognized the importance of blood in the transport of oxygen and carbon dioxide. In the latter part of the book the author directs attention to the circumstances which made Lavoisier's ideas acceptable while similar theories had failed in the past. He concludes that progress in the theory of animal heat depended simply on progress in physics and chemistry, and suggests that further development was made because scientists were able to deal with the body in parts, regarding the blood, for example, simply as a liquid. The advances made since the time of Lavoisier are not mentioned, being the subject of a further investigation by Mr. Mendelsohn.

Throughout the book there are numerous footnotes and references to writers of every period, and it is evident that the text is based on an extensive reading of the literature. The book would be useful reading for any student of biology.

D. L. INGRAM

ARCHITECTURE, TECHNOLOGY AND SOUTH KENSINGTON*

By Sir WILLIAM HOLFORD
Professor of Town Planning, University College, London

THE first nucleus of the present Imperial College of Science and Technology, London, came into existence in 1845 as the Royal College of Chemistry, and during that century despite the coming together of a number of scientific and teaching institutions—such as that which led to the establishment of this federated College in 1907—there have been continuous demarcations of subject and of professional practice.

One of the technologies which has taken a forked path has been that of construction; and now that the two directions taken by civil engineering and architecture are becoming once again parallel, or actually converging a little, it is interesting and revealing to trace some of the major changes of attitude that have occurred on the way from *A* to *B*.

I need not go back to the mid-seventeenth century when that experimental philosopher, Christopher Wren, having graduated bachelor of arts at the University of Oxford and carried out applied research in physiology and physics, became Gresham and then Savilian professor of astronomy before he became Surveyor of Works and what we now call an architect. Yet it is interesting to note that Wren, in drafting the preamble of the Charter granted by Charles II to the Royal Society of London, stressed the social value of the arts and sciences, both in theory and application.

Let me start instead at the early nineteenth century, when modern technology begins and when professions were emerging, other than medicine and the law, concerned for the first time with machines and with the application of scientific techniques to industry and commerce. Above all things at that time the new professional associations desired to achieve respectability and integrity. I stress the professional association because this has been powerful in architectural education from the very beginning and still gives a special flavour to the Architectural Association School in Bedford Square. In 1820, the embryonic Institution of Civil Engineers wrote from Gilham's Coffee House to Thomas Telford, Esq., Fellow of the Royal Society of Edinburgh, an invitation to "... patronize the Institution by taking on himself the office of President to the same". They declared its objects as being "... to facilitate the acquirement of knowledge in engineering; to *circumscribe the profession*; to establish in it the respectability which it merits; and to increase the indispensable public confidence". Telford accepted, and in his inaugural address the following year he shrewdly observed that talents and respectability are preferable to numbers. No doubt he recognized that the public, grown somewhat suspicious of lawyers and physicians, were not inclined to favour further professional associations. "From too easy and promiscuous admission", he said, "unavoidable and not infrequently incurable inconveniences perplex most societies."

Certainly there were a number of inconveniences perplexing the architects at this time, and perhaps they helped to lead them away from Telford and Brunel and into a deep cutting of their own. During the previous century they had achieved recognition as designers of buildings and landscapes. But all their clients—and they were then a limited class—possessed what was termed a 'gentlemanly knowledge' on the same subject. More than a gentlemanly knowledge, as Lord Chesterfield said, would have been lowering in the eyes of the fashionable world. On the other hand, the execution of designs was undertaken by builders and craftsmen, who needed only the minimum of drawings, and could at a pinch produce, reproduce or adapt these themselves. So the architect's special function was most apparent when he worked as an original artist. When it came to professional association the architect, like the civil engineer, sought respectability, integrity and public recognition, but his activities were less easy to circumscribe. On one hand, he had to know how to enclose space for an infinite number of human purposes; he must be aware of the capacity of the crafts, the limitations and possibilities of building materials and structural methods. Above all, he must heed his client's wishes but meet his real needs, and the two did not always coincide. On the other hand, the architect had to maintain his autonomy as an artist, because this was the very quality that gave him professional distinction. Yet, unlike the painter or the musician, he could not put his ideas into execution without a client and a builder. He had to spend other people's money in order to express himself.

So, although it is rare in practice to find the skills combined in any one individual, the professional image of the typical architect had to become that of a man who was competent simultaneously as a business adviser, technician and artist. Thus, in 1834, the Virtuosi and the Dilettanti, the Incorporated and the Free Societies of Artists, gave way to the Institute of British Architects whose professed aims were very similar to those announced by the Engineers sixteen years earlier. They were "... to facilitate the acquirement of architectural knowledge. the promotion of the different branches of science connected therewith, and to establish an uniformity and respectability of practice in the profession".

Again the emphasis on respectability, but each profession pursuing it in its own way. At one end of the widening scale the engineer-contractor concerned himself with machines and with constructions for industry and commerce, communications and utilities; while at the other end the artist-architect became more and more interested in the individual and social uses of buildings, and the style and setting appropriate to them.

The year 1834 was remarkable for another turning point. A hundred and thirty years ago, last week, the Old Palace at Westminster was burnt down. Soon afterwards a parliamentary committee announced a competition for a new design "in the Gothic or Elizabethan style". This proved to be the central building of the Gothic Revival, a movement which you will see, from the announcement of another parliamentary committee earlier this year, has not yet spent itself. Yet the Houses of Parliament—"a triumph of the Picturesque", as Sir Kenneth Clark called them—made no contribution to technology, although they did a great deal to stimulate craftsmanship.

Meanwhile, the engineers were developing continuous beam theory, inventing 'tarmac' for roads, hydraulic power tools and Bessemer steel, constructing canals and docks, the Menai and the Saltash Bridges. In the decade after 1840 they built nearly 5,000 miles of railroad in Great Britain, which is more than can be equalled in motorway mileage to-day: and when in 1842 Chadwick published his famous report on "The Sanitary Conditions of the Labouring Classes", it was the engineers who became professionally and statutorily responsible for under-

* Substance of an address delivered before the Imperial College of Science and Technology on Commemoration Day, October 22.

ground sewerage, water supply and other municipal services. During the nineteenth century and until the First World War all the major technological advances were made by engineers and scientists. The products of the first machine age were assimilated into the architects' world mainly as services and pieces of equipment, which at first scarcely altered their approach to design. Looking back, for example, to the Great Exhibition of 1851—with which so much in South Kensington was connected—one may well think of it, in terms of architecture, as grotesque: and in its worst manifestations it was. Paxton's enormous, utilitarian and yet magnificent 'greenhouse'—the Crystal Palace—was in itself the precursor of a new movement ; but we can still be amazed at its contents—the objects illustrated in the catalogue, or found surviving (because of their sturdy craftsmanship) in ancient hotels. We can still be amused at the character that Dickens invented —Mr. Pecksniff. "Of his architectural doings", wrote Dickens, "nothing was clearly known, except that he had never designed or built anything ; but it was generally understood that his knowledge of the science was almost awful in its profundity."

At the other end of the scale, the true architects were striving to keep alight a fire to which the technologists had little time to attend. They were concerned to distinguish the human and social purposes of building, and having found them, to extend them. They were trying to adapt their art, and the patronage under which it had grown up, to industrialization on one hand, and a fast-growing population on the other. They were passionate about architectural scholarship, about symbolism, about ecclesiology, about restorations.

At this point I want to say something about the origins of the Architectural Association and its School, which wove itself into the pattern of events in the 1840's. Sir John Summerson's centenary history of the Association, 1847–1947, gives a fascinating account of the profession seen, as it were, from the gallery, or through a minifying glass. The Association was formed from a group of architectural draughtsmen stirred into action by certain young architects disgruntled at their lack of education under the apprenticeship system. In other words, it was formed by students. The students started a School of their own. "What is to prevent such", said one of the young founders, aged eighteen, "if a number of us put our shoulder to the wheel . . . ?" It is interesting to note that at the first meeting of the Association (October 8, 1847) one of the speakers was Prof. Donaldson, described by Summerson as "that versatile, kindly character who had created the role of Professor of Architecture in the University of London". So there was at the start a sympathy between the academic establishment of the day and the irregular, independent and unconventional School designed by architects, for architects, and supported by architects for the next 120 years. This is a remarkable record. If its future is to be linked with that of the Imperial College of Science and Technology* it is not to be expected that it should abandon its training methods or the independence which has given it such vitality in the past.

Moreover, it is likely to share with the new universities the characteristic of being student-based. Throughout its history the Architectural Association has never allowed its teachers to go to sleep in their chairs. The school has been a nursery of the profession and the Association has been and remains attached to it as a special—indeed unique—form of convocation.

Now, looking back, one can see that although the two main constructional professions had started out in the nineteenth century with the same public aims, their pre-occupations have long been dissimilar. I have often thought that divergences in their approach to design, by an architect and an engineer, date from this period. The engineer tends to simplify and reduce his terms of reference, so as to bring his problem down to essentials and make it soluble by calculation. The architect tends to enlarge his terms, relating his structure to its social or emblematic purposes, its setting among other buildings, its whole environment. He must, therefore, complicate his answer to a building problem with a number of value judgments ; although this does not mean that the process is undisciplined ; simply that many disciplines are involved. This is a generalization, of course, and, like all generalizations, it can be proved wrong in certain cases. Yet it is broadly true to say that in the nineteenth century the technologists were extending their knowledge in depth ; the architects in breadth. Sir Edwin Lutyens, who was the last of our great architects to design convincingly in the grammatical, renaissance tradition, could say as late as the 1930's that " . . . architecture with its love and passion begins where function is achieved".

In the context in which Lutyens used these words, I believe them to be profoundly true. The question is whether they are true any longer. Science, too, can be pursued with passion ; and it can study emotion scientifically; but it does not introduce it into the process of scientific enquiry. Architecture, on the other hand, must include emotional response as one of the conditions of its brief ; and it can only become significant at this level by means of solving a functional problem. At what point can we say, then, that function has been achieved ? This phrase of Lutyens's, to a modern architect, would be the equivalent of saying that you cannot have cake until you have had the bread and butter; that the two are separate commodities—as Marie-Antoinette is said to have remarked in a totally different context. Whereas the contemporary approach is an integrated one ; our aims are to make the bread so good that it is—in effect—cake !

Now if one thinks this is a mere play of words, let me say that for the first time since the eighteenth century architects and their clients are now beginning to use common standards of performance and of criticism. Let me also quote a very distinguished modern architect, Mies van der Rohe, who has worked and taught for many years in institutes of technology. In an address to the Illinois Institute: "Technology", he said, "is far more than a method, it is a world in itself, something that has a meaning and a powerful form—so powerful, in fact, that it is not easy to name it. Is that still technology or is it architecture ? And that may be the reason that some people are convinced that architecture will be outmoded and replaced by technology. Such a conviction is not based on clear thinking. The opposite happens. Wherever technology reaches its real fulfilment, *it transcends into architecture*. That is the reason why technology and architecture are so closely related. Our real hope is that they grow together, that some day the one will be the expression of the other".

Well, I have now told you, in the words of Mies van der Rohe, what to expect if architecture is taken in among the scientists and technologists. Your technologists, when they surpass themselves, will be adopted as architects. We have already done so in the case of a number of men of world repute, such as Pier Luigi Nervi of Italy ; and I hope this will be seen as the gesture of recognition that it is, and not as a piece of professional gamesmanship.

The advantages of a real *rapprochement* rest on more than philosophical points. There is the whole strategy of coming to terms with our environment, not only the external environment in which we live and work and take our leisure, but the mental environment in which we create ideas and exchange them. It has often been said —and Lord Brain, the physician, said it again this year in his presidential address to the British Association for the Advancement of Science—that " . . . the potentialities of science and technology for the benefit of mankind . . . are almost inconceivably great, but the preparations which we are making for their use and development are

* It is planned that the School of the Architectural Association becomes the fourth constituent College of the Imperial College of Science and Technology.

pitiably small". All of us can see that there have been conspicuous failures in population and traffic forecasting, in the planning of resources, in conservation, in the control of land-use and land-development and in charting the many ways in which the human being shapes his environment and is shaped by it. Perhaps this is due partly to the fact that we apply old unscientific habits of action to new scientific concepts, or that we read the wrong lessons from history, or that we fail to distinguish between public demand—particularly in its statistical or commercial forms—and social need. I do not know. But I am sure that a technological university must interest itself increasingly in human behaviour and in social control mechanisms, at the same time as it makes advances in the mechanical and natural sciences.

The results of skill and invention can, on the other hand, prove inimical to human health and happiness. The nuclear deterrent is an obvious example. Not only the scientists but also all those who think at all into the future know very well that its use has to be rigorously and comprehensively controlled and the social and political checks have to be considered along with the technical ones. In the same way, but on a different scale, the legitimate desire of individuals, families and firms to own and use a means of mechanical transport—in other words a private car—has been a stimulus to automobile technology and productivity, but has caught us unprepared to control the environment which the automobile has invaded. It was a car designer (Alec Issigonis) who said, "The car is going to contribute very largely to wrecking our civilization". In this field Imperial College has been percipient. It recognized that Prof. Colin Buchanan had done useful research into the nature of traffic and its effect on towns; and by appointing him professor of transport the College is enabling him to do more. It is precisely this extension of technology for the purpose of studying related problems of use, control, development and design, that could also make the architectural school, with its large and active professional association behind it, of great potential value to Imperial College.

NEWTON, HOOKE, AND 'BOYLE'S LAW'

(DISCOVERED BY POWER AND TOWNELEY)

By Prof. I. BERNARD COHEN

Chairman of the Committee on the History of Science, Harvard University, Cambridge, Mass.

A CASE can be made out for at least six claimants to the law relating the pressure to the volume of a confined gas at constant pressure: Robert Boyle, Viscount Brouncker, Robert Hooke, Edme Mariotte, Henry Power and Richard Towneley. Called in Great Britain and in the United States 'Boyle's law', and on the Continent 'la loi de Mariotte' or 'das Gesetz von Boyle und Mariotte' (with all possible variations), the law was first published by Boyle in 1662.

The first edition of Boyle's *New Experiments physico-mechanicall, touching the Spring of the Air* (Oxford, 1660) did not contain a statement of the law. It appeared first in the second edition, *Whereunto is added a Defence of the Authors Explication of the Experiments, against the Objections of Franciscus Linus, and, Thomas Hobbes* (Oxford, 1662)[1].

The claims of Boyle and Mariotte have often been discussed. Mariotte's claim was substantially dismissed by P. G. Tait some eighty years ago[2], on the grounds that Mariotte's account of the law (1676) follows Boyle's prior statement by fourteen (or, perhaps, seventeen) years, that Mariotte used apparatus almost identical to Boyle's, and that the comparison of compressed air and squeezed sponges must have been taken from Boyle by Mariotte. Tait concentrated on evidence that Mariotte may have known Boyle's book and be thus disqualified from a claim to the law. But this procedure ignores the possible grounds for attributing (or, for not attributing) the law to Boyle. Douglas McKie[3] presents convincing evidence that the traditionally assigned date of 1676 for the publication of Mariotte's essay "may have crept in by some misprint" and that "no date earlier than 1679 can safely be assigned to Mariotte's essay at present".

As to Richard Towneley, C. Webster has recently restated his claim[4]. Basically, Webster points out that Boyle was acquainted with the results of experiments on air at different pressures carried out by Towneley and by Henry Power in 1660–61. Although Webster makes out a very good case for the priority and influence of Richard Towneley and Henry Power, he does not give any evidence to support the claim (occurring both in the text and in the title of the article) that Towneley rather than Power, or rather than both together, deserves the credit for the law. From these experiments Power and Towneley concluded: "So that here is now four Proportionals, and by any three given, you may strike out the fourth". Hence it was possible to "prognosticate the effects, which follow in all *Mercurial* Experiments, and predemonstrate them, by calculation, before the senses give an Experimental [eviction] thereof". Rewriting this statement from Power's book in the language of proportionality, either as $PV = P'V'$ or as $P : V :: P' : V'$, we may see at once that any three of these quantities determine the fourth. In 1663—a year after Boyle had received the data and the generalization based on them of Towneley and Power and had published the law—Power published his own book on *Experimental Philosophy*[5], in which any reader could learn for himself the nature of the pre-Boyle stage of 'Boyle's law'.

The Towneley–Boyle relation was studied carefully in 1909 by Prof. E. Gerland[6], who concluded that, despite the suggestion made by Towneley, the credit for the law should be assigned to Boyle (and surely not to Mariotte). But Webster has added new evidence from the unpublished correspondence of William Croone to show that: (1) Towneley and Power actually sent their data and conclusion to Croone, who forwarded these to Boyle; (2) although Boyle mentions only Towneley's name (as do those who have based their accounts on Boyle's statement), the suggestion of the constancy of the product of pressure and volume should apparently be divided between Power and Towneley.

In his book on the *Spring of the Air*, this is what Boyle himself had to say on the subject:

> . . . I shall readily acknowledge that I had not reduc'd the tryals I had made about measuring the Expansion of the Air to any certain *Hypothesis*, when that ingenious Gentleman Mr. Richard *Towneley* was pleased to inform me, that having by the perusal of my *Physico-Mechanical* Experiments been satisfied that the Spring of the Air was the cause of it, he had endeavoured (and I wish in such attempts other ingenious men would follow his example) to supply what I had omitted concerning the reducing to a precise estimate how much Air dilated of it self loses of its Elastical force, according to the measures of its Dilatation. He added, that he had begun to

set down what occurred to him to this purpose in a short Discourse, whereof he afterwards did me the favour to shew me the beginning, which gives me a just Curiosity to see it perfected. But, because I neither know, nor (by reason of the great distance betwixt our places of residence) have at present the opportunity to enquire, whether he will think fit to annex his Discourse to our *Appendix*, or to publish it by it self, or at all; and because he hath not yet, for aught I know, met with fit Glasses to make an any-thing-accurate Table of the Decrement of the force of dilated Air; our present design invites us to present the Reader with that which follows, wherein I had the assistance of the same person that I took notice of in the former Chapter, as having written something about Rarefaction: whom I the rather make mention of on this occasion, because when he first heard me speak of Mr. *Townley's* suppositions about the proportion wherein Air loses of its Spring by Dilatation, he told me he had the year before (and not long after the publication of my *Pneumatical* Treatise) made Observations to the same purpose, which he acknowledged to agree well enough with Mr. *Townley's* Theory: and so did (as their Author was pleased to tell me) some Tryals made about the same time by that Noble *Virtuoso* and eminent Mathematician the Lord *Brouncker*, from whose further Enquiries into this matter, if his occasions will allow him to make them, the Curious may well hope for something very accurate.[7]

There are three comments to be made on this statement:

(1) Boyle mentions Towneley but not Power. This is explained by Webster on the basis of the title of the transcription made by Power and forwarded to Croone: "Additional experiments made at Townley Hall, in the years 1660 and 1661, by the advice and assistance of that Heroick and Worthy Gentleman, Richard Townley, Esqr. and those Ingenious Gentlemen Mr. John, and Mr. Charles Townley, and Mr. George Kemp". Clearly, as Webster points out, "Although the manuscript emanated from Power, it is quite possible that Boyle overlooked Power's part in the work, which would not be easily guessed from the title"[8].

(2) As to Lord Brouncker, Boyle hoped for "further enquiries", but actually none was forthcoming. Nevertheless, "some trials made at the same time" as those made by Boyle's assistant and collaborator, Robert Hooke, also agreed "with Mr. Townley's theory". Boyle gives no evidence to enable us to guess whether Brouncker's experimental results merely confirmed the relation discovered by Towneley and by Power and given in the equation $PV = P'V'$, or whether he had found the relation for himself. (There is no biography of Brouncker nor, so far as I know, any published examination of his scientific work except that of J. F. Scott and Sir Harold Hartley[9].)

(3) Boyle refers explicitly to Hooke's claim that when he had first heard Boyle speak of the "proportion" supposed by Towneley, he had stated unequivocally that he himself "had the year before (and not long after the publication of my pneumatical treatise) made observations to the same purpose". Hence Hooke allegedly obtained results which proved to agree with the Power–Towneley relation or 'Boyle's law' late in 1660 or 1661, and undertook further experiments to verify "Mr. Townley's theory" even before Boyle did so himself.

Hooke's experiments, and his conclusion "that the Elater of the Air is reciprocal to its extension, or at least very neer", are to be found in his celebrated *Micrographia*. The detailed description begins as follows:

> I had several other Tables of my Observations, and Calculations, which I then made; but it being above a twelve month since I made them; and by that means having forgot many circumstances and particulars, I was resolved to make them over once again, which I did *August* the second 1661. With the very same Tube which I used the year before, when I first made the Experiment (for it being a very good one, I had carefully preserv'd it:) And after having tryed it over and over again; and being not well satisfied of some particulars, I, at last, having put all things in very good order, and being as attentive, and observant, as possibly I could, of every circumstance requisite to be taken notice of, did register my several Observations in this following Table. In the making of which, I did not exactly follow the method that I had used at first; but, having lately heard of Mr. *Townly's Hypothesis*, I shap'd my course in such sort, as would be most convenient for the examination of that *Hypothesis*; the event of which you have in the latter part of the last Table.
>
> The other Experiment was, to find what degrees of force were requisite to compress, or condense, the Air into such or such a bulk.
>
> The manner of proceeding therein was this: I took a Tube about five foot long, one of whose ends was sealed up, and bended in the form of a *siphon*, much like that represented in the fourth Figure of the 37. *Scheme*, one side whereof AD. that was open at A, was about fifty inches long, the other side BC, shut at B, was not much above seven inches long; then placing it exactly perpendicular, I pour'd in a little Quicksilver, and found that the Air BC was 7/8 inches, or very near to seven; then pouring in Quicksilver at the longer Tube, I continued filling of it till the Air in the shorter part of it was contracted into half the former dimensions, and found the height exactly nine and twenty inches; and by making several other tryals, in several other degrees of condensation of the Air, I found them exactly answer the former *Hypothesis*[10].

Taking Hooke at his own word, we may conclude that by the summer of 1660 he had completed a series of experimental measurements on the volume and pressure of a confined mass of air, that on August 2, 1661, he "was resolved to make them over once again" and put his results in a form which enabled him to test "Mr. Townly's Hypothesis", of which he had "lately heard". These experiments had been made to ascertain the relations between pressure and volume when air expands (that is, at pressures less than one atmosphere), using a very original form of apparatus. But he also made experiments "to find what degrees of force were requisite to compress, or condense, the Air into such or such a bulk". The apparatus he devised was a J-tube of glass, of which the short end was sealed, into the long (open) end of which Mercury was poured. Having made several trials, he "found them exactly [to] answer the former *Hypothesis*".

It should be clear then that whether or not Hooke's early experimental results (1660) agreed with what was to become known as 'Boyle's law', Hooke himself did not claim to have discovered the law, only to have verified it. (W. S. James[11]: The Discovery of the Gas Laws, *Science Progress*, **23**, 263 (1928), discusses Hooke's experiments (pp. 267), analysing Hooke's procedures and comparing them with Boyle's. I see no compelling reason to support James's claim that "certain doubt must be attached to Hooke's statement of 1664 that he verified the hypothesis [of Townsley and Power] on August 2, 1661". This point will be discussed further in the next paragraph.) Presumably it was from Boyle that Hooke first heard of the Power–Towneley relation, and the question of interest therefore is whether indeed Hooke verified the "hypothesis of Towneley" (and Power) before, and independently of, Boyle. It seems evident that Boyle was the source of information, since Hooke, like Boyle, refers only to Towneley and not to Power. If all this be so, then Hooke should be given credit for the law rather than Boyle, having had priority in verifying the 'hypothesis'.

Two cogent arguments for giving Hooke credit for 'Boyle's law' are made by Prof. Andrade in his celebrated Wilkins Lecture on Hooke in 1949[12]. The first is "that Hooke, who always expressed the greatest veneration for Boyle, would never have published this [statement] in 1665 [in the *Micrographia*] if it was likely to give pain to, or be disputed by, Boyle". The second is Boyle's own statement in 1662 that when Hooke first heard him "speak of Mr. Townley's suppositions about the proportion wherein Air loses its Spring by Dilation", Hooke told him "he had the year before . . . made observations to the same purpose, which he acknowledged to agree well with Mr. Townley's Theory". Prof. Andrade also cites a third argument raised by Louis Tronchard More in his life of Boyle in favour of Hooke's importance

in the formulation of this law: that after Hooke ceased to work with Boyle, Boyle never did any further quantitative scientific work[13].

To the foregoing arguments I now add a fourth. It is well known that Isaac Newton was generally reluctant to give credit to Hooke for any significant contribution to science. Hooke had challenged the Newtonian theory of light and colours in the 1660's, and in the 1670's he had made public a private letter of Newton's containing a scientific blunder in the dynamics of bodies falling on a moving Earth[14]. In 1686 Hooke's insistent demand for credit in the *Principia* almost resulted in Newton's suppression of Book 3, in which the abstract principles developed in the first two books of the *Principia* are applied to the "system of the world"[15]. Happily, Halley's tact and persuasion prevented this proposed disfigurement of Newton's masterpiece. It is amusing to note that in the MS. sent to the printer, and from which the printer composed the *Principia*, the text reads at one point: "Wrennus, Halleus et Hookius". But in the printed version this was altered (presumably by Halley) to "Wrennus, Hookius & Halleus". (Newton's MS., chiefly in the hand of Humphry Newton, with corrections by Isaac Newton and by Edmund Halley, is in the Library of the Royal Society. This MS. has been collated *verbatim et literatim* with the printed first edition for our forthcoming critical and variorum edition of the *Principia*.)

These things being so, any statement of Newton's in the years 1686–87, giving credit to Hooke for any discovery, is to be taken very seriously. In *De systemate mundi*, the first (and unused) version of Book 3 of the *Principia*, Newton discussed a "ratio, [by which] we may compute the rarity of the air in all places whatsoever (by the help of Cor., Prop. XXII, Book II), supposing the expansion thereof to be inversely proportional to its compression"[16]. He then stated that "this proportion has been proved by the experiments of *Hooke* and others". In an earlier composition, *De Ære et Æthere*, dating from the late 1660's or early 1670's[17], Newton also gives Hooke the credit rather than Boyle: "In just the same remarkable manner air rarefies and is condensed according to the degree of pressure. The whole weight of the incumbent atmosphere by which the air here close to the Earth is compressed is known to philosophers from the Torricellian experiment, and Hooke proved by experiment that the double or treble weight compresses air into the half or third of its space, and conversely . . .". (This important document was first published by Profs. A. R. and M. B. Hall.)

In some juvenile notes on Hooke's *Micrographia*, Newton wrote:

> 226. Mr Townlys Hypothesis is ye dimension (or expansion) of ye aire is reciprocall proportional to its spring (or force required to compresse it). By Mr Hookes experience . . .
>
> [*Then follows a table from the* Micrographia *giving in successive columns*: The dimension of ye aire; The perpendicular height of a Mercuriall cilinder compressing it; The Mercuriall cilinder counterpoised by ye Atmosphaere; The whole incumbent weight pressing ye aire; *and, finally, for a check on the theory*, By Mr Townlys Hypothesis ye incumbent weight should bee, . . .][18].

Shall we conclude that Newton was ignorant of Boyle's own statement and knew of the pressure–volume relation only through Hooke's *Micrographia*? Is this why Newton mentioned Hooke's name in connexion with the law rather than Boyle's? The catalogue of Newton's library lists "Boyle's Spring of the Air & its Effects, 8vo. 1660" but not the second edition of 1662 containing the law[19]. Such evidence is, however, far from conclusive, since Newton could have read this book in a copy other than one in his library, or he could have owned the book at one time and yet have had it no longer at the time of his death, or he could have heard about the law from someone by word of mouth—even from Boyle himself, whom he knew well and greatly admired. But it would be hard to deny the importance of the fact that Newton twice mentioned Hooke, whom he apparently detested, in relation to the law and never mentioned Boyle, for whom he had a great and sincere esteem. Hence we may also understand why Newton, in Prop. XXIII (and Scholium) to Book II of the *Principia*, mentions no name at all when discussing the law of gases—perhaps preferring to print nobody's name to having to link so important a discovery with Hooke.

The law relating the pressure and volume of a confined gas at constant temperature was discovered through experiments arising from Boyle's book on *The Spring of the Air*. Richard Towneley and Henry Power (with some "advice and assistance" of John and Charles Towneley and George Kemp) found data which they reduced to the proportion $PV = P'V'$, although they did not express this result in the most unambiguous clarity conceivable. From correspondence between Henry Power and William Croone (July 20, 1661; September 14, 1661; November 27, 1661; January 9, 1661 (1661/62)) we learn that Boyle was in possession of this material when he wrote his "continuation" (or "defence") for the second edition of the *Spring of the Air* (1662). Prof. McKie, *loc. cit.* (note 3 *supra*), has found MS. evidence that Boyle made a report to the Royal Society on September 11 and again on September 18, 1661, on "the experiment made by him of the compression of air with the quicksilver tube". The table of data (reproduced as Fig. 3 by Prof. McKie) presents experimental results "identical" with those in Boyle's publication of 1662. From this and other evidence it has been stated:

> Boyle's role in the stablishment of the gas law remains important; his experimental results were accurate and extensive; the apparatus which he devised has become the standard one for illustrating the gas law; most significantly he gave the weight of his great reputation to the law, and published it in a highly influential work. He became the publicist of the gas law, which would have remained unnoticed in Power's work and Towneley's correspondence with Boyle.[20]

Boyle, however, extended the Power–Towneley relation to pressures greater than one atmosphere. According to Boyle's statement of 1662 quoted above, Towneley had been concerned only with "the Decrement of the force of the dilated Air", whereas Boyle extended the relation to compression as well as rarefaction, that is, to pressures greater than one atmosphere (The question of whether such an extension be significant or not depends on whether the limitation in the first instance to pressures less than one atmosphere resulted from a failure to devise an instrument to make a test of this additional range or from a psychological inability to recognize that a law for the rarefaction of gases might equally be a law for the compression of gases. This and other questions concerning 'Boyle's law' are discussed by Prof. Joseph Agassi, of the University of Illinois, in a work in progress.)

If this be the basis for Boyle's name to be associated with the law, surely Hooke has an equal claim. He, too, obtained accurate experimental data to support the conclusion of Towneley and Power who discovered the law, at least for rarefaction, and whose statement of it was known to him as well as to Boyle. (Like C. Webster, I dismiss Messrs. John and Charles Towneley and Mr. George Kemp as having made contributions of a minor character.) Hooke also put his reputation behind the law and published it. It would seem that Hooke employed the *J*-tube before Boyle, and used it to show that the Power–Towneley relation holds for compression before Boyle did. The context of Hooke's experiments in the *Micrographia* is so entirely different from that of Boyle's in the *Defence* that Hooke's claim to have done this work independently is perfectly plausible. Considering this difference, and the fact that the quantitative law may be more Hookian than Boylian, is it not also plausible that Hooke contributed—in addition to the quantitative point of view—the apparatus used in experimenting, namely,

the *J*-tube? Furthermore, it was through Hooke, and not through Boyle as publicist, that Newton at least (and perhaps others) learned of the law. Hence, Hooke would appear to have an equal claim to Boyle's, and perhaps a greater one, likely anticipating Boyle in designing the apparatus, obtaining experimental confirmation, and in extending the law to compressed gases. Boyle's sole claim would then be priority in publication. We may dismiss Brouncker's claim, since his results apparently were not very conclusive. As to Mariotte, he probably made no original contribution to the law (but, then, neither did Boyle, really), but he too put his reputation behind it and published it in a highly influential work. Boyle was a prolix writer at best, and it may even be the case that Mariotte proved to be a far better publicist than Boyle. To answer this question fully, we need to examine the writings of men of science in the seventeenth century, in order to discover who was their source of information concerning the gas law—Boyle or Mariotte? I have not been able to learn who first called this law after either Boyle or Mariotte. So far as I know, we have only one documented example of a seventeenth-century scientist learning the gas law: that is, Newton, who learned of it through reading Hooke and who—in discussing it—mentioned only Hooke by name. Hence this is a law discovered by Power and Towneley, accurately verified by Hooke, accurately verified again by Boyle (aided in some degree by Hooke), first published by Boyle, but chiefly publicized by Mariotte, in short, the "law of Power and Towneley, and of Hooke and Boyle, and—to some degree—of Mariotte". This example certainly shows the complexities in making precise the individual contributions in the common multiply-discovered scientific law and thus argues the folly of eponymy in science.

I thank the U.S. National Science Foundation for its support.

INTERNATIONAL YEARS OF THE QUIET SUN, 1964–65*

By Prof. W. J. G. BEYNON, C.B.E.
President of the IQSY Committee

In its need for organized international co-operation, geophysics is, in a sense, in a different category from many other branches of scientific investigation. It is true that long-term measurements at one place of the atmospheric temperature or the pressure, the strength of the Earth's magnetic field or the height of ionized layers of the atmosphere have a certain intrinsic value, but ultimately such data only find their proper and useful place in relation to similar measurements made in other places. Geophysical investigations call for collaboration between the workers concerned; and to obtain a comprehensive understanding of natural phenomena, whether these be weather conditions, thunderstorm activity, magnetic or ionospheric storms, etc., demands international co-operation.

This essential need of geophysical research was clearly recognized in some of the earliest meetings of the British Association. Thus in 1838 the British Association, meeting at Newcastle, recommended that the network of magnetic observatories which had been established in Germany by Weber and Gauss during the period 1828–40 should be extended to British territories overseas and, with the co-operation of the President and Council of the Royal Society, sites were selected in both hemispheres, in the tropics, on continents and islands—a detailed statement of the objects of the investigation was drafted and, for the guidance of observers, an instruction manual prepared. It was planned to carry out careful magnetic observations for a period of three years, but not unexpectedly they found that most of the three years went in preparation and the enterprise had to be extended for an additional three years. Six years later the future of the project came up for review at an International Magnetic Congress organized by the British Association during the 1845 annual meeting at Cambridge. It was resolved "that the cordial co-operation which has hitherto prevailed between the British and foreign magnetic and meteorological observatories, having produced the most important results and being considered as absolutely essential to the success of the great system of combined observation which has been undertaken, it is earnestly recommended that the same spirit of co-operation should continue to prevail". Some of those magnetic stations established around 1840 are still—a century and a quarter later—contributing their data to the common store of knowledge on the terrestrial magnetic field.

The Bristol meeting of the Association in 1898 was distinguished by the fact that on that occasion the meetings of Section A were held in association with an International Conference on Terrestrial Magnetism and Atmospheric Electricity. The president of the conference, Prof. (later Sir Arthur) Rücker—then secretary of the Royal Society and later a president of the Association—underlined the need for international co-operation in

* Summary of Evening Discourse delivered on August 28 at the Southampton Meeting of the British Association.

studies of the terrestrial magnetic field in the following terms: "There are special and cogent reasons why the science of terrestrial magnetism should be cosmopolitan. The advance of some sciences is most easily achieved by the methods of guerilla warfare. In a hundred different laboratories widely separated workers plan independent attacks on Nature. In different universities and colleges little groups are devising stratagems and arranging ambuscades in the hope of wresting from our great opponent some of the treasures which she yields only to the violent who take them by force. But for those who would unravel the causes of the mysterious movements of the compass needle concerted action is essential".

Those brief extracts from British Association meetings 66 and 126 years ago indicate the noble part which the Association has played in fostering international scientific co-operation. It is indeed a happy thought that this spirit still prevails. Eight years ago, at the Sheffield meeting, Prof. Sydney Chapman, president of the International Geophysical Year Committee, delivered an evening discourse on the International Geophysical Year, and at this Southampton meeting I welcome the opportunity to outline the further world-wide project now under way with the somewhat romantic title of the "International Years of the Quiet Sun"—the 'IQSY'.

To understand the significance of the present project it is necessary to make brief reference to its immediate predecessor, the IGY. There can be little doubt that international co-operation in geophysical science reached a historic peak in 1957–58 with the International Geophysical Year. The underlying objective of the IGY was once summarized in the single phrase "the common study of our planet by all nations for the benefit of all", and it is certain that the enterprise successfully achieved that objective in full measure.

The IGY was not the first, but the third, international co-operative enterprise of this sort. The two earlier ventures were called "Polar Years" and were, of course, much more limited in scope. The first International Polar Year was organized in 1882–83 and the second 50 years later. In both these enterprises investigations were carried out mainly in polar latitudes over a period of one year. In the 1882–83 project the studies concerned were in meteorology, geomagnetism and aurora. These three disciplines also formed the main core of the studies in the second Polar Year of 1932–33, but on this occasion they were supplemented by a limited but important programme of radio investigations of the then newly discovered ionosphere. The IGY followed the second Polar Year after an interval of 25 rather than 50 years and there were two main reasons for this reduced interval. In the first place the period 1930–50 had witnessed an extremely rapid advance in scientific techniques and especially so in the field of radio—a science central to so many geophysical investigations. It was felt that the time was ripe for an intensive application of these advanced techniques to geophysical problems. The second reason for holding the IGY in 1957–58 was the fact that the second Polar Year of 1932–33 had occurred near a period of solar minimum activity and 1957–58 would be a time of maximum solar activity. As it happened, the choice of 1957–58 was excellent in that it turned out to be a period of most intense activity and the sunspot numbers during the IGY reached an all-time record—they were, in fact, larger than any previously recorded in the two centuries for which reliable figures are available.

Even in the early planning stages of the IGY it became clear that some observations should be continued at near the IGY-level through the waning portion of the solar cycle, and in certain disciplines there were sound scientific reasons for an enterprise on the scale of the IGY at the next period of minimum solar activity. It was clear that the full fruits of the IGY would only be reaped if data, comparable in quality and quantity, were available for a period of low activity—for a "quiet sun". Furthermore, such an enterprise could make full use of the powerful new space-research techniques developed since the IGY, and that is why the "International Years of the Quiet Sun" has been organized for the period January 1, 1964–December 31, 1965. Seventy nations—including all those which took part in the IGY—are taking part in it.

During the IQSY, investigations are being made in those branches of geophysics which are affected to a greater or lesser degree by solar activity—in meteorology, geomagnetism, auroræ and airglow, ionospheric physics, cosmic rays. There is also a very extensive programme of rocket and satellite studies, and throughout the two-year period a continuous watch is being maintained on the Sun with ground-based and satellite-borne instruments.

The following is a brief outline of the IQSY programme in the different disciplines.

Meteorology

The IQSY meteorological programme, like that in many other disciplines, is designed to complement and extend the programme carried out during the IGY. During the IGY the target in meteorology was the study of the atmospheric conditions below about 30 km. During the IQSY these studies are being extended to 100 or 120 km with particular attention to the 25–60-km height-range. The IQSY meteorological programme thus calls for a world-wide effort with high-flying balloons, with rockets and with satellites. At least 10 countries are carrying out regular rocket flights for meteorological studies, and the total number fired in the two-year period will be counted in many thousands.

Apart from its own intrinsic importance, the meteorological programme during IQSY is also required by workers in other disciplines. Thus, cosmic ray investigations call for some high-level aerological observations and data on thunderstorms and lightning flashes are required for the study of the propagation of atmospherics by the ionosphere.

Geomagnetism

It has long been known that disturbances in the Earth's magnetic field closely follow the variations in sunspot number and there is, of course, an intimate connexion between the Earth's magnetic field and many other geophysical phenomena. Investigations of the magnetic field must then inevitably occupy a prominent place in any programme of research concerning solar terrestrial relationships. The geomagnetic programme for the IQSY is principally directed towards a study of solar and lunar variations in this field, to a study of the geomagnetic effects of solar eclipses under the favourable conditions which prevail in the IQSY period and to a study of magnetic storm phenomena. Magnetic storms were, of course, a common occurrence during the IGY, but frequently these occurred in close succession and it proved difficult to sort out the phenomena arising from one storm from that of an earlier or later one. The quiet period of the IQSY should provide a good opportunity for the study of individual magnetic storms in comparative isolation. Studies of some of the large geomagnetic anomalies are being made using satellite-borne magnetometers co-ordinated with ground-based measurements. Further rocket studies of the equatorial electrojet are also being carried out during IQSY.

A new World Magnetic Survey was first discussed during the IGY and at the present time a number of geomagnetic surveys are in hand. The intensive geomagnetic studies of the IQSY will, in themselves, form an invaluable contribution to this longer-term overall study of the field.

Aurora

It has long been known that the frequency of occurrence of auroræ also follows the sunspot cycle. Recording the number of occasions on which an aurora is seen is not such

a straightforward task as recording disturbances in the Earth's magnetic field, since auroral observations are liable to be upset by the incidence of cloud cover on the one hand, or by moonlight on the other. Furthermore, until comparatively recently, we have had to rely on reports of visual observations from a very small number of voluntary observers. Hence the data on the occurrence of auroræ have not been all that complete or reliable. Nevertheless, 80 years ago, at the British Association meeting of 1884, Schuster presented a diagram to show that the incidence of auroræ showed changes which correlate with the solar cycle.

To-day we know that both magnetic storms and auroræ arise from the streams of charged particles—mainly protons which are ejected from the Sun, especially at times of high sunspot activity. These streams impinge on the Earth's atmosphere at high latitudes, having been deflected towards these high latitudes under the influence of the terrestrial magnetic field. The energetic incoming particles disturb the polar ionosphere, causing the atoms and molecules to emit radiation in the visible part of the spectrum (the aurora) and at the same time the particles stimulate great electric currents in the ionosphere and these currents, in turn, disturb the magnetic field. The streams of electrically charged particles from the Sun are most frequent and most intense at times of high solar activity, and hence the frequency of both magnetic storms and auroræ shows a close correspondence with solar activity and with sunspots.

Although visual observations still form a very important source of auroral data, increasing emphasis is now being placed on photographic recordings, and during IQSY new and improved 'all-sky' cameras are being used to study the aurora. These cameras record on one photograph the entire sky from horizon to horizon as it might be seen by an observer lying on his back and having a full 180° field of view in all directions.

Airglow

The phenomena of the aurora are a striking and impressive consequence of the interaction of solar particle radiation with the Earth's atmosphere in polar latitudes. But there is also a much weaker and less variable radiation of light from the high atmosphere which goes on all the time and at all places. This is the airglow or "light of the night sky" as it used to be called. The examination of these weak radiations also provides invaluable information on conditions in the high atmosphere and this for locations all over the Earth, not merely at the high latitudes at which auroræ are visible. In the presence of strong auroral radiations the airglow cannot be detected but, during the present quiet solar conditions, when the auroræ have receded to higher latitudes, studies of the airglow can be carried out at much higher latitudes than was possible in the IGY.

Ionosphere

Perhaps our most important source of information on conditions in the high atmosphere of the Earth comes from investigations of the ionized regions which exist above a level of about 60 km.

Like the magnetic field, the ionosphere plays a central part in many geophysical phenomena, and ionospheric studies inevitably form a very important part of the present enterprise. Thirty years ago, at the time of the second Polar Year, regular soundings of the ionosphere were just becoming established, and such work, although only carried out to a very limited extent at a few stations, was, nevertheless, a new and important part of the programme of that Polar Year. In the 25 years following the second Polar Year a great network of sounding stations grew up, and in the IGY there were about 150 of these ground-based stations with observations made regularly at ½-h or even 5-min intervals. For the IQSY this network has been still further strengthened and, in addition, a few stations have been added in which a new and powerful radio-sounding technique is being used. Conventional radio soundings of the ionosphere cannot yield information above a height of about 250–400 km. This arises from the fact that when radio signals are sent upwards to the ionosphere echo signals are received only if the frequency of the radio waves is less than a certain critical value which is determined by the prevailing ionospheric conditions—determined, in fact, by the maximum electron density in the ionosphere at the time. In general, the maximum electron density occurs at a height which may be anything between 250 and 400 km, and hence it is that conventional radio sounders cannot yield information on the ionosphere above this level. A limited amount of information on conditions in the upper side of the ionosphere can be obtained from moon echoes and from studies of signals from radio stars, but until recently we knew comparatively little about conditions in the 'top side' of the ionosphere. In recent years this situation has been dramatically changed and within the past two or three years it has been possible to study the top-side ionosphere in great detail. Many of these top-side data are coming from certain satellite experiments, but a great deal is also now emerging from a new ground-based technique, which is being used during IQSY at some locations. This 'incoherent scatter' technique which sounds the ionosphere not to a few hundred but to a few thousand km employs a very high-power, high-frequency, radar-type equipment. This yields weak scattered reflexions from *all* levels in the ionosphere and enables the electron density to be measured out to several thousands of kilometres.

However, the most complete information on the top side has come from a remarkably successful satellite experiment in which a complete radio-sounding equipment: transmitter, receiver and all auxiliary gear—in fact, a replica in miniature of that used at ground-based stations—has been carried in a satellite. This miniature 'ionosonde' was built by Canadian scientists and launched in an American satellite on September 29, 1962. Known as *Alouette*, it is still in orbit and has already provided hundreds of thousands of top-side ionospheric records of the highest quality.

At very great altitudes—from, say, 800 to 100,000 km above the Earth—the movement of the electrons and ions is influenced very considerably by the magnetic field, and the outermost parts of the ionosphere—in which these magnetic field effects dominate—has come to be called the 'magnetosphere'. One of the most fruitful sources of information on the magnetosphere has been the examination of strange naturally occurring radio signals. That these signals are strange can be inferred from the names which radio scientists have given to them: 'whistling atmospherics', 'dawn chorus' and 'hiss'. In recent years, and particularly during and since the IGY, it has been established that these radio noises have travelled very great distances and carry invaluable information about conditions in the atmosphere hundreds and thousands of miles above the Earth's surface. 'Atmospherics' are groups of radio waves of very long wave-length—tens of miles long—produced by lightning flashes. Sometimes these long radio waves from lightning flashes can penetrate the ionosphere and travel upwards into the high ionosphere along paths which follow the direction of the magnetic field lines. Thus an atmospheric, generated by a lightning flash somewhere in the northern hemisphere, can travel up to the ionosphere, there to be guided along by the magnetic field and gradually bent over and so down to the other end of the field line in the southern hemisphere. There it can be reflected at the ground and go back along the magnetic field again to the northern hemisphere. Under suitable conditions it may travel back and forth between the two hemispheres many times. At the radio receiver these atmospherics produce a characteristic whistling note of descending pitch, hence the term 'whistling atmospherics'.

At the highest point of their paths the whistling atmospherics may well be travelling through the atmosphere at altitudes of a few thousand miles, and they bring back with them a great deal of valuable information about the 'magnetosphere' at these great heights.

The second collection of strange radio noises—'dawn chorus'—was so named because of its resemblance to the familiar warbling of birds at dawn. Recent research indicates that both the 'dawn chorus' and the 'hiss' are radiations generated on the outer fringe of the Earth's atmosphere in the magnetosphere—by incoming streams of charged particles from the Sun. These phenomena are being closely examined during IQSY as part of an intensive investigation of the Earth's outermost ionosphere under quiet solar conditions.

Cosmic Rays

One of the primary objectives of cosmic ray studies during IQSY is an investigation of the emission of energetic particles by the Sun at the time of minimum activity, and the examination of their mode of propagation through the interplanetary magnetic field. The existence of quiet solar conditions is also being used to advantage in a search for intensity variations over the sidereal day, to determine the effect of meteorological factors on the intensity of the secondary radiation, and to investigate the composition, energy spectra, spatial and temporal variations of the geomagnetically trapped radiations during solar minimum.

Neutron monitors at nearly 70 stations distributed at all latitudes from the Arctic to the Antarctic have been supplemented at some stations by a number of super monitors with counting rates of 10^6/h. Special investigations include studies of rapid fluctuations in meson intensity, of the relations between cosmic ray intensity and the geomagnetic field, and measurements of the neutron albedo flux outside the Earth's atmosphere. It is hoped to carry out special experiments at both ground stations and in balloons and sounding rockets, in the vicinity of the South American/South African anomaly with the object of obtaining further information on the precipitation of particles from the inner radiation belt.

Rockets and Satellites : Aeronomical Studies

In the past five or six years our understanding of many solar and terrestrial phenomena has proceeded at a vastly quickened pace, and this has been due partly to the enormous stimulus given to geophysical research the world over by the International Geophysical Year of 1957–58 and partly to the advent of rockets and satellites.

The first artificial satellite was that launched by the Russians on October 4, 1957—during the IGY. From that historic day to the end of the IGY a total of seven satellites were put into orbit—three by the Russians and four by the United States. Some idea of the rate of progress since the IGY period can be gained from the fact that, according to the catalogue regularly published by the tracking stations, there are at this moment at least 24 active instrumental satellites in orbit and the number of bits and pieces (rocket casings, nose cones, etc.) orbiting round the Earth is about 280. Not only has the number of orbiting vehicles leapt up, but so, too, has the degree of sophistication of the scientific experiments and the complexity of the equipment carried in the vehicles.

In the IGY, rocket and satellite experiments formed only a small part—but nevertheless an exceedingly valuable part—of the whole programme. Seven years later, in the IQSY, the balance has changed tremendously and research with space vehicles forms a very major part of the IQSY programme.

Mention has already been made of the top-side ionospheric sounding satellite *Alouette*, which in its 23 months life has already produced vast numbers of high-quality records on the top side of the ionosphere. At least one other top-side sounding satellite (christened, appropriately enough, *Topsi*) has just been launched by American workers.

In a second IQSY satellite experiment the day-to-day flux of ultra-violet and X-radiation from the Sun is being measured. For a century and more the only direct means of quantitatively assessing activity on the Sun has been to count the spots or other obvious areas of activity to be seen on its surface. Several years ago it was found that the intensity of solar radiation in the decimetre wavelength band showed a very clear solar cycle variation and such measurements of the flux of solar radiation on 10 cm has provided another index of solar activity. It is to be emphasized that the sunspot number has proved a quite remarkable index of solar activity (at least when judged by the very striking way in which it correlates with so many geophysical phenomena) but, of course, it is necessarily only a qualitative and somewhat imprecise index of certain basic physical changes on the Sun. Long-term ionospheric and magnetic investigations have made it clear that the intensity of solar ultra-violet and X-radiations must undergo a very marked change over the sunspot cycle, and during IQSY, for the first time ever, these changes are being directly studied by the American solar radiation monitoring satellite. Launched in January 1964, this satellite is providing continuous data on the intensity of solar Lyman-α radiation and on intensities in three X-ray wave-length bands. Other satellites of interest to the IQSY programme which are either already in orbit or which will be launched during IQSY include the following:

Satellites *Electron 1* and *Electron 2* were launched simultaneously in the first month of IQSY by the U.S.S.R. These have the same perigee height (about 400 km) but vastly different apogees (about 7,000 and 70,000 km respectively). Observations are being made of the inner and outer radiation belts, magnetic fields, solar ultra-violet and X-radiation, cosmic rays, ion composition, etc. Earlier this year the U.S.S.R. also launched some additional satellites in its Cosmos series.

Explorer XVIII, launched by the United States in November last, is the first of four U.S. interplanetary monitoring satellites. It is making continuous observations out to 200,000 km on cosmic rays, on the spectrum of low-energy protons, the characteristics of the plasma and magnetic field.

The first Orbiting Solar Observatory (OSO) was launched in 1963 and it is planned to launch a second in 1965. The U.K.–U.S. satellite, *Ariel 1*, continues in operation and is concerned mainly with ionospheric, cosmic ray and aeronomic observations. *Ariel 2*—a second U.K.–U.S. effort—was launched earlier this year and is designed to measure galactic radio noise, the vertical distribution of ozone and the flux of micrometeorites.

In addition, a very substantial programme of IQSY rocket soundings is also under way. Wind motions and temperature in the ionosphere are being measured with rocket-borne instruments by groups of workers in 10 countries. About a score of rocket flights are being made to determine molecular and atmospheric densities by measuring the attenuation of solar radiation with height. Electron density and electron temperature rocket flights are being made at 15 different sites between latitudes 30° S. and 80° N., and other rocket firings will investigate features of the vast ionosphere current systems which are responsible for many of the variations in the magnetic field. There is also a very substantial programme of meteorological rocket soundings, at least 10 countries having plans for such firings.

All the information obtained during the IQSY is being exchanged through the World Data Centres which are now a well-established feature of the geophysical scene.

Much of the success of the IGY depended on organizing special days and periods for intensive schedules of observation and the organization of a world-wide alert system to warn workers everywhere of the imminence or start of

some solar or geophysical event of special interest. A similar scheme is being used in the IQSY with some special features appropriate to the solar minimum period. An IQSY geophysical calendar has been issued and the alerts will give warning not only of impending storm conditions but also of solar and magnetic calm.

The International Committee responsible for planning and organizing the IQSY is a special committee established by the International Council of Scientific Unions, and it is supported financially by that Council, by Unesco and by contributions from participating nations. It consists of representatives of the four scientific unions which are directly concerned with the IQSY together with representatives of other interested international scientific bodies such as the World Meteorological Organization, the Committee for Antarctic Research and the International Committee for Space Research (COSPAR). The Space Research Committee has no fewer than four representatives on the IQSY Committee—this being an indication of the importance which we have chosen to place on space research in the programme. The IQSY Secretariat has been set up in London—in accommodation kindly provided by the Royal Society.

One of the difficult features of establishing an international scientific committee is that the actual elected membership of the committee is often distributed very unevenly over the globe. In setting up the IQSY Committee we have tried to meet this problem to some degree by having four additional members elected on a regional basis.

An international project of this sort depends for its success on the goodwill of scientific academies, of national governments and their research institutions, and above all it depends on the willing co-operation of many individual scientific workers scattered throughout the world. The IQSY Committee has received warm co-operation on all sides, and it is good to report that no fewer than 70 nations are actively participating, including all those which co-operated in the IGY.

The IQSY is the fourth international co-operative effort in geophysics since 1882 and the second world-wide effort within a period of seven years. When the enterprise ends next year a vast store of geophysical results covering periods of both maximum and minimum solar activity will have been assembled and made readily available for further extended study. We may hope that some time in the future these data will yield the answers to some of the outstanding problems of the Sun and the Earth and thus, to quote again Sir Arthur Rücker at the British Association meeting of 1898, "crown the efforts not merely of those on whom the first glimpse of the truth may flash, but also the international co-operation which has, by way of preparation, made 'the crooked straight and the rough places plain'."

OBITUARIES

Dr. K. H. Barnard

Dr. K. H. Barnard died on September 22 at the age of seventy-seven, after fifty-three years working at the South African Museum in Cape Town. He was the director from 1946 until his retirement in 1956. With his death South Africa has lost one of her greatest zoologists.

Dr. Barnard was born in London on March 31, 1887, educated at a private school in England and at the Realgymnasium in Mannheim, Germany, where he went in order to learn German to help him with his studies. He went on to Christ's College, Cambridge, in 1905, where he took the Natural Science Tripos in botany, geology and zoology, and obtained his B.A. three years later. He also attended the new and then rather unusual courses on anthropology, ethnology and geography. After that he proceeded to study law, and was called to the Bar (Middle Temple) in 1911. He obtained his M.A. (Cantab.) *in absentia* in 1913. Science interested him more than law, however, and he returned to zoology. After a short time as honorary naturalist at the Marine Biological Laboratory in Plymouth he joined the staff of the South African Museum in 1911, where he continued to work until his death. He obtained the degree of D.Sc. from the University of Cape Town in 1924 for his work on the distribution of Crustacea, and in 1956 the University of Stellenbosch conferred on him the degree of D.Sc. *honoris causa*. During his life he produced more than two hundred articles, scientific papers and books.

At the South African Museum he took charge of the Marine collections, including the large collection amassed by the Cape Government trawler S.S. *Pieter Faure*. Based largely on an investigation of the collections in the South African Museum, he published many taxonomic works, including a series of papers on amphipods and isopods (1914–25), a monograph of South African marine fishes (1925–27), a monograph of South African crabs, prawns and mantis-shrimps (1950), and contributions to the South African marine mollusca (1958–64). He also made investigations of the Amphipoda from expeditions such as the *Discovery* and the *Terra Nova*, the *Great Barrier Reef*, the *John Murray*, the *Investigator* and the *Australasian Antarctic*, and contributed important papers in their reports. He also published reports for the British Museum, the Indian Museum, Transvaal Museum, Natal Museum and Durban Museum. His work has greatly increased our knowledge of the fauna of the seas around South Africa and farther afield. He published three popular books on fishes (1947), shells (1951) and shore life (1954).

His keen interest in mountaineering and the discovery of *Phreatoicus*, an Australasian genus of primitive Crustacea on Table Mountain, led to an intensive investigation of the mountain fauna of the south-west Cape ranges. Evidence of a relict fauna was investigated and studied in relation to the geology and topography. His presidential address to the South African Geographical Society in 1936 summarized some of the more important results of these investigations and the conclusions drawn from them concerning the former topography of the mountain ranges and the river courses. This work involved numerous collecting trips in the mountains of the South-west Cape. He made extensive collecting expeditions to the coast of Portuguese East Africa in 1912, the Natal coast in 1913, the Natal interior in 1917, Ovamboland and the Kaokoveld and north to the Kunene River in 1921, 1923 and 1926 (Zoological Survey of South West Africa) and Gordonia and the Orange River to the Aughrabies Falls in 1925. Some of these early trips were made by ox-wagon. He published many important papers on the fauna of the mountains and rivers of South Africa, based largely on his own collections.

He served as local secretary for the compilation of the international catalogue of scientific literature until the London secretariat took over the whole compilation, including records of papers published in South Africa. He helped in the formation of the South African Geographical Society in 1917, served on the Council for several years, was president for the session 1935–36 and the Society's representative at the International Geographical Congress at Cambridge in 1928. After his retirement he concentrated his research work on South African marine mollusca, his research work and publications being aided

by a senior bursary from the South African Council for Scientific and Industrial Research.

Dr. Barnard was awarded many honours during his life-time, including being elected a Fellow of the Royal Society of South Africa in 1920, and a Fellow of the Linnean Society of London in 1921. He received the Gold Badge of the Mountain Club of South Africa in 1924, the King George V Silver Jubilee Medal in 1935, the Senior Captain Scott Medal of the South African Biological Society in 1936, the Medal and grant of the South African Association for the Advancement of Science in 1945, the Queen Elizabeth II Coronation Medal in 1953. He was made an Honorary Fellow of the Royal Society of South Africa in 1956 and president of the Conchological Society of Southern Africa in 1962.

Dr. Barnard was recognized as a world authority in several fields, and it was often with astonishment that specialists in one of these subjects would discover his accomplishments in other fields. Dr. Barnard's world-wide reputation was built up on his unceasing and prodigious work over a long and active life. He was always willing to help his scientific colleagues or casual enquirers in his quiet, unassuming way. Despite his achievements, he remained a shy and modest man.

Our sympathy is extended to his wife and two children who survive him. JOHN R. GRINDLEY

Prof. F. H. Garner, O.B.E.

FREDERIC H. GARNER, emeritus professor of chemical engineering in the University of Birmingham, died suddenly at the age of seventy-one at his home at Wymeswold, Leicestershire, on September 19. Born in 1893, he attended the Market Bosworth Grammar School, going on to study chemistry at the University of Birmingham, and then proceeding to the Mellon Institute, Pittsburgh, for postgraduate studies.

After his return to England he was actively associated with the petroleum industry for many years, rising to become director of research of the Esso European Laboratories from 1935 until 1942.

He will be remembered particularly, however, for the enthusiasm he brought to bear in building up the Department of Chemical Engineering in the University of Birmingham. When in 1942 he was appointed to succeed A. W. Nash as professor and head of the Oil Mining Department, the latter was small and rather static; the undergraduate intake was only five students that year, and even fewer men were able to come as the Second World War progressed.

In 1946 Garner changed the name to the Department of Chemical Engineering, and began the programme of diversification and expansion that, in a little over a decade, transformed a small Department of Oil Mining into one of the largest Chemical Engineering Departments in the world. The academic staff increased from 3 to 28 and undergraduate admissions from 3 or 4 a year to about 80; postgraduate lecture courses were established both in chemical engineering and also (with remarkable foresight) in biological chemical engineering. The research school, too, increased in size and prestige, to an intake of about 23 new students each year. It was inevitable that the Department that he built up with such enthusiasm should become a dominant factor in his life. Inevitable also, perhaps, was Garner's role as the watchful, sometimes strict, father to his staff.

In his own research, he was particularly interested in later years in the surface phenomena associated with mass-transfer, and he was one of the pioneers in investigations of the circulation within falling drops and in the visualization of interfacial turbulence. Even after his retirement in 1960 he used to come into the Department to continue his experiments in these fields.

His death marks the end of an era—an era not only of the establishment of chemical engineering in British universities, but also of the benevolent-dictator type of professor who could, by his endeavours and by the impact of his personality, build up a large Department as his personal creation. Until the moment of his retirement it was *his* department in a very real sense, and he will long be remembered for his devotion to its interests and to those of his many students. J. T. DAVIES

NEWS and VIEWS

The Royal Society of Edinburgh: Elections to Council

AT the annual statutory meeting of the Royal Society of Edinburgh, held on October 26, the following were elected to the Council of the Society for the 182nd session: *President*, Prof. J. N. Davidson; *Vice-Presidents*, Dr. H. R. Fletcher, Prof. G. L. Montgomery, Prof. C. F. Davidson, Dr. Mowbray Ritchie, Prof. J. Allen and Dr. G. H. Mitchell; *General Secretary*, Prof. N. Feather; *Secretaries to Ordinary Meetings*, Prof. A. E. Ritchie and Dr. A. F. Brown; *Treasurer*, Dr. J. R. Peddie; *Curator of Library and Museum*, Dr. R. Schlapp; *Councillors*, Prof. R. B. Fisher, The Rev. A. M. Gillespie, Prof. A. Robertson, Prof. P. A. Sweet, The Rt. Hon. Lord Balerno of Currie, Dr. J. M. Jackson, Prof. I. N. Sneddon, Prof. P. E. Weatherley, Dr. N. Campbell, Prof. P. L. Pauson, Prof. J. R. Raeburn and Prof. J. D. Robertson.

Director of Smithsonian's Museum of History and Technology: Mr. John C. Ewers

MR. JOHN C. EWERS has been appointed director of the new Smithsonian Museum of History and Technology in succession to Mr. Frank A. Taylor, who has been serving as both acting director of the Museum and director of the U.S. National Museum. Mr. Taylor will continue in the latter post. A native of Cleveland, Ohio, Mr. Ewers began his service with the Smithsonian Institution in 1946. For the past six years he has been assistant director of the Museum of History and Technology, serving as planning officer for the new building. He was responsible for the design, construction, and installation of exhibits, which made it possible to open the building to the public in January 1964, a few months after its completion. Before joining the Smithsonian Institution, Mr. Ewers was a member of the Bureau of Indian Affairs, serving as the first curator of the Museum of the Plains Indian at Browning, Montana. He also has acted as museum planning consultant to the Historical Society of Montana, the Bureau of Indian Affairs, and the National Park Service. Recently he was consultant for the Canadian National Museum in planning its new museum of history and anthropology. A graduate of both Dartmouth College and Yale University, Mr. Ewers is a member of several professional societies, including the Washington Academy of Sciences, American Association of Museums, American Anthropological Association, Sigma *Xi*, Western History Association, and the American Indian Ethnohistoric Conference. He is also past-president of the Westerners, a Washington group interested in the history of the American West.

Environmental Design and Engineering at University College, London: Prof. R. G. Hopkinson

DR. R. G. HOPKINSON has been appointed to the new chair of environmental design and engineering in the Bartlett School of Architecture, at University College, London. The establishment of this chair has been made

possible by generous financial support from Messrs. G. N. Haden and Sons and Messrs. Pilkington Bros. Ltd. Dr. Hopkinson's aim will be to educate architects, engineers and scientists in ways of designing buildings that are pleasant and stimulating to live in, and at the same time functionally efficient and economical. He will be concerned with lighting, air conditioning, heating and the problems of noise. He will promote greater co-operation between engineers and architects, and encourage scientific research into the problems of improving human environment. Courses of study in which engineers, architects and research workers will work together will be set up at University College. Dr. Hopkinson is at present in charge of research on the lighting of buildings at the Building Research Station of the Department of Scientific and Industrial Research. His pioneer work on human adaptability and research into the needs of the human being in his environment has brought him into contact with architects and research workers throughout the world, and has resulted in many papers and publications, of which perhaps the most significant is his book *Architectural Physics: Lighting* published by H.M.S.O. in 1963. Dr. Hopkinson has lectured on environmental design in many universities in Britain and overseas and has acted as the University's 'opponent' in a 'doctorate disputation' in Stockholm, and he has directed a research programme in the Department of Electrical Engineering at Cornell University, where he spent a term as a visiting professor. He will take up his new post early in 1965.

The British Joint Corrosion Group

THE Councils of the Iron and Steel Institute and the Institute of Metals, together with the Council of the Society of Chemical Industry, have considered how best to meet the needs of corrosion specialists, metal producers, and metal users with regard to information concerning corrosion and its prevention. The excellent work of the Corrosion Group of the Society of Chemical Industry is fully acknowledged, but it has been recognized for some time that the publications of, and the discussions arranged by, the two institutes have not adequately catered for the interests of those of their members particularly concerned with the metallurgical aspects of corrosion, nor with the interests of those members who are corrosion specialists. The councils of the three societies have now agreed to form a joint group to be known as the British Joint Corrosion Group, with the view of: (*a*) providing a forum for discussion of papers on corrosion and protection of metals; (*b*) overcoming the present dispersion of papers dealing with corrosion throughout many publications, and strengthening the facilities for publishing such papers; (*c*) improving the arrangements for publication and discussion of the metallurgical aspects of corrosion; (*d*) representing United Kingdom corrosion interests internationally. The Institute of Metal Finishing was invited to join the Group and has accepted the invitation. The functions of the existing Corrosion Group of the Society of Chemical Industry will be incorporated into the new organization, and the co-operation of other bodies concerned with this field is also being sought.

Members of the four societies are entitled to register as members of the Group and, on so doing, to receive notices of Group meetings, and to attend such meetings without further payment. The Group will be administered by an organizing committee composed of representatives of the societies. A new publication to be called *The British Corrosion Journal* will be launched, sponsored by the Group, and controlled by a Publication Committee. The first issue of the *Journal*, which will be published in alternate months, will be circulated in July 1965. The Society of Chemical Industry will service the new Group, and provide editorial facilities for the Group's *Journal*. Manuscripts of papers submitted to the new *Journal* should be sent to the Editor, *The British Corrosion Journal*, 14 Belgrave Square, London, S.W.1. Members of the four co-operating societies are invited to register now as members of the British Joint Corrosion Group. Further information, and application forms for subscription to the *Journal*, can be obtained from the Secretary, the British Joint Corrosion Group, 14 Belgrave Square, London, S.W.1.

Interferon Information Exchange Group

AN information exchange group for research on interferon has been formed. The objectives and operations of an earlier established information exchange group have already been described in *Science* (143, 308; 1964). The new exchange will make it possible for a scientist working on interferon to communicate research findings or other scientific information quickly to all others in the same field throughout the world. Under the new scheme, the exchange member will send his communication to the exchange 'centre' where duplicate copies will be printed (by photo-offset) and distributed. Communications will include manuscripts (which will also have been sent to journals), discussions, criticisms, bibliographic omissions, memoranda of unpublished research findings, technical suggestions, unofficial notes of meetings or any other original communications. No editorial prerogatives will be exercised. Active investigators of interferon who did not receive the announcement letter are invited to apply for membership. The chairman is Dr. Alick Isaacs, National Institute for Medical Research, London, N.W.7, and the co-chairman, Dr. Samuel Baron, Laboratory of Biology of Viruses, National Institute of Allergy and Infectious Diseases, Bethesda, Maryland 20014. All correspondence should be sent to the co-chairman.

Advanced Educational Courses

A *Bulletin* issued by the London and Home Counties Regional Advisory Council for Technological Education describes the special advanced courses held in the London and Home Counties Region, which do not regularly appear in college calendars or prospectuses as part of a grouped course or as subjects offered for endorsement on Higher National Certificates (*Bulletin of Special Courses in Higher Technology, Management Studies and Commerce*, 1964–65. Part 1: Autumn Term. Pp. 126. London: London and Home Counties Regional Advisory Council for Technological Education, 1964. 5*s*.). As a rule they are part-time courses (usually evening), but full-time courses, which are specially arranged and are not longer than three months duration, are also included. Sessional evening postgraduate courses leading to higher degrees in science (including mathematics) and engineering are not included. Among the wide variety of courses are: cost engineering in the process industries (Borough Polytechnic); varactor diodes (Brunel College); silicon gate-controlled switches (Enfield College of Technology); high fidelity sound reproduction (Hendon College of Technology); predetermined motion time standards (Kingston College of Technology); management for the clothing trade (London College of Fashion); geotechnical processes and soil stabilization (Northampton College of Advanced Technology); tall buildings (The Polytechnic); trading blocs (Slough College); and autocode programming (Wimbledon Technical College).

Royal Society Films for Hire

IN 1961 the Royal Society mounted an expedition to Sabah, North Borneo. The purpose of the expedition was to study the undisturbed forest life and soil variation at different altitudes of Mount Kinabalu and the Pinosuk Plateau. A film was prepared by members of the expedition showing some aspects of their work, and has now been made available by the Royal Society for hire by schools, educational institutions, film societies, etc. The film is of approximately 35 min duration and is in colour with a dialogue. The charge for hiring is 25*s*. Other films available from the Royal Society are: "The Volcanic

Eruption on Tristan da Cunha, 1961–62" (20 min, colour and sound; hire 25*s*.), which was prepared largely by members of the Society's expedition to the Island during October 1961–March 1962; "South from Chiloé" (40 min, colour and sound; hire 42*s*.); which was prepared by the Society's expedition to Southern Chile during October 1958–February 1959; "Halley Bay" (20 min, colour and sound; hire 25*s*.). All films are available from the Executive Secretary, Royal Society, Burlington House, Piccadilly, London, W.1.

Marshes and Wetlands of Europe

In recent years, improved machinery has made draining and reclamation of marshland and wetland a practicable proposition, and these areas are rapidly dwindling in Europe. According to the International Union for Conservation of Nature and the International Wildfowl Research Bureau, not enough thought has yet been given to the loss and damage which such drainage policies incur. The case for marshes and wetlands is set out in a booklet entitled *Liquid Assets* (Pp. 16. London: International Union for Conservation of Nature, 19 Belgrave Square, 1964). It is considered that there is an urgent need to preserve these areas, which, it is emphasized, are in many cases natural assets. Land drainage, undertaken at public expense, is a form of farm subsidy, and admissible only if it compares favourably with other means of stimulating food production. The 'worthwhileness' of a project must be assessed not merely on expected cost and profit, but on long-term advantages and disadvantages. Wetlands provide an unlimited field for biological research, and marshes, especially those on the coast, are among the most naturally fertile areas in the world. The booklet considers that if such areas are destroyed great opportunities will be lost for discovering and possibly exploiting new sources of food. Besides their amenities value, such areas are invaluable in teaching and demonstrating the elements of zoology and botany—especially ecology. Governments throughout the world would do well to take stock of their marshes and wetlands in the light of this publication and ensure that their dwindling 'liquid assets' are not only protected but also conserved.

The Wildlife Youth Service

The Wildlife Youth Service has developed into a nation-wide organization with nearly 18,000 individual members since it was launched in May 1963. A further 10,800 members are represented through the 700 registered school groups—and applications are still steadily flowing in at the Headquarters Office, 37 Hertford Street, London, W.1. The launching of the Service was planned to take place in three phases: the first included the National Nature Week, followed by four months recruiting of individual members. The second phase—the School Group Scheme—was opened during the first week in October. This has already produced encouraging results with 700 school groups registered and more to come. These groups, many of which exceed a membership of 200 children, are being organized with the aid of interested teaching staff. Most of the groups have entered into one of the 'wildlife study' projects and activities suggested by the Director. The third phase is scheduled to take place in a few months time, when every effort will be made to set up permanent evening centres for Wildlife Ranger and Panda members throughout Britain. So far, the Wildlife Youth Service has arranged seven major film programmes for schoolchildren at cinemas in England, Scotland and Wales; these have been attended by a total of 8,200 children. The Director has given talks at 127 schools to a total of more than 10,650 children. The Information Service has dealt with more than 5,000 questions on wildlife and pet care, and the Wildlife Youth Service has sent out a total of more than 61,000 letters in thirty weeks since it was first launched (*News for Naturalists*, 5, No. 2; 1964).

National Heron Census

Ten years have elapsed since the last national heron census was carried out, and now the British Trust for Ornithology has announced that a further attempt is to be made to count all the herons' nests in Britain. In addition to the usual factors which have always affected the heron population, the position is now being complicated by the effects of toxic chemicals, and hence it is important to make this census as accurate as possible. Ornithologists in England and Wales wishing to help in the new census should contact Mr. J. Stafford, Westering, Moor Lane, Brighstone, Isle of Wight; those in Scotland should contact Mr. C. P. Rawcliffe, 35 Comely Bank Road, Edinburgh, 4; and those in the Irish Republic, Mr. O. J. Merne, c/o National Bank Ltd., Rathkeale, Co. Limerick, Eire.

New Words in Biology and Related Subjects

Dr. N. W. Pirie, head of the Biochemistry Department at the Rothamsted Experimental Station, has prepared a preliminary list of words for inclusion in the proposed *Biological Council Dictionary* of new words in biology and related subjects (*Institute of Biology Journal*, 2, No. 3; August 1964). Of the 96 words submitted, none is included simply because it is rare: a word is excluded if it appears, in the sense with which biologists are concerned, in the *Oxford English Dictionary* or the eighth edition of Henderson's *Dictionary of Biological Terms* (1963). The rule is interpreted flexibly when the spelling has altered. Words that do not seem to have been used by anyone except the coiner are not included unless it seems likely that they will catch on. On the other hand, inclusion or exclusion are not intended as comments on the usefulness of the words; there will be time enough for comment after the first definite list has appeared. The names of individual organisms, diseases and substances are excluded because they are easily found in the abstract journals; only names of categories are recorded. Among the words are:

Actinophage—an anti-actinomycete phage.

Air spora—the population of air-borne particles of plant or animal origin, including pollen.

Aposymbiotic—removed from symbiosis or separated from the symbiotic partner.

Cryptobiosis—the state of an organism when it shows no life-like activities while still being capable of resuscitation.

Darwin—the rate of evolution of a quantitative character, the natural logarithm of which changes by unity in a million years.

Epontic—growing on any surface, plant, animal or mineral. A broader term than epilithic or epiphytic.

Euphenics—the improvement of individual people by chemical or surgical means. Analogy with eugenics in the sense that phenotype is opposed to genotype.

Gangliospore—a fungal spore developed from the swollen tip of a hypha.

Kronism—the killing (and sometimes eating) of eggs and nestlings by the parent bird.

Lomasome—a sponge-like structure in fungi contiguous with the hyphal wall as revealed by the electron microscope.

Poxvirus—a group of viruses of complex structure, 200–300 nm in diameter, usually causing lesions involving skin in birds and mammals (includes vaccinia, variola and various animal poxes).

Tachyphylaxis—the diminishing response to successive doses of any material active in biological systems.

Teleonomic—a neutral word implying that an adaptation is useful for achieving a certain result without the implication that design of purpose was involved.

Trophogenic—the surface layer of a body of water in which photosynthesis can occur. Also used for an effect produced by feeding.

Bakery Planning

No baker intending to build new premises, or to expand or modernize his existing bakery, has had cause for complaint since June 1964. For since then there has been available for the would-be planner a comprehensive guide

published by the British Baking Industries Research Association at the modest price of 10*s*. (Report No. 72: *Some General Principles of Bakery Planning*. By Mr. D. E. Chapman and Miss E. M. Laing. Pp. ii+82. Chorleywood, Rickmansworth: British Baking Industries Research Association, 1964. 10*s*.). It may be added that the British Baking Industries Research Association reports are not normally available to the public, but an exception has been made with this one, as it was felt to be one of general interest. The report attempts to answer in advance and in order the questions which an intelligent baker would ask in these circumstances. Thus, after some preliminary advice to the baker confronted with the dilemma of whether to adapt his existing bakery or build an entirely new one, the authors guide him through the intricacies of site-choosing, and introduce him to the complexities of lay-out and planning. The foreword makes it clear, however, that, except for small projects, he will need the services of an architect; and the report is intended to help in the liaison with the latter rather than to displace him. The design of individual parts of the bakery is discussed in detail, and includes ancillary services such as the despatch area, test-laboratory and boiler room: even the refuse store is not forgotten. Special attention is directed throughout to considerations of safety, to comfortable working conditions, and to the reduction of unnecessary labour: reference is made in an appendix to appropriate legislation.

Hydatid Diseases in New Zealand

Hydatid disease in New Zealand is as old as the sheep industry. A circular from Dunedin in 1887 to medical practitioners revealed that nearly all, even at that time, had wide experience of the disease. Such a well-entrenched disease will not readily be overcome, and reports of past efforts at eradication are conflicting. It was with this knowledge that the National Hydatids Council asked Dr. F. S. Maclean to write a history of the fight against hydatid disease in New Zealand (*Hydatid Disease in New Zealand: an Account of the Events leading to the Establishment of the National Hydatids Council, and the Methods adopted to Eradicate the Disease*. By F. S. Maclean. Pp. 48. Wellington, N.Z.: National Hydatids Council, 1964). The lessons that emerge from his report are striking, and they are useful in fields far wider than hydatid prevention alone. First, there has been no sudden or dramatic advance in medical knowledge. The methods advocated in the 1880's—never to allow dogs to feed on raw offal—are just the same as those advocated to-day. Secondly, the problem is one of people rather than dogs and other animals. For nearly a hundred years many efforts have been made to bring knowledge of hydatid disease and the methods of prevention to all New Zealanders, and many thousands of pounds have been spent. On two occasions at least, regulations have been framed and passed to stop dogs eating raw offal. As a result, many thousands of New Zealanders knew the truth about hydatid disease but took no action to check it. Some felt that any action taken by the individual was made useless by the carelessness of others. Some had a quite unrealistic belief that dosing with arecoline would, in some miraculous way, relieve them from the responsibility of preventing their dogs from eating raw offal.

In spite of every effort by the Government, the various Government departments, the medical schools, the research units and the medical profession, hydatid disease continued to take its yearly toll of health and life. Apathy and hopelessness fed on confused thinking, stories of failure and avoidance of personal responsibility. As indicated by Dr. Maclean, the atmosphere in 1957 suddenly changed. There was a dramatic upsurge of interest. For the first time farmers worked individually to eliminate the disease from their own farms, they co-operated with their neighbours to form local anti-hydatid committees, they elected members to fight the disease at a provincial level and, in conjunction with the Federation of Young Farmers Clubs, they finally prevailed on the Government of the day to form a national body to campaign against hydatid disease in all parts of the country. The change in attitude was due to participation. Farmers were told of a disease which primarily affected them and were told of methods of prevention which only they could apply. They were given responsibility for action, were asked to make their own decisions, plan their own policies and become involved themselves in a campaign they could call their own. Organizations and individual farmers devised methods of disposing of or treating offal, destroying carcases, controlling dosing, and feeding their dogs. Local committees took the message to every local dog owner. District committees defined boundaries and co-ordinated the work of local committees. Within two years approximately 500 local committees were set up in rural areas throughout New Zealand. Later, a National Hydatids Council was formed: its success is described in the booklet.

Protein Requirements of Man

In 1963 the World Health Organization and the Food and Agriculture Organization requested the views of experts on various aspects of protein metabolism. Following on this request a working party was set up, under the chairmanship of Prof. F. G. Young, to investigate the human requirements of protein with special reference to the dietary background of the United Kingdom; the report of this working party has recently been published (*Reports on Public Health and Medical Subjects*, No. 111: *Requirements of Man for Protein*. Pp. vi+90. London: H.M.S.O., 1964. 5*s*. 6*d*. net). Physiological variations which can occur in protein metabolism and regulation are dealt with in the report, which then discusses the nutritive value of proteins both in relation to the composition of the proteins and the calorific value of the diet. The relationship between different forms of biological assay of protein quality is discussed and the importance of 'nitrogen balance' methods is emphasized. Factors which affect the nutritive value of protein foods are considered and human factors which affect the requirements are discussed at length, while the effects of disease and injury are reviewed briefly. The mean lower and upper limits of dietary protein intake per day for all age-groups are summarized and suggestions are made as to the use of such data in the recommendation of protein allowances. The report concludes with a number of appendixes dealing with specialized aspects of protein supply and requirements.

The Ramsay Memorial Fellowships Trust: Fellowships for Advanced Students of Chemistry

Applications for two Ramsay Memorial fellowships for advanced students of chemistry will be considered in February 1965. One of the fellowships will be limited to candidates educated in Glasgow, but they can apply to be considered for both fellowships. The value of each fellowship will be £750 per annum, to which may be added a grant for expenses of research not exceeding £150 per annum, and will normally be tenable for two years.

Travel Grants

Applications for three Ramsay travel grants for the year 1965–66 will also be considered in February 1964. No travel grant will exceed £500. Two of the travel grants will be limited to junior academic chemistry staff of universities and colleges of technology or advanced technology in England, Wales and Northern Ireland. One travel grant will be limited to junior academic chemistry staff of universities in Scotland.

Further information concerning fellowships and grants can be obtained from the Joint Honorary Secretaries,

Ramsay Memorial Fellowships Trust, University College London, Gower Street, London, W.C.1. Applications must reach them not later than January 13, 1965.

The Night Sky in December

NEW moon occurs on Dec. 4d 01h 19m U.T. and full moon on Dec. 19d 02h 42m. The following conjunctions with the Moon occur: Dec. 1d 04h, Venus 2° S.; Dec. 10d 12h, Saturn 3° N.; Dec. 16d 09h, Jupiter 2° N.; Dec. 24d 19h, Mars 3° S. Venus is in conjunction with Antares on Dec. 26d 00h, Venus being 6° N. There is a partial eclipse of the Sun on December 3–4, invisible at Greenwich. There is a total eclipse of the Moon on December 19, visible at Greenwich. Moon enters penumbra 00h 01m, Moon enters umbra 00h 59m, total eclipse begins 02h 07m, mid-eclipse 02h 37m, total eclipse ends 03h 07m, Moon leaves umbra 04h 15m, Moon leaves penumbra 05h 14m. Magnitude of eclipse 1·18. Mercury is too close to the Sun for observation. Venus rises at 4h 45m, 5h 25m and 6h 15m on December 1, 15 and 31, respectively. Its stellar magnitude is −3·4; its distance from the Earth increases during the month from 125 to 139 million miles and the visible portion of the apparent disk from 0·848 to 0·913. Mars rises at 23h 50m, 23h 10m and 22h 35m at the beginning, middle and end of the month, respectively. Mars is in Leo, its stellar magnitude is +0·8, and its distance from the Earth on December 15 is 116 million miles. Jupiter sets at 6h 00m, 4h 55m and 3h 55m on December 1, 15 and 31, respectively. Its motion is retrograde among the stars in Aries, its stellar magnitude is −2·3 and its distance from the Earth on December 15 is 388 million miles. Saturn is in Aquarius, setting at 22h 15m, 21h 30m and 20h 40m at the beginning, middle and end of the month, respectively. Its stellar magnitude is +1·1 and its distance from the Earth on December 15 is 938 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Dec. 12d 20h 23·5m, 30 Psc. (*D*); Dec. 12d 22h 14·8m, 33 Psc. (*D*); *D* refers to disappearance. The Geminid meteors are active during December 9–14, the maximum being on December 13; the radiant is near R.A. 7h 28m, Dec. +32°, and conditions for observation are favourable. The Ursid meteors are active during December 20–22, conditions for observation being unfavourable. The winter solstice occurs on Dec. 21d 19h 50m.

University News:

Birmingham

THE following appointments have been announced: *Senior Lecturer*, E. G. Knox (social medicine); *Lecturers*, Dr. J. E. Bowcock (mathematical physics); K. R. Chapman (physics); A. T. Clementson (engineering production); F. A. Garner (mining and minerals engineering); Dr. T. A. Hamor (chemistry); Dr. D. M. Hirst (chemistry); B. W. Jenney (engineering production); Dr. D. W. Jones (materials science); Dr. G. A. Parker (mechanical engineering); R. H. Saxton (civil engineering); R. M. Baddeley (surgery); Dr. D. A. Lewis (physiological chemistry); *Research Fellows*, M. J. Copsey (electron physics); Dr. W. P. Dodd (physics); Dr. A. Erndt (mining and minerals engineering); Dr. W. J. Feast (chemistry); Dr. U. Isaak (physics); R. J. Lumby (industrial metallurgy); Dr. T. F. Tuan (mathematical physics); A. Whittingham (chemistry); W. Young (mathematical physics); D. J. P. Barker (social medicine); Dr. T. Chojnacki (experimental neuropharmacology); Dr. R. Neisser (psychiatry); *Kenward Memorial Fellow*, J. A. Buzacott (engineering production).

London

DR. HILDE T. HIMMELWEIT, reader in psychology at the London School of Economics and Political Science, has been appointed to the chair of social psychology tenable at that School. Dr. G. L. Asherson of the Department of Immunology, National Institute for Medical Research, has been appointed to the readership in immunology tenable at the London Hospital Medical College. Dr. A. P. Willmore, lecturer at University College, has been appointed to a readership in physics tenable at that College. The title of professor of experimental pharmacology has been conferred on Dr. Franz Hobbiger in respect of the post held by him at Middlesex Hospital Medical School. The title of reader in embryology has been conferred on Dr. M. Ruth Bellairs in respect of the post held by her at University College.

Pennsylvania

DR. J. H. WILKINSON, reader in chemical pathology, of Westminster Hospital Medical School, University of London, has been appointed professor of clinical chemistry in medicine in the University of Pennsylvania, and expects to take up his new post in Philadelphia on April 1, 1965.

Strathclyde

MR. R. D. LORD, senior lecturer in mathematics in the University, has been appointed reader in mathematics. Dr. J. B. Helliwell, senior lecturer in mathematics in the University, has been appointed reader in gas dynamics. Dr. S. C. Hunter of the Royal Armament Research and Development Establishment, Ministry of Defence, has been appointed reader in solid mechanics. The three appointments became effective on October 1.

Announcements

DR. P. H. FOWLER, reader in physics in the University of Bristol, has been appointed to the Royal Society research professorship at the University of Bristol. Dr. Fowler is distinguished for his research work in high-energy physics and cosmic radiation, and for his contributions to the development of the emulsion technique. This is the sixth research professorship to be made by the Royal Society.

THE ninth congress on "Theoretical and Applied Mechanics" and symposium on "High-Speed Computation Methods and Machines" will be held at the Indian Institute of Technology, Kanpur, during December 20–24. Further information can be obtained from the Secretary, Indian Society of Theoretical and Applied Mechanics, Indian Institute of Technology, Kharagpur.

A SYMPOSIUM on "Hazards and Doses to the Whole Population from all uses of Ionizing Radiations and Radioactive Materials", arranged by the Hospital Physicists' Association, will be held in London on May 13. Further information can be obtained from the Secretary, Hospital Physicists' Association, 6 Paddington Street, Marylebone High Street, London, W.1.

THE one hundred and thirty-first meeting of the American Association for the Advancement of Science will be held in Montreal during December 26–31. The programme will include symposia on: primate behaviour; possible meteoric or lunar influences on meteorological phenomena; medical geology and geography; biochemical differentiation; science and the public mind—past and present; the sociology and ethics of science. Further information can be obtained from the Information Officer, American Association for the Advancement of Science, 1515 Massachusetts Avenue, N.W., Washington, D.C., 20005.

CORRIGENDUM. The top of Fig. 2 of the paper entitled "Limits of Human Vision" (*Nature*, 191, 471, 1961) by Dr. R. A. Weale contains an energy scale, inadvertently reduced by 1·477 log units. The bracket indicating an energy range thermally dangerous for the human eye will therefore correspond to a photometric reading of approximately 8·6 log scot. trol-sec.

EDUCATION AND RESEARCH IN ORAL SCIENCE IN THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

THE W. K. Kellogg Foundation of Battle Creek, Michigan, has made a grant of 440,000 dollars to the Massachusetts Institute of Technology for the further development of the Oral Science Program of graduate teaching and research in the Department of Nutrition and Food Science. The Oral Science Program in the Institute, directed by Prof. Robert S. Harris, professor of nutritional biochemistry, was established a year ago under a four-year grant in excess of 500,000 dollars from the National Institute of Dental Research, a division of the National Institutes of Health at Bethesda, Maryland.

The Kellogg grant, which will be used over a five-year period, represents collaboration among the private Foundation, the Massachusetts Institute of Technology and the National Institutes of Health in development of a broad programme of science-oriented graduate training for dental educators and research workers.

The Oral Science Program was initiated in response to the increasing need for the application of fundamental biological and physical sciences to the solution of problems in oral and dental disease and the growing demand for dental school faculty members, both dentists and life scientists, who possess a depth of understanding in the biological and physical sciences which underlie their professions.

Thus, the principal objectives of the Program embrace both the areas of professional education and fundamental research in the oral sciences. The Department of Nutrition and Food Science in the Massachusetts Institute of Technology was selected as the location for the Program, even though the Institute does not operate a dental school, because of the growing recognition of the importance of food and nutrition to dental health and because of the Institute's broad base in the underlying biological and physical sciences.

Several investigations are being carried out under the twin grants in the area of professional education, and foremost among these is a programme of graduate training in nutrition and oral science leading to a Ph.D. degree for selected graduate dentists and bioscientists of outstanding merit who will follow careers in dental education and research. This programme will normally require four years of study. Two post-doctoral students entered the programme a year ago; three more began recently, and eventually the number will increase to 15–20. The grant of the National Institutes of Health is being used to support students and their research. A substantial portion of the Kellogg grant will be used to provide specialized laboratories and clinical facilities.

A prime aim of the Ph.D. programme in oral science is to help broaden the scientific basis of America's dental school faculties and curricula by serving as a training centre for individuals who may become leaders in dental education and research. It is hoped that one result will be the eventual scientific broadening of the professional education provided to the nation's dental practitioners.

According to Prof. Harris, the research strides being made in understanding and preventing oral diseases, especially dental decay, will have the long-range effect of bringing about fundamental changes in the character of dental practice. Practitioners, in order to meet the demands of these changes, will need a broadened training in basic science in the course of their professional dental education.

Other activities being undertaken in this Oral Science Program to contribute to professional education include short summer courses for dentists and dental faculty members in nutrition and related biosciences, special seminars and conferences, educational television programmes directed to dental practitioners, and the publication and dissemination of research findings and critical reviews. There will also be activities intended to inform the lay public how nutrition and oral hygiene affect the teeth and gums.

Research under the Oral Science Program is focused on the biochemical, microbial and nutritional aspects of oral pathology. Much fundamental work remains to be done before a clear understanding can be obtained of the relationships between human nutrition, food-borne microbial agents, and human biochemical systems, and of their combined effects on oral and dental disease and health. [See also *Nature*, 204, 526; 1964.]

THE NUFFIELD FOUNDATION

THE nineteenth annual report of the Nuffield Foundation* covers the year ended March 31, 1964. It includes a just and dignified tribute to Lord Nuffield's interest in healing and research and civic welfare throughout the Commonwealth, as well as an appreciation of Mr. L. Farrer-Brown's services as director, from which office he retired at the end of the year. During the period covered allocations were made totalling £1,785,963, of which £240,493 was for biological research, £40,000 for research in rheumatism, £353,600 for other medical research, £322,300 for social research and experiment, £418,103 for education, and £407,535 for grants for the Commonwealth overseas. While the allocations followed the pattern of previous years, emphasis was placed on two grants for medical research, one of which, up to £350,000 to establish a unit for medical genetics in the University of Liverpool, is the largest single grant yet made by the Foundation for medical research. The other grant is one of £50,000 to the Royal College of Surgeons for a building at its Buckston Browne Farm to set up a colony of monkeys, including a section devoted to breeding, with the primary purpose of enabling the Department of Dental Science to make experimental investigations into dental caries. In directing attention to this grant the trustees comment that since 1946 the Foundation's support for dental research has been largely limited to its scheme of dental fellowships and scholarships and that the paucity of research grants reflects the lack of applications rather than any decline in interest by the Foundation.

With the last-mentioned observation should be set the later, more general, comment that, although the number of research applications submitted to the trustees increased during the year, there was not the overwhelming flood of applications that might have been expected from reports during the year of widespread lack of funds for research. In medicine and biology the Foundation made slightly fewer grants than in 1962–63, and the increase in the allocation reflects an increase in the average size of the grants. In the social sciences both the number of grants and their average size increased. The trustees do not

* The Nuffield Foundation. Report for the year ended March 31, 1964. (Nineteenth Report, 1963–64.) Pp. xvi+204+2 plates. (London: The Nuffield Foundation, 1964.)

anticipate any long-term decrease in the requests of the universities for Foundation support as a result of any Government action on the Robbins Report. On the contrary, the expected general increase in academic research may itself generate new demands, and perhaps also enable the Foundation in its choice of projects to adhere more closely to those areas most consonant with its policies and commission. Private foundations generally may well expect that their opportunities for useful action will always outrun their resources.

The £40,000 for research into rheumatism already noted includes a grant of £34,740 to the Middlesex Hospital Medical School to establish an Experimental Immunological Unit for the purpose of carrying out investigations into auto-immune phenomena in rheumatoid disease. Other grants for medical research include £52,800 over 5 years to the Department of Social and Occupational Medicine of the Welsh National School of Medicine for an investigation of bronchitis among steelworkers at Ebbw Vale and Port Talbot, and a further grant of £33,350 to the Unit of Biometry, University of Oxford, towards the cost of a small Elliot 803 computer, but the report records the failure, for lack of industrial support, of the promising occupational hygiene service at Slough. A grant of £15,000 over 5 years has been made in support of Dr. Stephen Black's investigation, by electroencephalogram studies and psychophysiological techniques, of the brain's responses to stimuli in different sensory modalities, and one of £11,000 to support studies of exploratory behaviour in children at the Park Hospital for Children, Oxford, for a period of 5 years.

Among the grants for biological and other scientific research may be noted one of £29,000 over 5 years to the Department of Botany, University of Cambridge, for an investigation into the mechanism governing the uptake and loss of ions by plant cells, and the distribution of ions within the tissue of the whole plant, while one of £42,150 over 5 years to the School of Biological Sciences, University of East Anglia, is to permit the building up of a team to study ion and water uptake by the roots of higher plants. A grant of £71,681 was made to provide accommodation for research at the Department of Botany, University of Glasgow, more particularly for research on the physiology of parasites, while a capital grant of £46,500 to the Strangeways Research Laboratory, Cambridge, now the largest centre for cell biology in Britain, is for equipment and increased accommodation for the Biophysics Section, particularly for investigation of the fibrous proteins of connective tissue and the constituents of the ground substance at different levels of structure. A grant of £11,250 over 3 years was made to the Department of Organic Chemistry, University of Manchester, for research into the transport of organic molecules across cell membranes, and £12,155 to the Department of Zoology, University of Sheffield, in support of biophysical work on the interaction of steroid hormones with macromolecular structures in the cell.

A new grant of £35,000 over 5 years was made to the Department of Metallurgy, Imperial College of Science and Technology, London, to enable a research group to be built up in process engineering metallurgy, while the Foundation is also assisting the Advanced School of Automobile Engineering, Cranfield, to develop its research activities with a grant of £15,000 over 5 years for an investigation of the effects of vibration on comfort and human performance. The Foundation has provided up to £250,000 to the Royal Society towards half the cost of the necessary reconstruction of part of Carlton House Terrace, on the understanding that the Government will secure the premises to the Society without charge for at least 99 years.

Of the grants for social research and experiment, the trustees direct particular attention to five: first, one of £70,000 over 5 years was made to the Institute of Race Relations for a survey of relations between the coloured communities in Britain and their host community; secondly, £45,000 over 4 years went to Prof. C. Buchanan of the Department of Civil Engineering, Imperial College of Science and Technology, for transport studies; thirdly, £42,000 over 4 years to the Institute for Operational Research for research into the planning processes of a local government authority; fourthly, £15,000 over a year and a half to the National Institute for Economic and Social Research for a study of the costs of bringing all the urban parts of Britain up to satisfactory standards in housing and other urban facilities; and, fifthly, £30,000 over 3 years to the Institute of Community Studies for the development of its plans for research through social experiments. A grant of £9,000 over 3 years was also made to the Institute of Social and Economic Research, University of York, for a study of the social and economic problems of urban redevelopment in the West Riding, while a similar grant was made to the Department of Social and Economic Research, University of Glasgow, for a comparative study of European regional economic problems. A further grant of £10,000 over 6 years was made to the Institute of Strategic Studies for its library, and a grant of £20,000 to Political and Economic Planning was to help with the removal to new premises; while one of £3,000 over 2 years went to the School of Architecture, University of Cambridge, for research into the design of science lecture-rooms.

Of the grants for education, one of £60,000 to the London School of Economics to finance a Unit for Economic and Statistical Studies on Higher Education is specially emphasized by the trustees. In the first place, the Unit will examine the relation between higher education, the structure of the labour force and economic growth, and will assess the demand from school-leavers for entry into different kinds of education beyond the compulsory school age and the relation of this demand to social, economic and educational factors. The Foundation is also particularly interested in investigations of language development and in fundamental work on intellectual development based on present-day biological research. A further £175,000 was allocated for the Science Teaching Programme, £75,000 was set aside for a project in science for 5–13-year-olds, and allocations of £6,000 were made for each of three groups concerned with identifying the main strategy and objectives in planning teaching material for physics, chemistry and biology at the Advanced Level of the General Certificate of Education. Of the £100,000 set aside for the Language Teaching Programme, £50,000 has been allocated to the Language Teaching Materials Project, and a grant of £22,000 over three years was made to the Communication Research Centre, University College, London, for research into the English language designed to contribute to the teaching of English in schools; £20,500 over five years to the Department of Psychology, University of Cambridge, for further investigation of the effect of personality factors on intellectual development; £10,500 over three years to the Department of Psychology, University of Hull, for research into learning transfer in young children; and £6,600 over three years to the Department of Statistics, University College, London, for research into university selection and performance.

Grants for the Commonwealth overseas include up to £4,800 for the first two years of a scheme of scholarships for economists from overseas to be run by the Overseas Development Institute; a further grant of £100,000 over five years to the Centre for Educational Television Overseas; and a final grant of £20,000 over three years to the Overseas Visual Aid Centre, conditional on satisfactory financial support from Government sources. A grant of £16,000 was made to the University of Ibadan to provide a nuclear magnetic resonance spectroscope for research on natural products in the Department of Chemistry; £26,050 over the next four years to the Nuffield Unit of Tropical Animal Ecology at Mweyz in Queen Elizabeth

National Park, Uganda; up to £12,000 for the production of a film illustrating the work on teacher training in the Kilimanjaro district of Northern Tanganyika; a further £7,500 for investigations in terrestrial ecology jointly by the University College of Rhodesia and Nyasaland and the University of Witwatersrand; and £3,800 over three years for research into the vegetation of swamps by Makerere College, University of East Africa. A grant of £80,000 was made to the Walter and Eliza Hall Institute of Medical Research, Melbourne, for extensions for immunological research, a similar grant to enable the Sydney Church of England Homes for Aged Persons to obtain a site and erect the Nuffield Garden Village, and £2,640 over three years for investigations by the Department of Biochemistry, University of Adelaide, into the association of deoxyribonucleic acid and the yeast cytochrome b_2 from which it is isolated and of the way in which deoxyribonucleic acid controls the behaviour of yeast. The University of Hong Kong received a grant of £26,650 over three years towards research in the Department of Zoology into the level of adrenocorticosteroids at cellular level, and one of £15,000 was made to the British Solomon Islands Protectorate for training college accommodation for women students.

As an experiment, the Foundation offered a special award for a medical fellowship to be held in Ibadan, Makerere, Vellore or the University of the West Indies, but although there was keen competition for the ordinary fellowships, of which four were awarded, only one candidate applied for the special fellowship, and as he did not wish to follow an academic career in medicine no award was made. One medical research fellowship was awarded, four fellowships, three assistantships for general practitioners, and 24 scholarships in tropical medicine, enabling senior students to spend three months attached to a Commonwealth medical school in the tropics. One research fellowship, five fellowships and three scholarships in dentistry were awarded, and the first six awards were made under the new scheme for food science. Two scholarships were awarded under the new scheme for sociological awards, and awards under the schemes for the Dominions and Colonies included 20 Dominion fellowships (six in medicine, eight in science, six in the humanities and social sciences) for graduates from Australia, Ceylon, India, Pakistan and New Zealand; three travelling fellowships for Canadian public officials and two for trade unionists; and nine short-term travel grants for senior Canadian scholars (one in medicine, five in science, three in the humanities and the social sciences). Two fellowships were awarded to Civil Servants from Pakistan; and under the scheme for training Africans in agriculture, a scholarship was awarded to a farmer from Kenya. The Foundation's grant to the joint scheme with the Royal Society for Commonwealth Bursaries was renewed for a further, final period of five years at £5,000 a year, and 24 awards were made.

COMBUSTION

THE tenth International Symposium on Combustion was held in the Department of Physical Chemistry, University of Cambridge, during August 16–21, 1964. Nearly 700 chemists, physicists and engineers from 25 countries attended. Among the overseas visitors were Dr. Bernard Lewis (President of the Combustion Institute) and Profs. Kistiakowsky, Kondratiev, Laffitte, Jost and Von Elbe.

The Plenary Lecture, entitled "The Study of Combustion by Photochemical Methods", was delivered by Prof. R. G. W. Norrish (Cambridge), who gave a broad survey of the development of understanding of the basic processes of combustion over the past forty years, with particular reference to the contributions made by kinetic spectroscopy and flash photolysis. The lecture was preceded by a short inaugural meeting and the presentation of the Combustion Institute Awards: the Sir Alfred Egerton Medal to Prof. P. Laffitte (Paris), the Bernard Lewis Medal to Prof. R. G. W. Norrish, and the Silver Combustion Medal, for the best paper presented at the ninth Symposium, to N. M. Howe, jun., C. W. Shipman and A. Vranos.

The papers in the discussion under the title "Elementary Combustion Reactions" fell into two groups—sixteen concerned with neutral species and nine with charged species. The review paper in the first group, "Elementary Combustion Reactions", was given by Prof. Ashmore (Manchester). The papers which followed centred round several topics. F. J. Wright (Esso Research) spoke on the nature of initial attack by oxygen atoms; C. F. Cullis, A. Fish and J. F. Gibson (Imperial College of Science and Technology) on the mechanism of spontaneous ignition of hydrocarbon mixtures; R. V. Blundell *et al.* (Dundee) on methane oxidation; G. B. Kistiakowsky and colleagues (Harvard) on methane and acetylene oxidation in shock waves; R. R. Baldwin and colleagues (Hull) on the use of the H_2—O_2 reaction for investigating the reactions between H and O atoms and OH and HO_2 radicals and hydrocarbons. G. Dixon-Lewis, M. M. Sutton and A. Williams (Leeds) reported measurements made in H_2—O_2 flames on the reaction rates of H atoms with O_2, D_2O and CO_2. P. Gray (Leeds) and J. C. J. Thynne (Edinburgh) discussed the kinetics of H atom abstraction by methyl radicals from substances containing the N—H bond, and L. Phillips and R. Shaw (Explosives Research and Development Establishment) discussed the reactions of methyl and methoxy radicals with NO and NO_2. The effect of SO_2 on H_2—O_2 explosion limits was considered by P. Webster and A. D. Walsh (Dundee). Several authors discussed atom and radical recombination: F. S. Larkin and B. A. Thrush (Cambridge), H atoms; K. L. Wray (Avco-Everett Research Laboratories), O atoms; C. P. Fenimore and G. W. Jones (General Electric Research Laboratories), radical recombination and heat release. J. R. Airey, J. C. Polanyi and D. R. Snelling (Toronto) considered hydrogen–halogen chain reactions. Carbon formation in premixed hydrocarbon–oxygen flames at reduced pressure was the subject of a paper by U. Bonne, K. H. Homann and H. Gg. Wagner (Göttingen), in which evidence was presented suggesting a correlation between the formation of poly-acetylenes in the reaction zone and the appearance and growth of soot particles. (Soot formation was also considered by K. S. Narasimhan and P. J. Foster in the General Session.) An interesting paper by A. A. Westenberg and R. M. Fristrom (Johns Hopkins) discussed a promising method of measuring free radical concentrations in flames by electron spin resonance. With probe sampling of flame gases combined with standard electron spin resonance techniques and using O_2 as a reference gas, they obtained absolute O and H atom profiles in hydrocarbon–oxygen flames at reduced pressure.

The second group of papers, concerned with ions, was preceded by a review, "Charged Species", by Dr. T. M. Sugden ('Shell' Research). Several papers in this section discussed the mechanism of chemionization in flames. In contrast to the ninth Symposium, where there appeared to be general agreement about the $CH + O \rightarrow CHO^+$ mechanism, there was no such agreement here. Prof. Kistiakowsky and colleagues (Harvard), on the basis of shock tube experiments, revived an earlier suggestion of Knewstubb and Sugden (later dismissed by them) that

$C_3H_3^+$ was the primary ion, formed by the reaction $CH^* + C_2H_2 \rightarrow C_3H_3^+$, CHO^+ having no importance; while A. Fontijn, W. J. Miller and J. M. Hogan, and H. F. Calcote, S. C. Kurzius and W. J. Miller (Aerochem. Research Lab., Inc.), from flow system and atomic flame experiments, and from a study of low-pressure flames, respectively, suggested that both CHO^+ and $C_3H_3^+$ were primary ions, which could predominate under different conditions.

J. L. Franklin and M. S. B. Munson (Humble Oil Co.) produced data on positive ions in crossed-beam experiments with methane and acetylene and oxygen. K. Schofield and T. M. Sugden (Cambridge) discussed observations on the ionization of alkali and alkaline earth metals and their compounds in hydrogen flames and proposed mechanisms for the formation of the positive ions known to be present. Two papers, by H. F. Calcote, S. C. Kurzius and W. J. Miller (Aerochem. Research Lab. Inc.) and by A. Feugier and A. Van Tiggelen (Louvain), provided data on negative ions in flames, but there appeared to be little agreement between them on the relative importance of the species observed. A. V. Phelps and J. L. Pack (Westinghouse Research Lab.) and M. A. Biondi and co-workers (Pittsburgh) reported results obtained with relatively simple plasmas, which might contribute to the understanding of more complicated flame systems. The former dealt with electron attachment and detachment in O_2 and in O_2—CO_2 and O_2—H_2O mixtures, and the latter with positive ion (Ne_2^+, N_2^+, O_2^+ and NO^+)-electron recombinations.

The discussion "Electrical Properties of Flames" centred round twelve papers. Three were concerned with the measurement of ionization. A. J. Borgers (Utrecht) described the application of the high-frequency resonance method to the measurement of electron concentrations in flames. B. E. L. Travers and H. Williams (Rocket Propulsion Establishment) discussed the use of probes for the measurement of positive ion densities in flames and suggested that double-probe measurements are more reliable, particularly when electron temperatures are required, and G. Wortberg (Aachen) reported some ion concentration measurements on flat, atmospheric pressure flames. G. N. Spokes and B. E. Evans (Stanford Research Institute) considered various factors which may influence the results when ions are sampled from chemical plasmas in mass-spectrometric work. U. W. Balwanz (U.S. Naval Research Lab.) reported on ionization in rocket exhausts. D. L. Turcotte and W. Friedman (Cornell) discussed the interaction between seeded combustion products and cold electrodes, and S. L. Soo and R. C. Dimick (Illinois) that between an ionized gas and solid particles. F. J. Weinberg and co-workers (Imperial College of Science and Technology) read papers on flames augmented with electric discharges and on the effect of electric fields on droplets and particles in an ionized gas. R. M. Davies (Gas Council) described heat transfer measurements in electrically boosted flames. N. I. Yushchenkova and S. I. Kosterin (U.S.S.R.) dealt with ionization in seeded air on supersonic expension; R. Friedman (Atlantic Research Corporation) described a method of producing electron-rich gases from a solid fuel mixture burning to CO, N_2 and Cs.

Twelve papers were grouped under the heading "Flame Chemistry". Several of these were devoted to various problems connected with the experimental determination of the composition of flame gases: K. N. Bascombe (Explosives Research and Development Establishment) described the measurement of H-atom concentrations in fuel-rich, highly diluted H_2—O_2 flames; W. G. Agnew and J. T. Agnew (General Motors), the mass spectrometric determination of composition profiles for two-stage flat diethyl ether–air flames; N. Bradley *et al.* (Liverpool), a mass-spectrometric examination of cool flames of aldehydes. The behaviour of cool flames of hydrocarbons was investigated by B. H. Bonner and C. F. H. Tipper (Liverpool); monopropyl pentaborane flames by W. G. Berl and co-workers (Johns Hopkins); hydrogen azide decomposition flame by P. Laffitte, I. Hajal and J. Combourieu (Paris); the kinetics of H_2—Cl_2 flames by R. Corbeels and K. Scheller (U.S.A.F. Aerospace Research Lab.); the inhibition of CH_4—O_2 flames by CH_3Br by W. E. Wilson, jun. (Johns Hopkins); and the reactions of alkali metals in fuel-lean H_2—O_2—N_2 flames by W. E. Kaskan (General Electric). Two papers, by P. H. Kydd and W. I. Foss (General Electric) and H. C. Hottel and colleagues (Massachusetts Institute of Technology), were concerned with the processes occurring in stirred reactors (the more practical aspects of stirred reactors were considered in the discussion on aerodynamics in combustion), and two with non-thermal emission from flames—H. G. Wolfhard (Institute for Defense Analyses) and collaborators (Thiokol Chem. Corp.) OH radicals in low-pressure flames, and P. J. Th. Zeegers (Utrecht) OH radicals and K atoms.

Of the twelve papers under the heading "Reaction Kinetics", five dealt with various aspects of the H_2—O_2 reaction. T. Asaba, W. C. Gardiner, jun., and R. F. Stubbeman (Texas), and V. V. Voevodsky and R. L. Soloukhin (U.S.S.R.), described shock wave investigations. Problems associated with the induction period were discussed by F. E. Belles and M. R. Lauver (N.A.S.A., Lewis Research Center); ignition kinetics by R. S. Brokaw (N.A.S.A., Lewis Research Center); inhibition of the second limit by HBr and HCl by D. R. Blackmore, G. O'Donnell and R. L. Simmons (Manchester). M. A. A. Clyne (Cambridge) discussed the reactions of the HNO molecule; V. N. Kondratiev (U.S.S.R.), thermal cracking of methane; A. Martinengo, J. Melczer and E. Schlimme (Göttingen), the analysis of stable reaction products from the adiabatic compression of hydrocarbon–air mixtures; J. Hay, J. H. Knox and J. M. C. Turner (Edinburgh), homogeneous and heterogeneous processes in the gas-phase oxidation of isobutane and isobutene. Three contributions in this section were devoted to hydrazine: pyrolysis kinetics, on the basis of a shock tube investigation, were considered by E. T. McHale, B. E. Knox and H. B. Palmer (Pennsylvania State); pyrolysis and oxidation by K. W. Michel and H. Gg. Wagner (Göttingen); and decomposition of hydrazine and its methyl derivatives by I. J. Eberstein and I. Glassman (Princeton).

The "Flame Spectroscopy" section comprised seven papers; two of these were concerned with the determination of the properties of hot gases by spectroscopic means: C. C. Ferriso, C. B. Ludwig and F. P. Boynton (General Dynamics) described an infra-red method of determining the CO_2/H_2O ratio and the flame temperature, and G. J. Penzias (Warner and Swasey Co.) discussed the CO_2 concentration. U. P. Oppenheim and A. Goldman (Israel Institute of Technology) presented data on the infra-red emissivity of water vapour, and S. H. Bauer (Cornell) and J. H. Jaffé (Weizmann Institute, Israel) on the collision broadening of infra-red emission lines of OH. S. Tsuchiya and K. Kuratani (Tokyo) considered the excitation and quenching of Na atoms behind a shock wave. Results of investigations on molecular radiative transfer in non-isothermal gases (such as a rocket exhaust plume) were presented by F. S. Simmons (Michigan). Problems connected with mass spectrometric sampling of flame gases at atmospheric pressure were discussed by T. A. Milne and F. T. Greene (Midwest Research Unit).

The seven papers in the "General" group contained no obvious unifying factor and appeared to be an 'overflow' from the Flame Chemistry and Reactions Kinetics sections.

The thermal ignition theory in autocatalytic reaction was considered by P. G. Ashmore and T. A. B. Wesley (Manchester), ignition of gases at a hot surface under non-steady state conditions by G. Adomeit (Aachen), the explosive decomposition of azomethane by N. Y. Gerri and F. Kaufman (Ballistic Research Laboratories). R. H.

Atalla and K. W. Wohl (Delaware) dealt with the effect of added N_2 on the light emission from butane–oxygen flames. Radiation processes connected with high-pressure H_2—O_2 combustion were considered by M. C. Barrows (NASA, Lewis Research Center), and supersonic firings into H_2—O_2 and H_2–air mixtures by H. Behrens, W. Struth and F. Wecken (Inst. Franco-Allemand). Results on soot formation on introducing CH_4 into burnt flame gases were presented by K. S. Narasimhan and P. J. Foster (Sheffield).

There were twenty-two papers grouped in the discussion "Aerodynamics in Combustion"; eight of these were placed under the heading "Free Burning Fires". The fundamental problems of free-burning fires were discussed by H. W. Emmons (Harvard). The influence of various factors on such fires was considered by a number of authors; the effect of irradiation, humidity and air velocity on the spreading of fire over controlled fuel beds by H. C. Hottel, G. C. Williams and F. Steward (Massachusetts Institute of Technology) and by H. E. Anderson and R. C. Rothermel (U.S. Forest Service), the effect of cross-winds on turbulent diffusion flames of gas by A. A. Putnam (Battelle Memorial Inst.). Some theoretical aspects of buoyant fire plumes were discussed by H. J. Nielson and L. N. Tao and by B. R. Morton (Illinois Institute of Technology); measurements on buoyant diffusion flames were reported by P. H. Thomas, R. Baldwin and A. J. M. Heselden (Fire Research Station, U.K.). C. Sandches Tarifa, P. Perez del Notario and F. Garcia Moreno (Madrid) presented results on the flight paths and lifetimes of burning wood particles.

Related topics were considered in a group of five contributed papers under the heading "Fire Research". Four of these, by S. Martin (U.S. Naval Radiological Defense Lab.), by W. D. Weatherford, jun., and D. M. Sheppard (Southwest-Research Inst.), by P. L. Blackshear, jun., and K. A. Murty (Minnesota) and by E. R. Tinney (Washington State), were concerned with the ignition and burning of cellulosic materials. D. Gross and A. F. Robertson (National Bureau of Standards) considered enclosed fires, and K. Akita and T. Yumoto (Fire Research Inst. of Japan) the combustion of liquid methanol.

The remaining fourteen papers in the discussion on aerodynamics in combustion were largely concerned with engineering problems connected with combustion. Of the four papers on rocket combustion instability, two, by R. W. Hart and F. T. McClure (Johns Hopkins) and by L. Crocco (Princeton), dealt with the theoretical aspects of solid and liquid rocket propellant combustion instability, respectively. The other two, by E. W. Price (U.S. Naval Ordnance Test Station) and by R. S. Levine (Rocketdyne), discussed the experimental data on instability.

The ten papers on low- and high-speed combustion processes were concerned with the problems associated with different types of combustors of industrial interest. A. M. Brown and M. W. Tring (Sheffield) discussed the application of pressure-jet burners to marine boilers, and F. Mauss, E. Perthius and B. Sale (Inst. Français du Petrole) low-frequency oscillations in fuel-oil boilers. Efficiency problems of combustors were investigated by J. M. Beer and K. B. Lee (International Flame Research Foundation), using suitable models. Results of theoretical and experimental examinations of high intensity combustors were presented by W. E. Francis (Gas Council). Oscillatory effect, in tunnel burners were considered by J. K. Kilham, E. G. Jackson and T. J. B. Smith (Leeds). Practical problems connected with gas turbine combustion were discussed by A. H. Lefebvre (College of Aeronautics, U.K.). Combustion rates in confined turbulent flames were investigated by N. M. Howe, jun., and C. W. Shipman (Worcester Polytechnic Inst.), and the burning of propane in a spherical combustor by A. E. Clarke *et al.* (Lucas Gas Turbine Equipment, Ltd.). F. S. Billig (Johns Hopkins) presented results on the supersonic combustion of aluminium alkyl fuels, and M. M. Gibson (Northern Research and Engineering Corp. International) data on flames in supersonic premixed combustible gas streams.

The "Detonation" session consisted of twelve papers. Six were concerned with condensed phase. Various aspects of the subject were considered—detonation limits in composite explosives by W. E. Gordon (Combustion and Explosive Research, Inc.), critical diameter by A. N. Dremin and V. S. Trofimov (U.S.S.R.), pressure measurements during shock initiation by V. M. Boyle, R. L. Jameson and F. E. Allison (Ballistic Research Labs.), detonation front structure by B. G. Craig (Los Alamos), the application of a shock wave approximation to detonation initiation by D. C. Pack and F. J. Warner (Royal College of Science and Technology, Glasgow). B. Hayes (Los Alamos) reported the results of electrical conductivity measurements on reaction zones of explosives and revived the long discarded (at least for flames with no visible soot formation) solid carbon theory to account for his observations. Six papers dealt with gaseous detonations: R. W. Getzinger *et al.* (Berkeley) discussed steady detonations in ozone; D. R. White and G. E. Moore (General Electric), induction zones in H_2—O_2 and CO—O_2 mixtures; P. A. Urtiew, A. J. Laderman and A. R. Oppenheim (Berkeley), the generation of pressure waves by accelerating flames; E. K. Dabora, J. A. Nicholls and R. B. Morrison (Michigan), the influence of a compressible boundary on detonation propagation; J. H. Lee, B. H. K. Lee and T. Shanfield (McGill, Montreal), two-dimensional unconfined detonation waves; M. L. Wilkins, B. Squier and B. Halperin (California University, Livermore), equations of state for selected explosives.

The contributed papers in the "Combustion and Flow" section centred round topics similar to those in the discussion on aerodynamics in combustion, and mainly related to flame instability and turbulence. Stability and oscillations of laminar jet flames were considered by I. Kimura (Tokyo), mechanisms of acoustic effects associated with flames by Tau-Yi Toong *et al.* (Massachusetts Institute of Technology); high-frequency oscillations in a rocket motor by H. Tsuji and T. Takeno (Tokyo), the combustion of droplets in a gas stream undergoing acoustic oscillations by W. C. Strahle (Princeton). Turbulence problems were dealt with by numerous authors: turbulent boundary layers, by G. A. Marxman (United Technology Center) and by C. E. Wooldridge and R. J. Muzzy (United Technology Center); concentration intermittency in jets by H. A. Beckers, H. C. Hottel and G. C. Williams (Massachusetts Institute of Technology); turbulent exchange behind flameholders by G. Winterfeld (D.V.L. Inst. für Luftstrahlentriebe); turbulent flashback by L. N. Khitrin *et al.* (U.S.S.R.). N. H. Pratt and J. E. C. Topps (National Gas Turbine Establishment) described a new experimental method for the investigation of heat release in expanding combustion products, and H. Edmondson and J. E. Garside (Leeds) the lifting of diffusion flames; H. Phillips (Safety in Mines Research Establishment), experiments on buoyant methane flames.

The "Solid Propellant Combustion Fundamentals" section comprised six papers. Three of these discussed perchlorates: G. A. McD. Cummings and R. A. Hall (Rocket Propulsion Establishment), premixed flames of perchloric acid with CH_4, C_2H_6 and CH_3OH; J. Powling and W. A. W. Smith (Explosives Research and Development Establishment), the surface temperature of burning ammonium perchlorate; M. Barrère and L. Nadaud (ONERA, France), the combustion of ammonium perchlorate spheres in a stream of gas. Chemical kinetics of cordite explosions were considered by G. Sotter (Sheffield); emittance of solid metal oxide particles in propellant combustion products by D. J. Carlson (Philco Research Labs.); regression rates of solid fuels and polymer degradation by B. Rabinovitch (United Technology Center).

The Symposium received support from U.S. Army Ballistic Research Laboratories, National Aeronautics and Space Administration, National Science Foundation, National Academy of Sciences—National Research Council Committee on Fire Research, the British Section of the Combustion Institute, and from many industrial firms in Britain, the United States and Canada.

The next symposium will be held in 1966 at Berkeley, California.

THERMAL CONDUCTIVITY

THE expanding field of new materials and their use in all branches of technology, particularly those involving transfer of heat, has increased the scope of work on thermal conductivity during the past two decades and created a revival of interest in the subject. The problems are international, and this was apparent during July 15–17 when 150 invited delegates, representing 11 countries, met at the National Physical Laboratory to discuss their work in this subject. For many years the Laboratory has been involved in work on the thermal properties of materials and it was, therefore, a most appropriate venue for such a gathering.

The comprehensive programme of 50 papers contained a majority which were devoted to methods of measurement, supplemented by others which included results for some particularly important materials in solid, liquid or gaseous state. In some of the cases where metals or semiconductors were reported on, the results were accompanied by an analysis which was of value in relating the behaviour of real materials to the theory of solids.

Much attention was directed to the difficulties encountered in the measurement of thermal conductivity over the very wide range of temperature now considered of practical importance. It was also realized that poor experimental work cannot be explained with elaborate hypotheses; measurements to high accuracy are required before any attempt is made to assess materials or investigate theories. Significant advances have been made in methods for all conductivity ranges both for fundamental purposes and for the less accurate but rapid practical requirements.

Some particularly important developments have been made to the original unmatched guard apparatus first proposed by M. J. Laubitz (National Research Council, Ottawa). He has dispensed with the guard tube and now undertakes the measurement of temperature profile along the axis of his two-sectioned centrally heated rod by means of a tightly fitting thermocouple sliding inside an axial hole. These accurate measurements coupled with a reasonably simple mathematical analysis of the system seem capable of yielding results very quickly, since equilibrium conditions are attained rapidly, at temperatures up to 1,000° C. For basic studies of materials at these temperatures this is an important step forward and the possibilities of extending its temperature range by using optical pyrometry were seen immediately.

H. E. Robinson (U.S. National Bureau of Standards) discussed forms of line heat sources that could be used as heaters in apparatus for measurements at lower temperatures on insulating materials in disk and slab form. These new configurations lend themselves more readily to mathematical analysis, they are more simple to use and would appear to be able to yield more accurate results.

R. Berman (Clarendon Laboratory, Oxford), during a session devoted to low temperatures, described a significant new measurement technique whereby thermal conductivities can now be undertaken between 1° and 300° K using a single method involving thermocouples for temperature measurements. These couples are a combination of gold alloyed with 0·02–0·03 per cent iron together with chromel or a semi-conductor as the opposite element. The thermocouple sensitivity over the whole range is never less than 10 μV/°C and temperature differences of 0·001° C can be measured to a few per cent. By this means it has been possible to study solid helium in the body-centred cubic phase which exists only over a temperature range of a few hundredths of a degree. The method is also being applied to measurements on lithium fluoride using different concentrations of the ^{6}Li and ^{7}Li isotopes, in order to obtain a better understanding of the effects of phonon scattering.

In the two sessions devoted to fluids it soon became apparent that there was a division of interests between precise and practical requirements. B. Vodar (Centre National de la Recherche Scientifique, Bellevue) and his collaborators satisfied those delegates interested in the former by describing several new methods together with their results estimated to be accurate to 1 per cent for a series of gases and liquids over a 600° C temperature range and pressures up to 1,000 bars. There is, however, a very great interest in quick and reliable methods capable of yielding the more practical accuracies of 5–10 per cent. The thermal comparator method developed by R. W. Powell (National Physical Laboratory) and others, and the hot-wire method as suggested by D. T. Jamieson (National Engineering Laboratory), are two which should fulfil these needs. The whole subject of thermal conductivity of liquids is overshadowed by the very large discrepancies in the results that are available for a number of liquids in general use. H. Poltz (Physikalisch-Technische Bundesanstalt, Braunschweig), in discussing the effects of radiation in liquids, has found that the effective conductivity is dependent on the optical thickness of a liquid layer. There are measurable contributions due to this mode of heat transfer even at room temperature. It is possible that this radiation effect, if studied further, may well be a significant contribution towards resolving the existing divergencies which cannot as yet be fully explained.

The design and efficient operation of nuclear reactors are greatly dependent on a knowledge of the thermal properties of the materials used. These facts were emphasized in three contributions devoted to materials at present in use and two dealing with those for advanced reactors. Results for post-irradiated uranium, UO_2 during neutron irradiation and *Dragon* fuel cartridge materials were presented by D. Shaw, D. J. Clough and J. Milne (U.K. Atomic Energy Authority), respectively, and were supplemented by McElroy's (Oak Ridge National Laboratory) two reports, one on graphite materials to 1,000° C and the other dealing with UO_2 to 400° C. The borides and nitrides of Ti, Zr, Hf and Nb are now being considered as high-temperature materials of the future, and recent work has shown that they have valuable practical physical properties coupled with unusual electronic and lattice conductivity behaviour which have yet to be fully explained. R. Mendez-Penalosa (University of Madrid) discussed his work on zirconium nitride, and M. Hoch (Cincinnati University) presented results for a collection of these materials up to 1,800° C obtained using an inductive heating method. The evaluation of thermal conductivity required an accurate knowledge of emissivity and specific heat, which in this case were independently measured. This last-mentioned factor served to highlight the controversy that existed during several sessions whereby the relative merits of the measurement of thermal conductivity, as opposed to its evaluation from thermal diffusivity determinations, were elaborated. G. C. Danielson (Iowa State University) has indicated that

there is no doubt that thermal diffusivity can be measured both accurately and quickly. However, the derivation of thermal conductivity from this measured quantity is still dependent on an accurate knowledge of specific heat and density.

Since 1961 there have been three informal conferences restricted mainly to workers concentrated on the North American continent and devoted almost entirely to solid materials. The growth of the work has been sufficient to justify an international meeting which covered the subject more comprehensively. General benefit has resulted from the exchange of information concerning the problems and the anticipation of future requirements. However, it would appear that there are two important matters which workers in the field should settle without delay. The first point relates to the standardization of units and symbols, a case where physicists, engineers and chemists must co-operate before the number of units exceeds the number of methods. Secondly, there is an international requirement for the production and property evaluation of reliable and reproducible reference materials for a very wide range of thermal conductivity and temperature.

Abstracts of all the papers presented are available on application to the Basic Physics Division, National Physical Laboratory.

SPACED-SITE OBSERVATIONS OF JUPITER IN 1963

By C. H. BARROW and G. M. RESCH
Department of Physics, Florida State University, Tallahassee, U.S.A.
F. W. HYDE
Radio Astronomy Observatory, St. Osyth, Essex, Great Britain
AND
G. M. GRUBER and M. C. BOSCH
Department of Physics, Rhodes University, Grahamstown, South Africa

JUPITER has been monitored at 18 Mc/s for 16 h daily during 133 days in 1963. This was achieved by combining observations from three stations in the United States, in Great Britain and in South Africa. Correlation coefficients between Jupiter activity and various indicators of solar activity have been computed, but these do not indicate any statistically significant cross correlation. The occurrence probability of the Jupiter radiation was found to differ considerably at each site.

It has been suggested by several investigators that the radiation from Jupiter is in some manner related to solar activity, in that periods of Jupiter activity frequently follow periods of solar activity within a few days. This effect was first reported by Warwick[1] and has also been observed by Carr *et al.*[2], by Douglas[3], and by Barrow[4]. There is, however, no general agreement as to an average delay time between periods of solar activity and possible related periods of Jupiter activity, estimates of from two to ten days having been proposed by the various investigators.

Roberts[5], using data obtained in 1960 by Carr *et al.*[2], computed the correlation coefficient between Jupiter activity and geomagnetic activity index A_p. A peak corresponding to a delay of eight days was indicated, but at the same time another peak of comparable significance indicated a negative delay of eight days, that is, for geomagnetic activity after Jupiter activity. Roberts mentions similarly inconclusive unpublished results obtained by Higgins and concludes that all the apparent correlations observed so far may be merely statistical fluctuations.

If the phenomena are in fact related, there are two possible explanations of these different results. Either the statistics are unsound, due to the fact that insufficient Jupiter observing time was available daily for comparison with solar activity, or else the relationship between the two phenomena is too complex to be expressed by a simple cause-and-effect explanation. A preliminary investigation of the former possibility was conducted during 1963 by Florida State University Radio Observatory in collaboration with observatories in Great Britain and in South Africa.

The experiment was simply to record the radiation from Jupiter for as long as possible each day and to compare the periods of Jupiter activity with periods of solar activity as indicated by flares, 10-cm solar radiation, sunspots, and geomagnetic activity. The Sun can be observed from somewhere on the Earth almost 24 h daily, whereas most Jupiter observers are limited to some 4–8 h according to their aerial systems. The daily period of observation of Jupiter was, therefore, increased to some extent by combining observations made at two additional sites, in Great Britain and in South Africa, with results obtained at Tallahassee. The locations of the sites, the corresponding altitudes of Jupiter at meridian transit and the aerials used are shown in Table 1. The combined observations from the three sites operating in tandem amounted to some 16 h continuous monitoring each night, a period corresponding to about 1½ rotations of Jupiter.

Table 1. Locations of the Three Stations monitoring Jupiter during the 1963 Apparition

Site	Latitude	Longitude	Altitude of Jupiter at transit	Aerial
Tallahassee	30° 27′ N.	84° 18′ W.	64° S.	Square corner reflector
St. Osyth	51° 47′ N.	01° 02′ E.	42° S.	Square corner reflector
Grahamstown	33° 19′ S.	26° 26′ E.	53° N.	Single dipole and eight dipole array

The aerial-receiver-recorder systems were identical at Tallahassee and at St. Osyth. Each consisted of a square corner reflector containing a single folded half-wave dipole fed to a commercial short-wave communications receiver. The bandwidth of the receiver was about 5 kc/s and the recorder constant was 0·25 sec. All the observations at these two sites were monitored following the procedure given recently by Barrow[6].

At Rhodes University a single folded dipole was used in conjunction with a broadside array of eight dipoles at another site some 100 miles away. The receiver bandwidth was 8 kc/s and the recorder constant was 0·8 sec. Some of the observations were monitored, but identification was also based on a comparison of the records taken at the two sites. The total observing time amounted to about 70 per cent of that at Tallahassee or at St. Osyth.

The first co-ordinated period of observation by all three sites was July 17–November 25, 1963. The combined observations are shown in a histogram in Fig. 1. The histogram has been compiled in terms of 'numbers of events' rather than 'occurrence probability', as the occurrence probability was found to be different at each site.

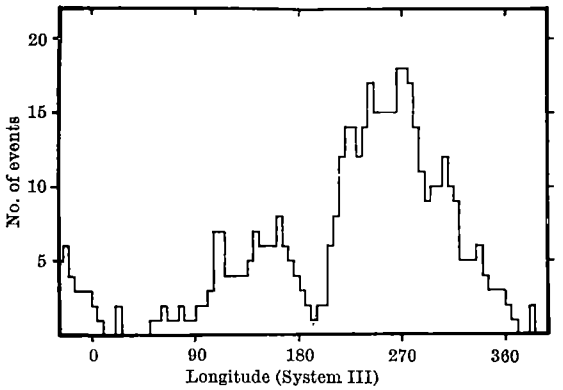

Fig. 1. Histogram showing the total number of Jupiter events recorded at 18 Mc/s by the three stations at Tallahassee, St. Osyth, and Grahamstown during 1963

Following Roberts[5] a preliminary examination of the data has been made by computing cross-correlation coefficients between the days on which Jupiter was active and the days on which the Sun was active, as evidenced by the following quantities: geomagnetic activity index A_p; Zurich relative sunspot number R_z; 10-cm solar radiation flux; solar flare activity, *HAO* index. The computed correlation coefficients are shown in Fig. 2. Although one or two peaks occur slightly above the 1 per cent significance level these can scarcely be regarded as any more than statistical fluctuation. Thus it appears that increased daily observation of Jupiter does not, by itself, produce any significant improvement in a search for simple cross correlation. This result does not, however, exclude the possibility of any relationship at all between Jupiter activity and solar activity as there are various factors which might obscure simple cross correlation. For example, if Jupiter activity is initiated by solar corpuscles, as Carr *et al.*[2] have suggested, both the magnitude and the direction of the velocity of the corpuscles would have a bearing on the situation. Particles travelling with different velocities on different days would give rise to different delay times and a direct search for cross correlation would be useless.

An interesting feature of the experiment is the pronounced difference in Jupiter activity recorded at each site. The day-by-day frequency of occurrence was found to be considerably higher at Tallahassee than at St. Osyth and considerably higher at Grahamstown than at Tallahassee. Such differences have also been reported by Carr[7] for observations made at Gainesville, Florida, at Santiago, Chile, and at Sydney, Australia. Effects such as these, as well as the spaced-site burst studies of A. G. Smith *et al.*[8] and Douglas and H. J. Smith[9], further emphasize the need for a comprehensive study of the effects of the Earth's ionosphere and magnetic field on the Jupiter radiation. Towards this end an experiment is to be conducted by Florida State University Radio Observatory during the 1964 apparition. Standard 18-Mc/s systems have been

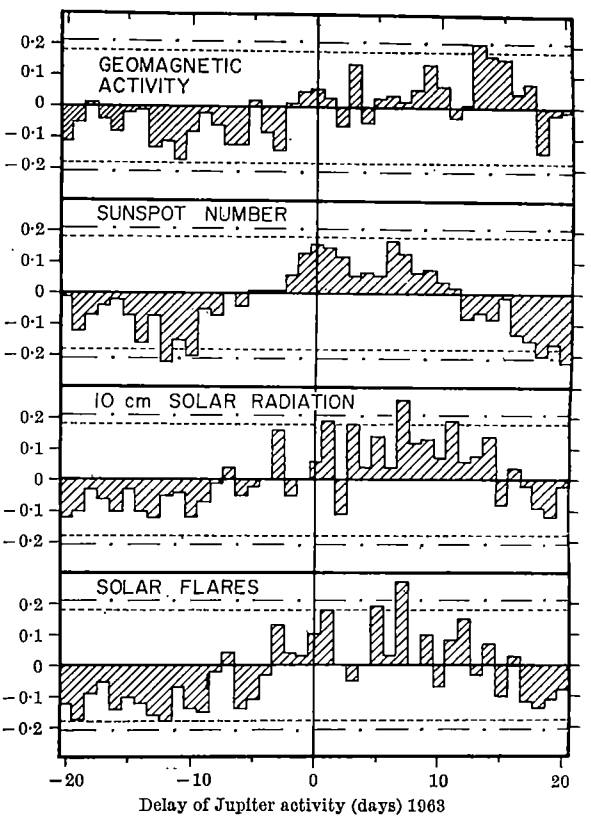

Fig. 2. Computed correlation coefficients between Jupiter activity and geomagnetic activity, sunspot number, 10 cm solar radiation, and solar flares. The significance levels (not allowing for serial correlation in the data) are 0·18 and 0·21 for 5 and 1 per cent respectively

installed in Nigeria, Spain, England and Norway along a rough north–south line through St. Osyth. Collaboration with the Rhodes University group is to continue and simultaneous observations will be made from all these sites. The occurrence probability and burst structure at each site will be compared.

This work was supported by U.S. National Aeronautics and Space Administration grant *NSG*–224–61, and, in South Africa, by the Council for Scientific and Industrial Research.

ISOTOPIC AGES OF ASSYNT DYKES

By Dr. C. R. EVANS
Imperial Oil Enterprises Ltd., Calgary, Canada
AND
Dr. J. TARNEY
Department of Geology, University of Birmingham

THE so-called 'Scourie' dykes which cut the Precambrian gneisses of the north-west Highlands of Scotland have assumed considerable importance in recent years on account of their usefulness in distinguishing between the effects of the early ('Scourian') and late ('Laxfordian') Lewisian metamorphisms in that area[1]. The initial concept of Sutton and Watson[1], that the abundant dolerite dykes were intruded during a single phase of uplift of the basement rocks between the two metamorphisms, has been modified to a varying degree

according to the more detailed work and interpretations of later workers. Thus O'Hara[2,3] and Tarney[4] have argued that the dykes were intruded at considerable depth into hot country rock. Bowes[5], Park[6], and Wright[7] have maintained that the dykes are not all of the same age, and that some may be contemporaneous with, or later than, the Laxfordian metamorphic event. In the Outer Hebrides, Dearnley[8] has suggested that a second granulite-facies event affected the dykes before the Laxfordian, while Evans[9–11] and Tarney[4,12] have cited evidence that in the Assynt district amphibolite-facies metamorphism occurred before and pene-contemporaneously with the intrusion of the dykes. Evans[10] has proposed the name 'Inverian' for this metamorphic event. In addition, O'Hara[3] and Tarney[4] have emphasized that while the typical 'Scourie' dolerites (tholeiites) are the dominant dyke type in the Lewisian, a variety of other dyke-types also occur.

It is largely the importance of the dykes in the elucidation of the metamorphic and structural history of the Lewisian, and the controversy surrounding their relations to the proposed metamorphic events, that have initiated this study of their isotopic ages.

Giletti *et al.*[13] made considerable progress towards an absolute chronology of Lewisian events when they established that almost 800 m.y. separated the two series of pegmatites (at about 2,400 m.y. and about 1,600 m.y.) assigned respectively to the Scourian and Laxfordian metamorphisms by Sutton and Watson[1]. They were unable at that time to date the dykes. Evans[9], summarizing his results from the Lochinver area, showed that the Scourian gneisses were older than 2,600 m.y., while the biotite pegmatites previously thought to be Scourian did in fact give ages about 350 m.y. later at about 2,250 m.y. He also established that amphibolite-facies gneisses which had been affected by major folding on west-north-west—east-south-east axes, and which were cut by the dykes, gave ages within the range 2,200–1,900 m.y.

The apparent potassium/argon and rubidium/strontium ages of the dyke samples studied are given in Table 1. An attempt has been made to date most of the dyke types listed by O'Hara[3] and Tarney[4] in order to establish, if possible, the period over which the dykes were intruded, and in particular to decide whether or not any of the fresh dykes are Laxfordian in age.

Potassium was determined using an EEL flame photometer coupled to an automatic strip recorder. An addition–dilution method[10] was used to correct for suppression of the potassium flame by other ions. A series of gravimetrically prepared standards were used in such a way that the difference between the unknown solution and the two standard solutions was always less than 1 p.p.m., thus avoiding the difficulty of non-linear response. Argon was determined by isotope dilution. After baking the sample overnight in vacuum an argon-38 tracer was added and the sample melted with a radio-frequency induction heater. The ratio of radiogenic argon-40 to tracer argon-38 was measured in a high vacuum mass spectrometer. The experimental error in measuring the potassium/argon ratio was small enough to give an error of less than ±50 m.y. on the ages quoted. An exception was 39*D* biotite with an error of ±88 m.y. The decay constants for potassium-40 were taken as $\lambda_e = 0{\cdot}584 \times 10^{-10}\text{yr.}^{-1}$, and $\lambda_\beta = 4{\cdot}72 \times 10^{-10}\text{yr.}^{-1}$.

The analytical techniques used for rubidium and strontium determinations were essentially those used by

Rubidium-Strontium Ages

Spec. No.	Grid Ref.	Sample	Rb (p.p.m.)	Sr (p.p.m.)	$\left(\frac{^{87}Sr}{^{86}Sr}\right)$ * now	$\left(\frac{^{87}Sr}{^{86}Sr}\right)$ initial	Age (m.y.)
Bronzite-picrite Dyke, Brackloch Farm							
E. 605	*NC*121238	Biotite	345	21·9	2·196	0·709	2,190 ± 50
E. 605		W.R.	15·7	50·9	0·739	0·709	2,190 ± 200

This gives a biotite/whole-rock intersection age of 2,190 ± 50 m.y.

* Normalized to an $^{86}Sr/^{88}Sr$ ratio of 0·1194.

Giletti *et al.*[13], but differed in two respects: (1) a pre-column separation of rubidium and strontium was carried out with ethyl acetate; (2) an additional pre-spectrometer clean-up of strontium samples was accomplished by mounting the filaments in specially prepared vacuum systems and passing a current of about 2 amp through them for about 2–3 h prior to mounting in the mass spectrometer. This procedure ensured complete freedom from rubidium and also enhanced strontium emission. The half-life of rubidium-87 was taken as $4{\cdot}7 \times 10^{10}$yr.

The concordant rubidium/strontium and potassium/argon ages for the bronzite-picrite dyke at Brackloch Farm, near Lochinver, constitute a convincing datum at 2,200 m.y. It is interesting to note that the margins of this dyke are rather badly amphibolized and that much of the olivine in the sample is serpentinized. The potassium/argon Laxfordian age given by the biotite indicates expulsion of the accumulated radiogenic argon at this time, although the rock as a whole remained a closed system. The serpentinized nature of the olivine and saussuritized character of the plagioclase suggests that this radiogenic argon has probably been retained in the pyroxenes.

The abundant thick and coarse-grained dolerites and metadolerites ('epidiorites'), those usually referred to as the 'Scourie' dolerites, were intruded before the picrites and later than the 2,250 m.y. pegmatites; their true age must also be about 2,200 m.y. However, the spread of whole rock potassium/argon apparent ages for the freshest representatives of these dykes, between 3,860 and 1,550 m.y., is clearly well outside the limits of experimental or sampling error, and indicates on one hand accumulation of an excess of argon in these dykes in addition to that produced since their intrusion by normal decay of potassium-40, and on the other hand expulsion of radiogenic argon from apparently fresh rock by the reheating or tectonic activity of the Laxfordian.

The presence of excess argon in these ancient dyke rocks is an interesting feature which requires consideration. Damon and Kulp[14] have noted that excess argon (and helium) may occur in beryl, tourmaline, etc., in pegmatites formed early in the Precambrian, and the problem has also been discussed by Hart[15] and by Kulp[16]. In the present instance, two hypotheses can be invoked to account for it: (1) A fundamental assumption of the potassium/argon dating method applied to igneous rocks is that any argon originally present in the magma along with other dissolved gases is expelled at the time of intrusion. This assumption may not be valid under conditions of intrusion at considerable depth with impervious wall rocks. Hence the excess argon-40 present in these dykes may have originated in the mantle, and may have been incorporated in the pyroxenes, etc., during crystallization. (2) If the dykes were intruded under waning metamorphic conditions as suggested by Tarney[4], or indeed by any reasonable interpretation of the age data, then, being intruded into an area of high argon flux, it is not unlikely that radiogenic argon being expelled from the gneisses could find its way into the fresh dyke centres, and may now perhaps be located in the dyke pyroxenes. Certainly it would be no more difficult for argon to diffuse into the dykes than to migrate through several kilometres of country rock.

The relative merits of these two hypotheses will be outlined in a later contribution. Sufficient to state here that on either hypothesis it is necessary to invoke dyke intrusion at considerable depth. Two other interesting suggestions can be made on the basis of these age data, however. All the dykes found to contain excess argon have, like others, substantial proportions of green hornblende and bear a plagioclase having a strong greyish clouding. The hornblende in these dykes has been attributed to the initial stages of Laxfordian metamorphism by Watson[1], and to autometamorphism by O'Hara[2], while Dearnley[8] has argued that the clouding has resulted from the effects of Early Laxfordian granulite-facies metamorphism. The dating clearly favours an interpretation regarding both hornblende and clouding either as primary features of crystallization, or as resulting from metamorphism very shortly afterwards.

Those dolerite samples which are completely amphibolized came from areas affected by Laxfordian movements. The spread of ages, if real, indicates continuing Laxfordian activity over the period 1,640–1,390 m.y., though it is apparent that movements continued even later in the Torridon and Gairloch areas[13,17].

The other dykes can be dealt with more briefly. The olivine-gabbro dykes are probably related to the picrites, and seem to be, within experimental error, of roughly the same age. That at Badnaban (the 'biotite-diorite') has been affected by Laxfordian shearing along its northern margin and has been up-dated accordingly.

It is difficult from the data available to give a complete assessment of the ages of the amphibolite and norite dykes at Badcall, near Scourie[3]. Allowing for the strong, but localized, Laxfordian shearing in this locality, it is not unlikely that both dykes have in fact been slightly up-dated by these shears. The norite is mineralogically and chemically similar to the two-pyroxene dolerite from the south side of Loch Assynt[4], dated at 2,200 m.y.

There is little direct field evidence in Assynt that any of the dykes were intruded after the Laxfordian shearing movements, though it has been the experience of both authors that shear structures simulating those of the Laxfordian were in existence in Assynt before dykes now known to be 2,200 m.y. old. However, thin basic veins are seen to cut the picrites and early dolerites in the area west of Loch Assynt. In consequence the two thin dykes noted by Tarney[4] just west of Loch Assynt, which are noteworthy in being extremely fresh compared with other dykes in their vicinity, have been sampled as dykes more likely than most to be Laxfordian in age. Both are intruded into amphibolite-facies gneisses, those gneisses in the vicinity of the dated alkali basalt sample giving an age of 2,200 m.y. The apparent ages of 2,030 m.y. for the alkali basalt dyke and 1,950 m.y. for the tholeiitic dyke may well be real considering the fresh state of the samples, though the fresh chilled margin of the alkali basalt gives a 2,200 m.y. age. Clearly they are not Laxfordian in age.

Treated as a whole (Fig. 1) the dyke ages show a distinct concentration at 2,200 m.y., with a steady fall-off towards the Laxfordian. The ages older than 2,200 m.y. are distinctly wild.

To conclude, the results suggest that (in Assynt) the majority of the 'Scourie' dolerites were intruded shortly before 2,190 m.y. ago, while emplacement of other dyke

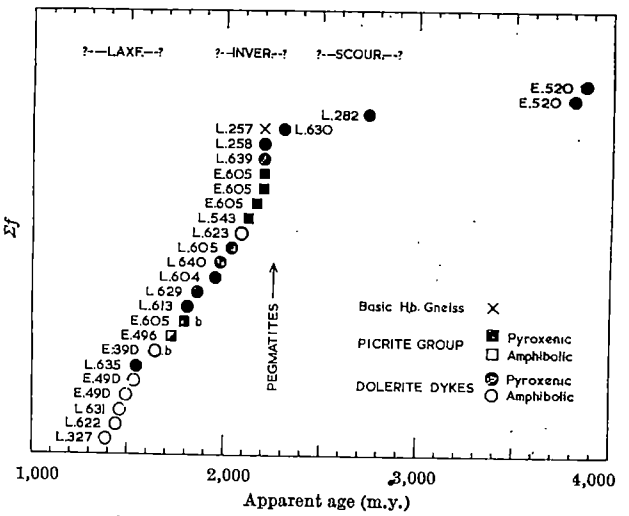

Fig. 1. Frequency distribution of dyke ages

types followed over a period which may have extended to as late as 1,950 m.y. No dykes of Laxfordian age appear to be present, though dykes of this age have been recognized in the Canadian Shield[18,19]. The close association in time between pegmatites, dykes, and amphibolization of the gneisses indicated by the dating, and the presence of excess argon in the earliest dykes, suggestive of intrusion of the dykes of considerable depth, and into a metamorphic environment. The problem of excess argon is an important one which may well occur, without realization, in other metamorphic terrains. There is clearly scope for further investigation here. The data on the early dolerites alone show how a single age determination in such an area may well be in error by as much as 1,000 m.y., and that even with a large number of determinations knowledge of the field relations is still of paramount importance in their interpretation.

EFFECT OF CALCIUM ON INTRACELLULAR SODIUM AND POTASSIUM CONCENTRATIONS IN PLANT AND ANIMAL CELLS

PROF. GENE A. MORRILL, DR. H. RONALD KABACK and DR. ELLIOTT ROBBINS
Departments of Physiology and Neurology, Albert Einstein College of Medicine, Yeshiva University, New York

IT has been reported that mammalian brain[1,2], liver[3–5] and muscle[6,7] require calcium in the medium for maintenance of high intracellular potassium concentrations when examined under *in vitro* conditions. This is also true of red blood cells in lower vertebrates[8,9] and for human red blood cells under special conditions[10]; however, a calcium requirement for maintenance of high intracellular potassium has been looked for but not observed in frog and chicken red blood cells[8]. This article presents evidence that calcium is essential in maintaining both high intracellular potassium and low intracellular sodium concentrations in several different plant and animal systems, and suggests an explanation as to why this calcium requirement has not been demonstrated in all cell systems previously investigated.

The intracellular sodium and potassium concentrations of mouse pancreas, *R. pipiens* oocytes, HeLa cells, ascites tumour cells, yeast and *E. coli* were compared after incubation in medium containing calcium and in calcium-free EDTA medium. The systems were prepared as follows and incubated under the conditions outlined in Table 1.

Mouse pancreas was excised and each pancreas incubated in 3 ml. of Krebs III medium at 37° as described previously[11].

R. pipiens oocytes were excised from the ovary of a pithed animal and the epithelial membranes were removed with fine forceps. Fifty oocytes were pooled for each sample and incubated in amphibian Ringer's solution at 25°.

HeLa cells, strain *S*-3, were maintained as monodisperse cultures in Eagle's spinner medium[12] supplemented with 6 per cent fœtal calf serum and with equimolar NaCl substituted for the prescribed Na_2HPO_4. Cell density was kept at approximately 2×10^5 cells per ml.

Table 1. INCUBATION CONDITIONS FOR PLANT AND ANIMAL CELLS

Cell or tissue	Incubation medium*	*p*H	Time (min)	°C
Pancreas	Krebs III medium	7·0	15	37
Oocytes (frog)	Amphibian Ringer's	7·4	15	25
HeLa	Modified salt soln.†	7·0	15	37
Ascites	Modified salt soln.†	7·5	15	37
Yeast (baker's)	Salt solution‡	7·0	15	37
E. coli	Grey and Tatum's	7·0	15	37

* Magnesium ion omitted from all media.
† Modified salt solution contained per litre: NaCl, 144 mM; KCl, 5 mM; Na_2HPO_4, 0·08 mM; *tris* buffer, 30 mM; glucose, 5·6 mM.
‡ Salt solution for yeast contained per litre: NaCl, 40 mM; KCl, 40 mM; *tris* buffer, 50 mM; glucose, 5·6 mM.

Ascites tumour cells were obtained by aspiration from the peritoneal cavities of Swiss mice carrying cell populations which ranged in age from 4 to 8 days. The cell suspension was washed several times in a modified salt solution (Table 1).

E. coli were grown at 37° in Grey and Tatum's minimal medium[13] to the end of the log phase (10^8–10^9 cells/ml.).

Fresh baker's yeast (*Saccharomyces cerevisiae*) was thoroughly washed with distilled water and resuspended in the saline medium described in Table 1. Aeration and mixing were obtained by bubbling air through the cell suspension.

The calcium concentrations used in the incubation media for ascites, HeLa, oocytes and pancreas were those normally contained in the media. The calcium concentrations in the yeast and *E. coli* incubation media were arbitrarily adjusted to 1·0 mM/l. All calcium-free media contained 1·0 mM EDTA/l. Unless otherwise noted, magnesium ion was omitted from all media.

The monodisperse cell systems were studied in calcium-containing and calcium-free EDTA medium as follows: cells were collected by centrifugation and the supernatant fluid was discarded. One to two hundred milligrams of cells were taken for each sample. The cell sample was rinsed with the incubation medium, resuspended in 50 ml. of the same medium, and incubated at 37°. After 15 min the cells were again collected by centrifugation, transferred with about 0·7 ml. of the medium to hæmatocrit tubes, and packed at high centrifugal force. The supernatant fluid was removed, and the wet and dry weight of the cells determined. Ascites and HeLa cells were collected at 800*g* for 2 min and packed in hæmatocrit tubes at 6,000*g* for 1 min. Yeast and *E. coli* were collected at 20,000*g* for 5 min and packed in hæmatocrit tubes at 30,000*g* for 3 min. The volume of trapped extracellular fluid was measured by adding ^{14}C-inulin at the end of the incubation period. The packed cells were digested with 2–3 volumes of fuming nitric acid for 3 h at room temperature. The digests were diluted 1 : 100 with ion-free water and aliquots were either analysed for sodium and potassium or plated and counted in a windowless gas flow counter. Sodium and potassium were determined by internal standard flame photometry (Baird-Atomic *DB*-4).

Table 2. Effect of Extracellular Calcium on Sodium and Potassium Distribution between the Cell and its Environment

Cell or tissue	$[Ca]_o$	$[Na]_i$*	$[Na]_o$	$\frac{[Na]_o}{[Na]_i}$	$[K]_i$*	$[K]_o$	$\frac{[K]_i}{[K]_o}$	Sum $[Na]_i+[K]_i$
Pancreas	2·5	71	140	2·0	108	6	18·0	179
	0	149	140	0·94	60	6	10·0	209
Oocytes (frog)	1·1	69	114	1·6	108	2	54·0	177

*Average values for 4 or more experiments; standard error ±4 mM or less for $[Na]_i$, ±5 mM or less for $[K]_i$.

The sodium and potassium analyses were corrected for trapped extracellular fluid and expressed in mM/l. cell water.

The intracellular sodium and potassium concentrations found in each of the six cell systems after an incubation for 15 min in calcium-containing and calcium-free EDTA medium are given in Table 2. The results show that in the presence of extracellular calcium all cell systems maintain a potassium gradient. The values for the ratio of $[K]_i$ to $[K]_o$ shown in col. 8 ranged from 6·3 for *E. coli* to more than 50 for *R. pipiens* oocytes. It has been shown by Abelson and Duryee[14], and more recently by Naora *et al.*[15], that 85 per cent of the intracellular sodium of the *R. pipiens* oocyte does not exchange with sodium in the medium. Correcting the intracellular sodium values shown in Table 2 for non-exchangeable or bound sodium, one obtains an exchangeable sodium concentration of about 10 mM/l. cell water in the oocyte. With the exception of *E. coli*, the intracellular sodium concentrations were lower than that of the extracellular fluid. The ratio of $[Na]_o$ to $[Na]_i$ given for *E. coli* in col. 5 is 0·8. This implies either: (1) a concentrating mechanism for both sodium and potassium, or (2) as in oocytes, that part of the intracellular sodium in *E. coli* does not readily exchange with the medium. One cell system, yeast, had no measureable intracellular sodium when incubated in a sodium and potassium salt solution containing 1·0 mM of calcium/l.

In calcium-free EDTA medium all cell systems gained sodium and lost potassium. These changes in cell sodium and potassium occurred within 5 min and the new values were relatively stable for at least 1 h. The one cell system, *E. coli*, in which initial intracellular sodium was higher than extracellular sodium in calcium-containing medium, further increased intracellular sodium in calcium-free medium. This suggests the exchange of sodium for calcium on anionic sites in the bacterial cell.

Under the conditions shown in Table 2, the gain in intracellular sodium and loss of intracellular potassium were readily reversed by the transfer of the cells to calcium-containing medium. Magnesium ion did not prevent the loss of potassium and gain of sodium when substituted for calcium in equimolar quantities.

In the two plant systems, yeast and *E. coli*, the sum $[Na]_i+[K]_i$ decreased by one-half on incubation in calcium-free medium. In the four vertebrate cell systems the sum $[Na]_i+[K]_i$ either increased slightly (pancreas and HeLa) or did not change (oocytes and ascites). The difference was due mainly to a greater percentage loss of total potassium in the plant cells, and may indicate that the potassium concentrating mechanism is less efficient in plant cells in general.

These investigations imply that extracellular calcium ion is of universal importance in maintaining low intracellular sodium and high intracellular potassium in living systems. It thus becomes necessary to explain reports where this role has not been observed. It may be that these results were due to uncontrolled conditions of *p*H, since we have found that when cells are incubated in calcium-free medium intracellular sodium and potassium vary with changes in extracellular *p*H. In HeLa cells, for example, intracellular sodium was low and potassium high at *p*H 5·0 in calcium-free medium, but sodium increased and potassium decreased with increasing *p*H and approached the extra values at *p*H 9·0. This *p*H effect is being examined and compared in the different cell systems.

INFLUENCE OF CHEMICAL COMBINATION ON ALUMINIUM *K* DIAGRAM AND NON-DIAGRAM LINES

By WILLIAM L. BAUN and DAVID W. FISCHER
Materials Physics Division (MAYA), Air Force Materials Laboratory, Wright-Patterson Air Force Base, Ohio

RECENTLY it was shown that the wave-length of aluminium $K\alpha$ is slightly influenced by the co-ordination number (number of nearest neighbours) of the site occupied by aluminium[1]. It has also been noted that the aluminium *K* spectrum is markedly affected by a change in valence of the aluminium, especially in the α satellite lines and the $K\beta$ band[2,3]. In that work[2,3], results were shown only for aluminium and aluminium oxide. This communication reports on the aluminium *K* spectrum from a number of aluminium compounds including intermetallic conductors, semiconductors, and insulators.

The vacuum spectrometer and associated equipment were specially designed and built by Picker X-Ray Corporation[4]. X-rays are produced by bombarding the

sample with electrons from a tungsten filament electron gun which is controlled by a Picker generator modified to operate at low voltages. The voltage was held at 6 kV and currents of 1–2 m.amp were used for aluminium K excitation. The analysing crystal was ethylenediamine ditartrate having a $2d$ spacing of 8·8030 Å. This crystal was chosen because it allows measurements to be made fairly far back in the back reflexion region (129·41° 2θ for $K\beta$ to 142·64° 2θ for $K\alpha_{1,2}$ using aluminium metal). The detector was a thin window flow proportional counter of the Siemens type using an argon methane (P–10) flow gas. Recording electronics including a pulse height analyser were standard Picker equipment except for a low noise pre-amplifier by Tennelec. A sample chamber containing four samples was used so that samples could be compared under the same conditions without breaking vacuum between samples. Usual operating vacuum was 1×10^{-5} torr. As a check for oxidation, the satellite line ratio α_4/α_3 was measured immediately on each sample. This ratio was then remeasured at the conclusion of all measurements. If the ratio changed, then earlier measurements were not used. As noted by Nordfors[2], this method is a very sensitive test for oxidation in aluminium. Intermetallic compounds were prepared from metal powders of commercial purity using induction heating.

The lines of the aluminium K spectrum studied in this work were the diagram lines $\alpha_{1,2}$ and β and the non-diagram or satellite lines α', α_3, α_4, α_5 and α_6. The $K\alpha$ doublet is the line least influenced by chemical combination and change in valence. However, since it is the most intense line in the spectrum, previous workers[1,5] have used this line with secondary excitation in determining effects of change of co-ordination number. Our results using primary excitation do not agree well with the referenced work, but the disagreement in $K\alpha$ can probably be attributed to two things. One is that because of low intensities in the secondary excitation technique, a fairly low resolution system was used which perhaps allowed α', α_3 and α_4 to influence the peak position of the parent $K\alpha$ doublet. Since these lines shift more in going from the metal to the oxide, for instance, than $K\alpha$ they would cause the $K\alpha$ line to appear to have shifted more than it actually had. The other obvious reason is that where co-ordination depends on water, as in many minerals, the electron beam probably causes dehydration and therefore a change in co-ordination. This effect is reflected in this present work by kaolinite the spectrum of which is very similar to Al_2O_3.

The satellite lines $K\alpha_3$ and $K\alpha_4$ are greatly affected by the chemical combination of aluminium. The lines shift two to three times as much as the parent doublet,

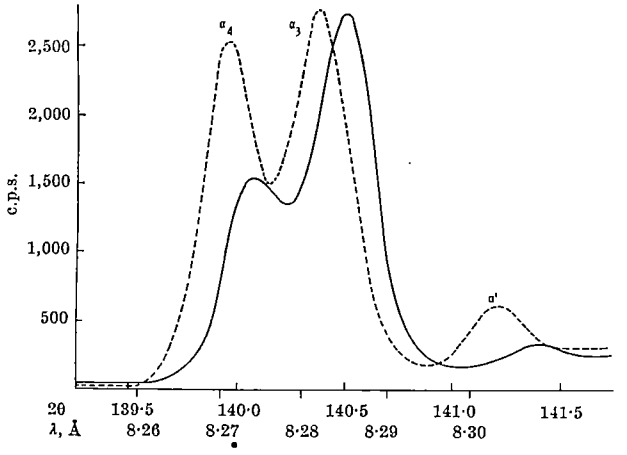

Fig. 1. Aluminium K satellite lines α', α_3 and α_4 for aluminium metal and Al_2O_3 (anodized coating), EDDT analysing crystal
——, Metal; – – –, oxide

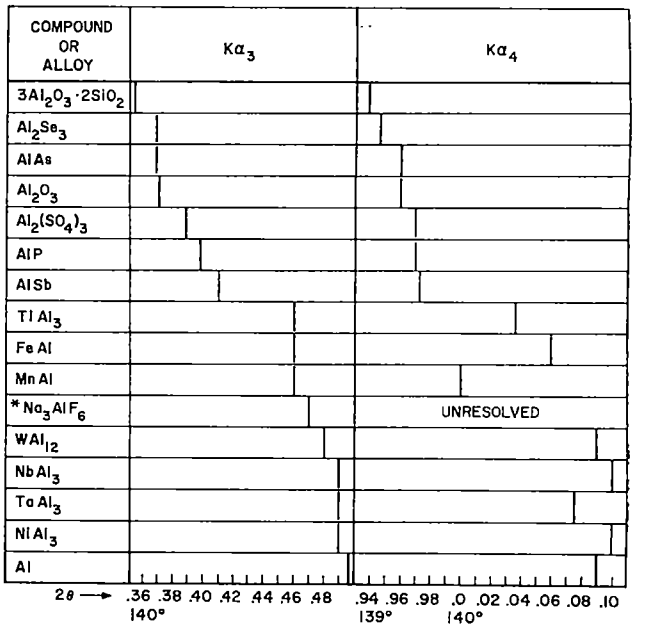

Fig. 2. 2θ positions of aluminium $K\alpha_3$ and $K\alpha_4$ using an EDDT analysing crystal

and the α_4/α_3 ratio changes from 0·50 in the metal to 0·94 in the oxide and 1·00 in mullite. Fig. 1 shows traces of $K\alpha'$, $K\alpha_3$ and $K\alpha_4$ for aluminium and Al_2O_3. The intensities shown in these traces are not relative between oxide and metal. They have been normalized to show α_3 at the same count rate for better comparison of spectra.

The 2θ positions of $K\alpha_3$ and $K\alpha_4$ using EDDT are shown in Fig. 2 for a number of conductors, semiconductors, and insulators. As can be seen, both lines shift to shorter wave-length in going from metallic species to insulator species. Cryolite (Na_3AlF_6), for which only $K\alpha_3$ is shown, apparently is decomposed in the beam, and appears among the metallic species, rather than with the insulators. No correlation can be made here between line position and co-ordination number. Exactly the same relative position is not occupied by each compound in Fig. 2 for both α_3 and α_4. This points up the complex changes that take place in α_3 and α_4. It has been predicted that α_3 and α_4 are not simple lines but are made up of α_3, α_3', α_3'' and α_4 where α_4 has two components[6]. The change of intensity of α_3 and α_4 is perhaps more significant than the wave-length change. Fig. 3 shows a plot of the intensity ratio α_4/α_3 for the compounds shown in the last figure. Here there is a rather gradual increase in the α_4/α_3 ratio in going from the metal to insulator species. Intermetallic compounds cluster about midway between metal and insulators, and compounds having the same structure such as $TaAl_3$ and $NbAl_3$ have essentially the same α_4/α_3 ratio. The III–V compounds appear together between the intermetallic compounds and the insulators, with AlSb having an energy band gap of 1·52 eV, appearing nearest the more metallic species. Again, cryolite does not seem to fit here, adding further proof to possible decomposition in the beam. Using secondary excitation, α_4/α_3 is unity for cryolite and the lines are much better resolved.

$K\alpha_5$ and $K\alpha_6$ are weak lines whose intensities are much less affected by chemical combination. Wave-length shifts are about the same or slightly greater than α_3 and α_4 in going from the metal to the oxide. The same sort of clustering of insulators at short wave-length and conductors at longer wave-length was observed for these lines.

The diagram line $K\beta$ is very weak in the aluminium K spectrum, but shows the greatest shift due to chemical

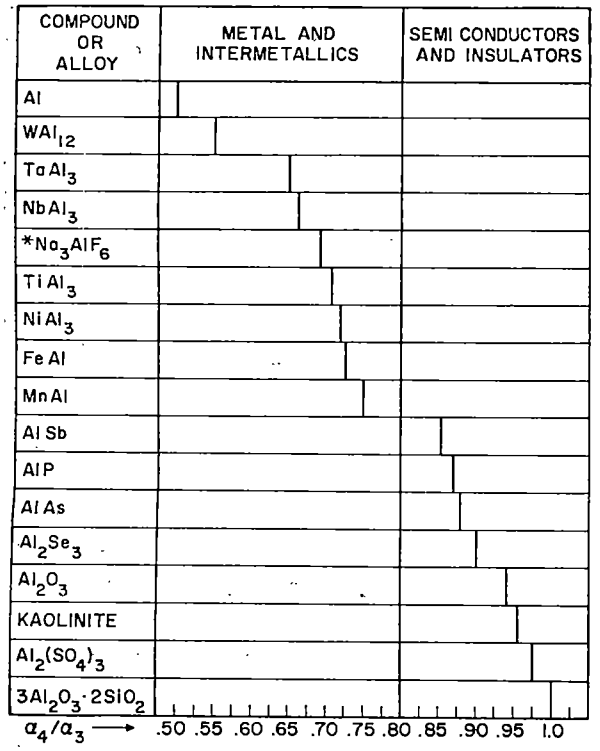

Fig. 3. Intensity ratio α_4/α_3 for aluminium compounds
* Decomposes in beam. $\alpha_4/\alpha_3 = 1$ using secondary excitation

combination of aluminium. In Fig. 4 the 2θ position of $K\beta$ is plotted for the compounds shown previously. The shift of nearly three-quarters of a degree going from metal to oxide is in the opposite direction compared to the shift of $K\alpha$ and $K\alpha$ satellites. As in all the other lines there is a clustering of compounds having similar properties except, again, cryolite which gives a doubled $K\beta$, one component near the metal and the other near the oxide. The true β position for cryolite (obtained with secondary excitation) is the one shown at the bottom of the figure, at 130·15°2θ. In addition to the large shifts, the shape of $K\beta$ is quite indicative of the electrical characteristics of aluminium compounds. In metallic compounds the $K\beta$ band is very asymmetrical, rising rapidly on the short wave-length side and falling off slowly on the long wave-length side. In the oxide and poorly conducting compounds, the $K\beta$ band is very symmetrical and has a slightly narrower half-width.

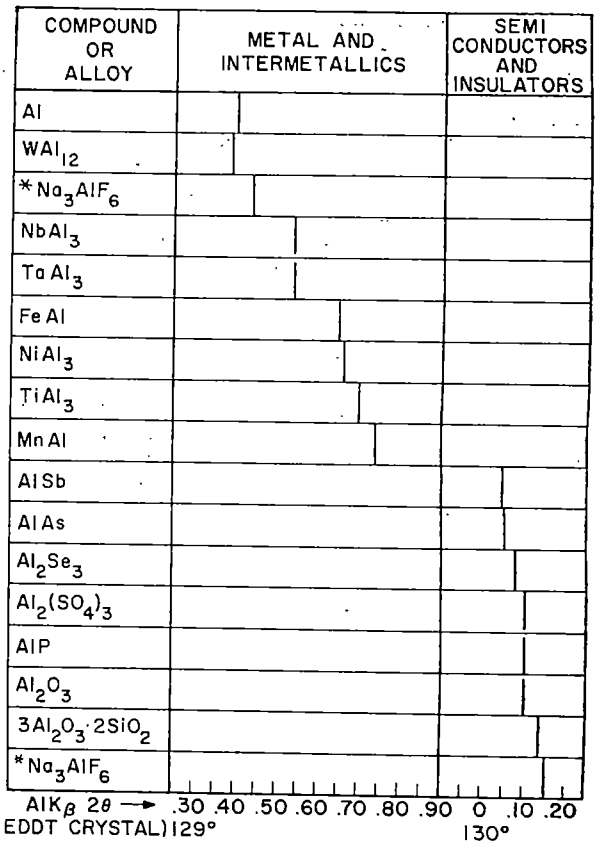

Fig. 4. 2θ position of aluminium $K\beta$ using an EDDT analysing crystal
* Decomposes in beam

It is possible to correlate physical properties of aluminium compounds with line position, and, in the case of satellite lines, with changes in line intensities. No direct correlation has been observed with changes in co-ordination number in intermetallic compounds. Probably co-ordination number may be determined reliably only where aluminium is co-ordinated by the same element.

CRYSTAL STRUCTURE AND ELECTRICAL PROPERTIES OF SOME COBALT-GROUP CHALCOGENIDES

By Dr. F. HULLIGER
Cyanamid European Research Institute, Cologny, Geneva, Switzerland

In a previous paper[1] I have discussed the relations between the electrical properties of cobaltite-type compounds and the electronic configuration of their cations. The cobaltite family consists of two distinct groups formed by CoAsS (cobaltite) and NiAsS (gersdorffite) and their chemical analogues. In the former the trivalent cation acquires an electron configuration $d\varepsilon^6$, that is, its $d\varepsilon$ sub-shell is completely filled and, hence, non-metallic properties result. In the latter, however, the additional d electron occupies the incompletely filled $d\gamma$ band and, therefore, all representatives of the gersdorffite family show metallic behaviour. The cobalt-group dichalcogenides have the same number of valence electrons as the gersdorffite phases so that one would expect a close analogy to exist between their respective crystal structures and physical properties. Actually the analogy is restricted to a few cases only, a fact which makes these compounds all the more interesting.

Complete analogy to the cobaltite phases is exhibited only by the pyrite modifications of the rhodium chalcogenides, the properties of which are closely similar to those of the ternary palladium compounds (PdAsSe, etc.).

As evidenced by the magnetic data (see Table 1) the excess *d* electron responsible for the metallic character of these compounds is completely delocalized, thus allowing for the occurrence of superconductivity in $RhSe_2$ (ref. 2) and $RhTe_2$ (ref. 3). Among the cobalt compounds only the sulphide and the selenide are isomorphous with their ternary nickel analogues. The sulphide CoS_2 has particularly interesting properties. In the paramagnetic temperature-range its susceptibility follows a Curie-Weiss law with $\theta_p = 161^\circ$ K (ref. 4) or 150° K (ref. 5) and $n_p = 1{\cdot}85$ (ref. 4) or $1{\cdot}99\mu_{Bohr}$ (ref. 5). Below 110° K CoS_2 is ferromagnetic. From its saturation magnetization at low temperatures a magneton number $n_f = 0{\cdot}84\mu_{Bohr}$ (ref. 4) was determined.

It is somewhat surprising that the magneton number as measured in the paramagnetic temperature range is compatible with a localized $d\gamma$ electron whereas in the gersdorffite phases the magnetic moments are appreciably lower. Moreover, the observed S–S distance of 2·124 Å (ref. 6) corresponds to a single bond and thus agrees well with the ionic formula $Co^{2+}(S_2)^{2-}$. However, the deviation from the 'localized-spin value' of $1\mu_{Bohr}$ in the ferromagnetic temperature range indicates a certain overlapping of the $d\gamma$-level (or band) with an empty band. This would then account for the observed metallic behaviour[7,8]. In the paramagnetic pyrite modification of $CoSe_2$, on the other hand, a considerable deviation of the magnetic moment from the localized-spin value is found. The susceptibility of cubic $CoSe_2$ is reported to obey a Curie-Weiss law with $n_p = 2{\cdot}56\mu_{Bohr}$ and $\theta_p = -440^\circ$ K (ref. 9). These results, together with an Se–Se distance of 2·53 Å (single bond distance, 2·34 Å), agree well with the observed metallic conduction[7,8]. Synthetic, as well as natural, $CoSe_2$ normally occurs in the pyrite modification (mineral trogtalite), but the mineral hastite was reported to be a marcasite modification of $CoSe_2$ (ref. 10). No physical data other than the lattice constants are known of this modification, but I expect it to be metallic.

Among the remaining cobalt-group dichalcogenides no other pyrite phase is met. I found CoSeTe (high-temperature modification?) to have a CdI_2 structure with $a = 3{\cdot}70$ Å, $c = 5{\cdot}09$ Å, $c/a = 1{\cdot}38$. This compound, as well as the isostructural $CoTe_2$, is metallic. This is not surprising since the CdI_2-type phases are not polycompounds, so that tetravalent cobalt would be needed to make them semiconducting. But Co^{4+} is rarely obtained even in combination with strongly electronegative anions. On this point I disagree with Regel[11], who claims that $CoTe_2$ is a semiconductor. Not even in the low-temperature modification α-$CoTe_2$ (which might be the stoichiometric 1 : 2 compound[5] whereas the C6-type compound seems to have an anion deficiency) do we expect semiconducting properties, because the localized unpaired $d\gamma$ electron of hypothetical $Co^{2+}(Te_2)^{2-}$ would require a low symmetry of the cation co-ordination. The symmetry of cobalt in α-$CoTe_2$, however, is the same as that of iron in the semiconducting $d\varepsilon^6$ marcasite FeS_2, since the axial ratios of both compounds are very similar[12]. This is possible only if uncompletely filled *d*-levels form a metallic band. The electronic structure of α-$CoTe_2$, therefore, might be similar to that of cubic (and orthorhombic) $CoSe_2$ and this is confirmed by its magnetic behaviour: the susceptibility of α-$CoTe_2$ obeys more or less a Curie-Weiss law[5] leading to a magneton number $n_p = 2{\cdot}81\mu_{Bohr}$ and a Curie-Weiss constant $\theta_p = -540^\circ$ K (ref. 5). No magnetic measurements have been reported in the literature on β-$RhTe_2$ (ref. 3) and $IrTe_2$ (ref. 13) which are again metallic CdI_2-type phases; but we expect smaller and less temperature-dependent values for their magnetic susceptibilities.

It is interesting to note that rather wide ranges of miscibility exist between corresponding cobalt, rhodium and iridium dichalcogenides crystallizing in the pyrite structure. Complete miscibility was observed in the (Co, Rh) Se_2 system. Though one might expect solid solutions of $Co_xRh_{1-x}Te_2$ to crystallize in a CdI_2 structure, pyrite-type mixed crystals are formed up to about $x = \frac{1}{2}$. On a sample of nominal composition $x = \frac{1}{2}$, we determined a lattice constant $a = 6{\cdot}386$ Å, which seems to indicate that the actual cobalt content was somewhat lower. Even $Co_{1/2}Ir_{1/2}Te_2$ ($a = 6{\cdot}388$ Å) was found to have the pyrite structure though no C2 modifications are as yet known of the binary compounds. From X-ray patterns of two-phase material we conclude that the pyrite lattice is stable in $Co_{1-x}Ir_2S_2$ up to $x \approx \frac{1}{4}$ and in $Co_{1-x}Ir_xSe_2$ up to $x \approx \frac{1}{2}$. A broad homogeneity range was detected in the system (Co, Rh) S_2. However, pure RhS_2 does not seem to exist. All attempts to prepare this compound resulted in Rh_2S_3, RhS_3 or other phases. In $Co_{1/2}Rh_{1/2}S_2$ and in $Co_{\sim 0{\cdot}3}Rh_{\sim 0{\cdot}7}S_2$ which both crystallize in the pyrite structure we obtained $a = 5{\cdot}639 \pm 3$ Å and $5{\cdot}667 \pm 4$ Å, respectively. Extrapolation from these values leads to a lattice constant $a \approx 5{\cdot}73$ Å for hypothetical RhS_2. Moreover, on replacing cobalt by rhodium in a pyrite structure the lattice constant is increased by about 0·2 Å (ref. 15), which, with $a = 5{\cdot}535$ Å (ref. 6) for CoS_2, confirms the extrapolated value. The lattice constant $a = 5{\cdot}574$ Å reported by Thomassen[14] therefore seems much too small for RhS_2 but is very similar to the value which we obtained for $RhS_{\sim 3}$ ($a \approx 5{\cdot}58$ Å, neglecting a small splitting of the lines). Furthermore, Juza *et al.*[16] also found no evidence for RhS_2 from a tensimetric analysis of the Rh–S system.

In the structures discussed so far it is impossible for the cation to acquire the electron configuration $d\varepsilon^6$ which would give rise to semiconducting properties. The remaining compounds illustrate how a cation valency favourable for non-metallic properties can be achieved in the 4*d* and 5*d* compounds by a slight modification of the crystal structure. Orthorhombic $IrSe_2$ represents a first example of this behaviour. Its unit cell[17] contains eight formula units and in parts is built similarly to the marcasite structure. Each iridium atom is located at the centre of a distorted octahedron with three Se neighbours at a distance of 2·44 Å and three others at 2·52 Å. One half of the selenium atoms are tetrahedrally surrounded by three iridium atoms and one selenium atom, the Se–Se distance being 2·57 Å. The other half of the selenium atoms have a similar neighbourhood, but adjacent selenium atoms are spaced at 3·27 Å, so that there is no longer an anion–anion bond. The corresponding chemical formula is $Ir_2^{3+}Se_2^{2-}(Se_2)^{2-}$. The observed diamagnetism (Table 1) confirms the postulated $d\varepsilon^6$ configuration (neglecting the small splitting of the $d\varepsilon$ levels due to the deviation from exact octahedral symmetry, which does

Table 2. Lattice Constants of the New $IrSe_2$-type Compounds

Compound	a (Å)	b (Å)	c (Å)
RhSSe	20·48 ± 5	5·749 ± 9	3·629 ± 6
$RhSe_2$	20·91 ± 3	5·951 ± 6	3·709 ± 4
IrS_2	19·78 ± 3	5·624 ± 4	3·565 ± 4
IrSSe	20·43 ± 3	5·756 ± 4	3·649 ± 3
$IrSe_{3/2}Te_{1/2}$	21·43 ± 5	6·027 ± 7	3·813 ± 5

not alter their occupation). The expected non-metallic behaviour has been substantiated by electrical measurements.

The $IrSe_2$ type of structure was also found in IrS_2 and IrSSe. IrSTe does not seem to exist but, as evidenced by X-ray patterns, a small fraction of sulphur in IrS_2 can be replaced by tellurium. In $IrSe_2$ about one-quarter of the selenium can be substituted by tellurium without changing the structure. IrSeTe, however, was not obtained in a pure form. The $IrSe_2$ structure also occurs in RhSSe and in a low-temperature modification of $RhSe_2$. Complete miscibility was observed in the system (Rh, Ir) Se_2, whereas under the same conditions $Co_{1/4}Rh_{3/4}Se_2$ was obtained only in the pyrite structure. All these compounds have been prepared by sintering the powdered components at 700°–850° C. The $IrSe_2$-type phases are all diamagnetic and semiconducting. Lattice constants are listed in Table 2.

A second possibility to achieve non-metallic properties is shown by the compounds $MX_{\sim 3}$ (with M = Rh or Ir and X = S, Se or Te) which crystallize in a cation-deficient pyrite lattice[18]. The actual composition of these compounds appears to deviate somewhat from the ideal value. By sintering pressed powders at 600°–700° C I obtained samples of composition $MX_{2\cdot8-2\cdot9}$. Biltz *et al.*[19] gave the stoichiometry of the iridium sulphide as Ir_3S_8. Hockings and White[13] also proposed a 3 : 8 ratio for iridium telluride, Ir_3Te_8. This assumption seems to be justified from a crystallographic point of view, since in this case one of the four cation sites in the pyrite lattice remains empty, whereas in $IrTe_3$ one-third of all cation sites would have to be unoccupied. However, the fact that I found $RhS_{\sim 3}$, $RhSe_{\sim 3}$, $IrS_{\sim 3}$ and $IrSe_{\sim 3}$ to be diamagnetic semiconductors favours the formula MX_3 or $M_{2/3}(X_2)^{2-}$, which then shows the close analogy to the diamagnetic pyrite-type semiconductors RuS_2, $RuSe_2$, etc.[20]. It is not surprising that the lattice of the compounds with the highest cation deficiency remains no longer exactly cubic. A trigonal splitting of the pyrite lines was observed for $RhS_{\sim 2\cdot9}$, $RhSe_{\sim 2\cdot9}$ and $IrSe_{\sim 2\cdot9}$. For $RhSe_{\sim 2\cdot9}$ the lattice constants are:

$$a = 5{\cdot}962 \pm 2\ \text{Å}$$
$$\alpha = 90°\ 44 \pm 2'$$

Those for $IrSe_{\sim 2\cdot9}$ are almost identical.

It is interesting to note that by filling the cation holes the semiconductor $RhSe_{\sim 3}$ is converted into a superconductor. At the composition $RhSe_2$ the transition temperature lies already above 1° K (ref. 2) (T_c = 4·43° K, determined on a sample with a lattice constant a = 6·092 Å (ref. 21)) and reaches its maximum of about 6° K at $RhSe_{\sim 1\cdot8}$ (refs. 2 and 3). The pyrite structure is reported as far as $RhSe_{1\cdot78}$ (ref. 22). At the composition $RhSe_{1\cdot5}$, however, the character of the compound has definitely changed. In my attempts to prepare RhS_2 I obtained a semiconducting phase which turned out to be Rh_2S_3. Rh_2Se_3 and Ir_2S_3 were also synthesized and proved to be isostructural. My X-ray patterns are, however, different from that given by Rudnev and Malofeeva[23]. The non-metallic properties of these compounds lead to the conclusion that rhodium and iridium are in octahedral co-ordination displaying the diamagnetic configuration $d\varepsilon^6$. For Rh_2Se_3 we occasionally obtained somewhat diffuse X-ray patterns in which the main lines could be indexed by assuming a hexagonal unit cell with $a \approx 5{\cdot}4$, $c \approx 3{\cdot}6$, $c/a \approx 1{\cdot}5$. The lattice constants seem to vary with the Rh : Se ratio. We believe that these patterns can be attributed to a high-temperature modification of the Cr_2S_3 type. However, attempts to synthesize the mixture $CrRhSe_3$ failed.

I thank Dr. P. Giesecke, Cyanamid Research Laboratories, Stamford, who carried out diffuse-reflectance measurements on many of my samples, Mr. H. U. Boelsterli and Miss Elfriede Rittershaus for their assistance in sample preparation and X-ray work, and Dr. E. Mooser for his advice.

INTERMEDIARY REACTIONS IN THE WATER-SPLITTING PART OF PHOTOSYNTHESIS

By V. BÜLTEMANN, H. RÜPPEL and Prof. H. T. WITT
Max-Volmer-Institut für physikalische Chemie der Technischen Universität, Berlin

A SIMPLIFIED scheme of the electron transport system in photosynthesis is depicted in Fig. 1. Electrons are transferred from water to TPN (coenzyme 2) through several intermediates. The electron flow is driven by the energy of two light absorptions $h\nu_I$ and $h\nu_{II}$. The development which leads to this scheme especially by the technique of flash photometry[1] and recently also by periodic relaxation[2] is published in refs. 3–18. Nothing is known so far about the mechanism of water splitting and the intermediate-reactions between water and Chl-a_{II} because this part of the reaction is not accompanied by measurable changes of absorption. First details, however (depicted in Figs. 1 and 3), have now been obtained, using the following technique.

Thirty years ago, Emerson and Arnold[16] tried to estimate the turn-over rate of photosynthesis. They measured the oxygen yield on *Chlorella* excited with periodic flashes of light. Short flashes were used with a duration of $\sim 10^{-5}$

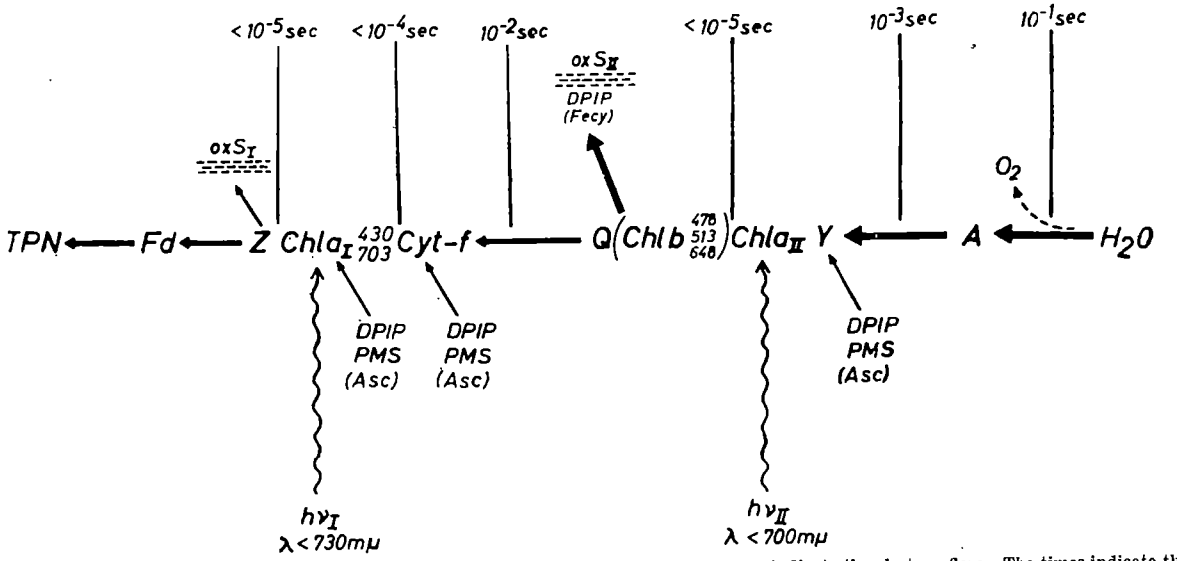

Fig. 1. Simplified scheme of electron transport in photosynthesis of green plants. The arrows indicate the electron flow. The times indicate the duration of the electron transfer. The back reactions[15,18] are not included in this scheme. TPN, triphosphopyridinenucleotide; Fd, ferredoxine; Cyt-*f*, cytochrome-*f*; Q, plastoquinone; Chl-a_I, special chlorophyll, absorption at 430 and 703 mμ; Chl-a_{II}, special chlorophyll-*a*; Chl-*b* (formerly called *X*), special chlorophyll-*b* with absorption at 478 and 648 mμ[16]. The reduced Chl-*b* has an absorption at 513 mμ (the brackets indicate that the position of Chl-*b* is yet not known exactly). *Z*, *Y* and *A*, detected but not identified substances. Chl-a_I can be excited with $\lambda < 730$ mμ and Chl-a_{II} with $\lambda < 700$ mμ. *Ox.S*I and *ox.S*II, artificial electron acceptors. DPIP, dichlorophenole-indophenole; *Fecy*, ferricyanide; PMS, phenazine-methosulphate; *Asc*, ascorbate

sec. In these experiments the oxygen-yield per flash is a function of the time t_d between the flashes. The time giving half the maximum yield of oxygen per flash was interpreted as the reaction time of the rate-determining step of photosynthesis. (As we shall see here, this interpretation cannot be sustained any longer.) This half-time was evaluated as $t_{d1/2} \approx 2 \times 10^{-2}$ sec (20° C). A similar value was found for chloroplasts[20].

The method of Emerson was used by us with two essential variations. (1) In chloroplasts the reaction system of Chl-a_I was blocked by trapping the electrons already at the position indicated in Fig. 1. This was attained by addition of oxidized dichlorophenole-indophenole DPIP (with ferricyanide in excess). The concentration of DPIP was kept at such a value that the trapping was fast (re-oxidation of Chl-*b*⁻ in $\tau_{1/2} \approx 5 \times 10^{-4}$ sec) compared with the normal reaction of Chl-*b* (ferricyanide without DPIP, re-oxidation of Chl-*b*⁻ in $\tau_{1/2} = 10^{-2}$ sec). Measurements of the oxygen yield per flash on such a separated system (arrows in Fig. 1) were expected to give information on the rate limiting step within the unknown reaction path between water and Chl-a_{II}. (2) The oxygen yield was measured on chloroplasts excited by periodic flashes (duration 5×10^{-5} sec) and also by flash groups (two flashes per group and long constant dark times between the groups; flash duration 5×10^{-5} sec).

Exciting the separated reaction system (arrows in Fig. 1) with periodic flashes (open circles in Fig. 2), half the oxygen-yield is obtained by $t_{d1/2} = 3 \times 10^{-2}$ sec (20° C). This value is nearly as large as that which was found by Emerson *et al.*[19] on the whole system.

If the half-time $t_{d1/2} = 2 \times 10^{-2}$ sec could be interpreted as the half-life of the rate determining reaction, the same result would be expected to excite the separated reaction system by flash groups. The result with flash groups, however, is completely different. The oxygen-yield per flash as function of t_d is bi-phasic. The first phase is characterized by $t_{d1/2} \approx 7 \times 10^{-4}$ sec and the second phase by $t_{d1/2} \approx 7 \times 10^{-2}$ sec (solid circles in Fig. 2). Owing to this discrepancy it is impossible to interpret the dark time for half oxygen-yield in periodic flashes ($t_{d1/2} \approx 3 \times 10^{-2}$ sec) as the half-life of the rate determining reaction.

Excitation by flash groups. The results in flash groups (solid circles in Fig. 2) can be interpreted in terms of two intermediates *A* and *Y* between water and Chl-a_{II}. These intermediates are characterized by the following data (Figs. 1 and 3):

(*a*) *Y* and *A* form a complex. The total amount of *Y* is equal to that of *A*: $Y_0 = A_0$. Therefore, the reaction between both is of first order.

(*b*) The value of the rate constant between *Y* and *A* is $k_1 = 10^3$ sec⁻¹, and that one between *A* and water $k_2 = 10$ sec⁻¹, $k'_2 = 4{\cdot}3$ sec⁻¹.

(*c*) The equilibrium constant *K* for $A^+ + \frac{1}{2}$ water $\underset{k'_2}{\overset{k_2}{\rightleftharpoons}}$ $A + H^+ + \frac{1}{4}$ oxygen is $K = 2{\cdot}3 = \frac{k_2}{k'_2}$. In equilibrium $0{\cdot}7\ A_0$ is in the reduced and $0{\cdot}3\ A_0$ in the oxidized state.

During the first flash *YA* (70 per cent) is oxidized to Y^+A, and YA^+ (30 per cent) to Y^+A^+ (Fig. 3). In the dark Y^+ is reduced by *A*, and A^+ is reduced by $\frac{1}{2}$ water (splitting in H^+ and $\frac{1}{4}$ oxygen). The yield of oxygen produced by the second flash at the time t_d after the first flash is given by the amount of *Y* which is reduced in the dark time t_d:

$$Y(t_d) = Y_0(1 - c_1 e^{-k_1 t_d} - c_2 e^{-k_2 t_d} \qquad (1)$$

$c_1 + c_2 = 1$, $c_1 = 0{\cdot}7$. Thus, the relative amount $Y(t_d)/Y_0$ must be equal to the relative oxygen-yield of the second flash at t_d:

$$\frac{Y'(t_d)}{Y_0} \text{ (solid line, Fig. 2)} = \frac{O'_2(t_d)}{O_2(t_d)} = \alpha' \text{ (solid circles, Fig 2).}$$

(It was proved that oxygen$(t_d \to \infty) \approx$ oxygen$(t_d =$ 250 msec) (see Fig. 2).)

Periodic excitation by short flashes. The extremely different results which are obtained by periodic flash excitation and, on the other hand, by flash groups (open and solid circles, Fig. 2) are both in complete accordance with the reaction scheme (Fig. 3). The exact calculation based on the reaction scheme (Fig. 3) gives namely for the relative oxygen-yield $\alpha''(t_d)$ in periodic flashes:

$$\alpha''(t_d) = \alpha'(t_d) - c_1 \frac{(e^{-k_2 t_d} - e^{-k_1 t_d})^2}{1 - e^{-k_1 t_d}},\ c_1 = 0{\cdot}7 \qquad (2)$$

$\alpha''_{max} = \alpha'_{max} = 1$. The theoretical curve (dotted line, Fig. 2) is in good agreement with the result of the oxygen measurements (open circles, Fig. 2).

Periodic excitation by long flashes. Tamiya and Chiba[21] also reported about oxygen-yield measurements in periodic flashes. Unlike Emerson and Arnold[19], flashes of long durations (0·6–8 msec), however, were used by these

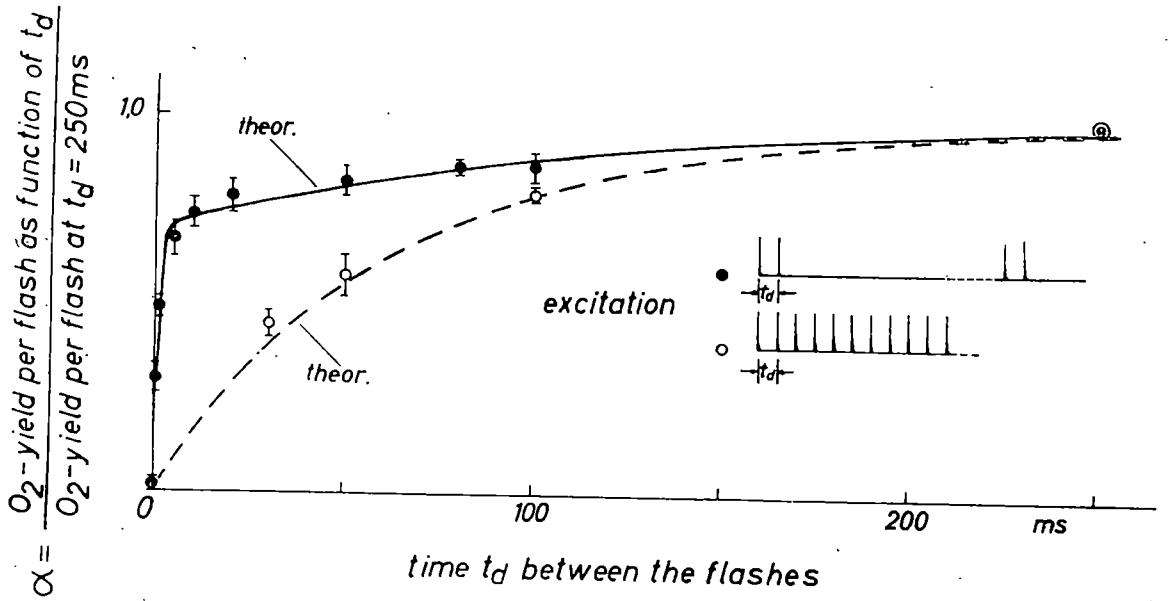

Fig. 2. Relative oxygen-yield per flash on chloroplasts as function of the dark time t_d between the flashes. Addition: 10^{-4} mole/l. dichlorophenole-indophenole (ferricyanide in excess, 10^{-3} mole/l.); flash duration 5×10^{-6} sec, saturating light intensity. *p*H 7·2; temperature 20° C. Chlorophyll contents, 0·5 in 2 ml. Solid circles: experimental results by flash groups; solid curve calculated according to the reaction scheme in Fig. 3 (see equation 1). Open circles, experimental results by periodic flashes; dotted curve, calculated according to the reaction scheme in Fig. 3 (see equation 2)

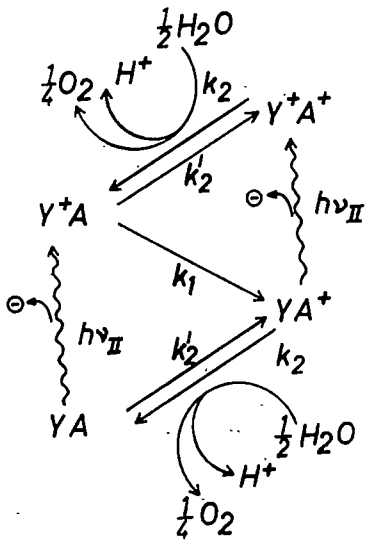

Fig. 3. Detailed scheme of Fig. 1 for the reactions between water and Chl-a_{II}. After long dark times 70 per cent of the total amount of Y and A is in the state YA, and 30 per cent in the state YA^+. The waved arrows indicate excitation of Chl-a_{II} by $h\nu_{II}$. Excited Chl-a_{II} transfers an electron from Y to DPIP (Fig. 1). Y^+ is reduced by A, and A^+ by water. $k_1 = 10^3$ sec^{-1}, $k_2 = 10$ sec^{-1}, $k'_2 = 4{\cdot}3$ sec^{-1}

authors. The results of Tamiya *et al.* were different from those of Emerson *et al.* Exciting by long flashes, they found: (*a*) that the half-time is $t_{d1/2} \approx 10^{-1}$ sec (by short flashes $t_{d1/2} \approx 2 \times 10^{-2}$ sec); (*b*) that the maximum oxygen-yield per flash ($t_d \rightarrow \infty$) is about twice the yield in short flashes; (*c*) that the maximum oxygen-yield is a function of temperature, whereas the maximum yield in short flashes is temperature independent.

As yet no satisfactory explanation for this discrepancy could be given. A calculation on the basis of the reaction scheme (Fig. 3), however, gives for the relative oxygen-yield $\alpha''(t_z)$ in periodic flashes of long duration (flash duration $t_f > 3/k_1$):

$$\alpha''(t_d) = k_2 t_f + (1 + c_1)(1 - e^{-k_2 t_d}),\ c_1 = 0{\cdot}7$$

$\alpha''_{max} = k_2 t_f + 1{\cdot}7$. This calculation agrees with the results of Tamiya and Chiba[21].

(*a*) The time dependence of α'' is a function of k_2 only; $\ln 2/k_2 = t_{d1/2} = 7 \times 10^{-2}$ sec. This half-time equals the experimental value of Tamiya *et al.*

(*b*) $\alpha''_{max} = 0{\cdot}10 + 1{\cdot}7 = 1{\cdot}8$, for $t_f = 10$ msec. This value is nearly twice the maximum yield which was found by Emerson *et al.* using short flashes.

(*c*) The maximum yield α''_{max} is a function of k_2. k_2 is dependent on temperature, therefore, α''_{max} is a function of temperature, too. In the case of short flashes, however, the maximum yield is $\alpha_{max} = 1$ and, therefore, independent of temperature.

The application of flash groups and the measurements on the separated reaction system (arrows, Fig. 2) opens a way to detect details of the reaction path of water splitting. The reaction scheme derived from these experiments gives a quantitative explanation for the manifold and apparently discrepant results obtained by flash groups and periodic excitation with short and long flashes.

As manganese has been shown to be an essential co-factor in water oxidation[22], it may be possible that the intermediate A is closely related to manganese. Finally, it may be noted that the mechanism for YA as depicted in Fig. 2 is supposed to be valid for the reaction of Chl-a_I·*Cyt-f*, also.

MOLECULAR SIEVING BY CELL MEMBRANES OF *Bacillus megaterium*

By Dr. RENÉ SCHERRER and Prof. PHILIPP GERHARDT

Department of Microbiology, University of Michigan, Ann Arbor

MOST bacterial cells are enclosed by two permeability barriers: a cell wall and an underlying cytoplasmic membrane. The wall in the Gram-positive bacteria seems to be an irregular meshwork of mucopeptide strands with openings (pores) permeable to water and certain solutes[1]. Solutes of high molecular weight are excluded, the threshold size varying among different bacteria[2–4]. Isolated cell walls of *Bacillus megaterium* KM seem to be heteroporous and they exclude dextrans or polyethylene glycols above molecular weight 57,000 (ref. 4). The prevailing concept of a triple-layered cytoplasmic membrane, with two protein sheets and an intermediate lipid layer, emphasizes the role of lipid solubility in permeation. A possible hexagonal arrangement in the ultrastructure[5,6] suggests that the membrane is isoporous and may contain water-filled channels. Oligosaccharides larger than disaccharides do not diffuse through the cytoplasmic membrane of representative Gram-positive bacteria[2,7].

The relationship between the cell structure of *B. megaterium* KM and permeating molecules has been investigated, using a series of commercially available ethylene glycols ranging from mono-ethyleneglycol to poly-ethyleneglycol, molecular weight 70,000 (Union Carbide Co. and Dow Chemical Co.). *B. megaterium* KM was grown in 10-litre batches of half-strength trypticase-soy-broth (Baltimore Biological Laboratory) at 30° C under constant aeration and agitation in a glass and stainless-steel fermentor. Late in the log phase of growth the bacteria were separated by centrifugation, washed twice in distilled water at 4° C, and suspended in water. The thick suspension or space technique[4,8] was used to determine the percentage of intracellular weight (R^w) occupied by the solute at 'diffusion equilibrium'. This technique is based on several assumptions: well mixed extra- and intra-cellular compartments; equal distribution of the solute in the entire available intracellular space; no changes, or correction for changes, in the cell volume; and determination at diffusion equilibrium of the final solute concentration in the extracellular compartment. Experiments were performed at 4° C under semi-anaerobic conditions (thick suspension) to preclude active transport or metabolism, although neither was demonstrated.

Polymer concentrations of the suspensions were determined by precision refractometry, using a correction for ultra-violet-absorbing material. Leakage of absorbing material was identical in polymer-containing and control suspensions. All the polymer was recovered by subsequent washings of the suspension after exposure. Cell viability was not affected by the polymers.

A linear relationship occurred between initial polymer concentration and amount of polymer taken up by the cell pack (Fig. 1), but because of possible association of polymers[9] and plasmolysis at higher solute concentrations, initial concentrations of 0·25–3·0 per cent (w/v) were used. Under these conditions, no change in cell volume was detected by determining ^3H_2O space during and after the experiments.

Extracellular space was $21{\cdot}3 \pm 4{\cdot}1$ per cent (w/w) standard deviation, when measured with non-permeating dextrans (Pharmacia,* Inc.) of molecular weight ($\bar{M}_w$) 158,000–2,000,000 and cells centrifuged at 21,000g for 90 min. Water space, measured with tritiated water, was $78{\cdot}0 \pm 1{\cdot}55$ per cent of cellular weight. This result corresponds with the total water content of 78·5 per cent in *B. megaterium*[4] and suggests that all intracellular water is available for diffusion.

A semilogarithmic plot of intracellular space occupied by polymers as a function of molecular weight showed a complex curve (Fig. 2). Three segments were distinguished: (I) polymers of molecular weight above 30,000 occupied no intracellular space; (II) polymers of molecular weight decreasing from 30,000 to 1,500 occupied an increasing intracellular space, to $R^w \sim 18$ per cent; (III) polymers of molecular weight from 2,000 to 62, and to 20 for ^3H_2O, occupied still more cell space, up to $R^w = 78$ per cent, as molecular weight decreased.

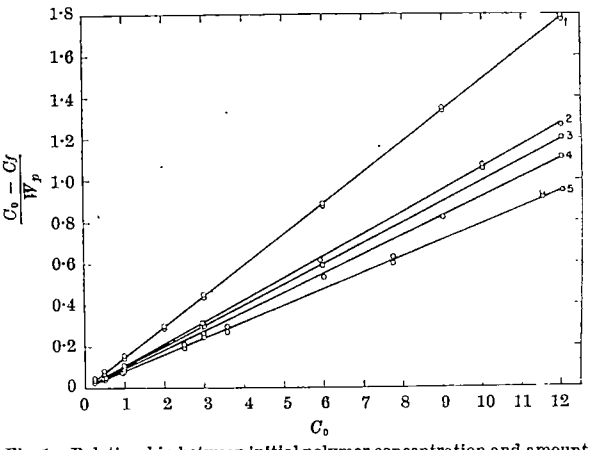

Fig. 1. Relationship between initial polymer concentration and amount of polymer taken up at diffusion equilibrium by *Bacillus megaterium* KM. C_0, initial concentration of polymer (per cent w/v); C_f, final concentration; W_p, weight of wet cell pack. Curve 1, ethyleneglycol; 2, methoxypolyethyleneglycol ($\bar{M}_n$, 550); 3, polyethyleneglycol ($\bar{M}_n$, 1,000); 4, polyethyleneglycol ($\bar{M}_n$ 6,750); 5, dextran ($\bar{M}_w$, 285,000)

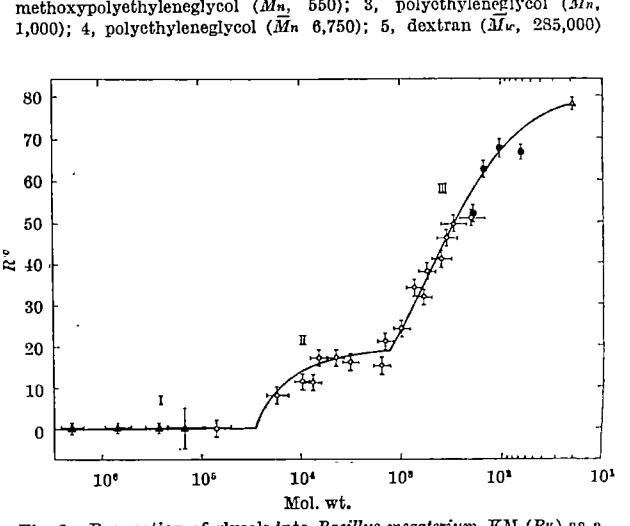

Fig. 2. Permeation of glycols into *Bacillus megaterium* KM (R^w) as a function of molecular weight ($\bar{M}_n$). △, ^3H_2O; ●, monodisperse ethyleneglycols; ○, polydisperse polyethyleneglycols; ▲, dextrans. Standard deviations are indicated for each point. Segments of the curve indicating cell exclusion, cell wall uptake, and cytoplasmic membrane penetration are indicated by I, II, and III, respectively

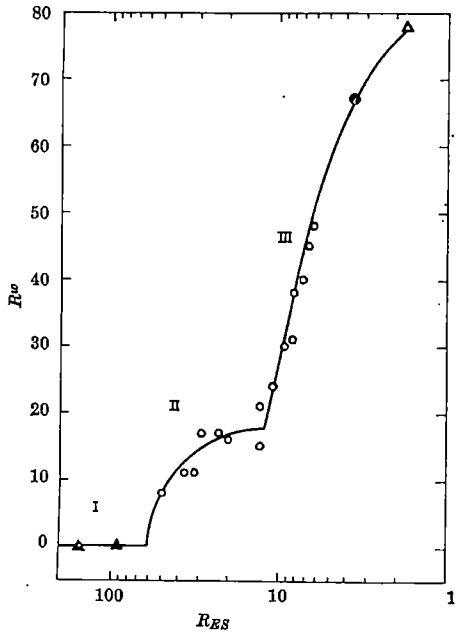

Fig. 3. Permeation of glycols into *Bacillus megaterium* KM (R^w) as a function of the Einstein–Stokes diffusional radius in Å (R_{ES}). The symbols are the same as in Fig. 2

Cell-wall weight is about 20 per cent of total cell weight, when estimated in the logarithmic growth phase[10]. Relative volumes, determined from electronmicrographs of thin sections of *B. megaterium* KM, indicated that cell-wall weight was 20–23 per cent of total cell weight (volume × 1·10 specific gravity = weight)[4]. Segment II of the curve in Fig. 2, approaching $R^w = 20$ per cent, may correspond to the cell wall region of *B. megaterium* while segment III may represent uptake through the cytoplasmic membrane into the cytoplasm.

Lipid solubility and molecular size are the two main criteria generally used to explain permeation phenomena with uncharged molecules[11]. Since lipids are not present in measurable amounts in cell walls of *B. megaterium* KM[12], they should not influence cell-wall uptake. Lipid solubility of glycols increases with increasing molecular weight[11], but solute space values decreased. Furthermore, polypropyleneglycols have a higher partition coefficient in oil–water systems than do polyethyleneglycols[11]; but both series, up to molecular weight of 425, gave the same solute space values. Thus, lipid solubility does not seem important in permeation of glycols into *B. megaterium*.

Diffusional size[13] of solute molecules, principally a function of molecular weight, is apparently important in dialysis and molecular sieving[13,14]. Molecular radii of the polyglycols were taken directly or by extrapolation from experimental data[15,16]. Fig. 3 shows a semi-logarithmic plot of diffusional size of glycols as a function of their uptake values in *B. megaterium*. The same three segments as in Fig. 2 were observed. Polymers with a diffusional radius above 60 Å were excluded from the cell wall, while smaller molecules penetrated it. Polymers of diffusional size above 10 Å radius could not penetrate the cytoplasmic membrane. The exclusion threshold for the cytoplasmic membrane was higher than a previous estimate[2], but for the cell wall was comparable to that obtained with isolated cell walls[4].

Molecular shape may be important in the penetration of macromolecules into bacterial cells. Polymers used in these experiments are 'high-pressure' polydisperse compounds, readily soluble in water[16–18]. A constant of 0·72–0·76 obtained for the Mark–Houwink equation indicated that none of the polyethyleneglycols was spherical in water[15,16]. Those of molecular weights less than 1,000, however, were found to be spherical in water, while higher polyethyleneglycols became more rod-shaped[17]. A comparison of glycols with differently shaped compounds might indicate the importance of molecular shape in penetration.

URINARY EXCRETION OF BETA-AMINO-ISOBUTYRIC ACID AND TAURINE IN MONGOLISM

By Prof. H. O. GOODMAN*
Department of Preventive Medicine and Genetics
Dr. J. S. KING, jun.*
Department of Urology, Bowman Gray School of Medicine, Winston-Salem, North Carolina

THE theoretical basis for the distortion of phenotypic ratios among human trisomics has been partially established[1–3]. Such distortions provide another avenue for the detection of linkage. The only locus reported as possibly located on chromosome 21 and supported by extensive data is that regulating the ABO blood group[3].

The urinary excretion of β-amino-isobutyric acid (BAIB) has been thought to be regulated in part by genetic factors, that is, high excretors are thought to be homozygous for an autosomal recessive gene[4–6]. Wright and Fink[7] and

* Recipients of Research Career Development Awards, U.S. National Institutes of Health.

Lundin and Gustavson[8] have reported high excretors to be more frequent among mongoloids than among either non-mongoloid mental retardates or normal individuals. Perry, Shaw and Walker[9] were unable to confirm Wright and Fink's observation. However, previous investigations have been based on one- or two-dimensional paper chromatographic analyses of urine, with their inherent limitations[10]. The importance of detecting linkage in man, the relatively high-frequency of the gene regulating high BAIB excretion[1-3], and the fact that the reported excess of high excretors among mongoloids exceeded theoretical expectation[11], prompted examination of urinary amino-acid excretion patterns of mongoloid and non-mongoloid subjects using the Technicon amino-acid analyser system, which permits higher resolution and greater reproducibility than paper chromatographic methods.

Urine was collected from 33 (19 male, 14 female) institutionalized mongoloids. Of the samples, 26 were accurate 24-h specimens and 7 were haphazard (not 24-h) specimens; 24-h urines from 20 normal subjects were examined as controls. All mongoloids were karyotyped and found to have the usual 21 trisomy abnormality. Urine was kept frozen until analysed. The analytic procedure was as previously described[12]. Among the 70–80 ninhydrin-positive peaks found in the usual pattern under these conditions, only two have been quantified thus far, namely, those produced by BAIB and by taurine.

BAIB excretion is expressed in terms of mg BAIB/day for urine samples with volumes greater than 600 ml. (39 subjects) and as mg BAIB/l. for specimens with volumes of 600 ml. or less (14 subjects). The latter was found to be a close approximation of mg BAIB/g creatinine, another mode of expression sometimes used with haphazard specimens.

BAIB is considered to be derived only from the breakdown of thymine and its urinary excretion rate appears normally to be independent of diet, age and sex, except that younger subjects (< 5 years of age) appear to excrete increased amounts. Haphazard urine samples collected months apart from two mongoloid subjects contained 88, 111 and 115 mg BAIB/l. in one and 43 and 63 mg BAIB/l. in the other, bearing out the relative constancy of excretion. In the only previous investigation using comparable methods, Armstrong *et al.*[14] reported a range for 3 oriental high excretors of 92·8–150 mg BAIB/day. The mean value (104·7) for the first-mentioned subject was the only value falling within this range among both mongoloids and controls. The small number of subjects (9) under 10 years of age precluded regression analysis of BAIB excretion on age. Sex differences were not detected ($t = 0{\cdot}63$, $P > 0{\cdot}50$ excluding 9 youngest subjects, 8 of whom were males).

The positive skewness in both mongoloid and normal distributions of BAIB excretion was normalized by conversion to their logarithms (Table 1). Variability in BAIB excretion among mongoloids was significantly higher than that among normals ($F = 3{\cdot}28$, $P < 0{\cdot}01$). Using the Fisher–Behrens test, the mean log of BAIB excretion was also significantly higher for mongoloids than for normal individuals ($d = 5{\cdot}49$, $P < 0{\cdot}01$). However, when the 9 mongoloids 10 years of age or younger are excluded from the calculation (the highest excretor is in the younger group), the significance disappears ($d = 0{\cdot}86$, $P > 0{\cdot}05$). Hence, our results corroborate those of Perry, Shaw and Walker[9], but with the suggestion of an excess of higher excretors among mongoloids which may become significant in the larger sample being collected.

Table 2 compares our results for mongoloids with those of Wright and Fink. The two classes with highest excretion levels were lumped because of small expected numbers. Our distribution of mongoloids included significantly fewer with high and more with low levels of BAIB excretion ($\chi^2 = 16{\cdot}8$, $P < 0{\cdot}001$). Whether the disparity arose from differences in age distributions or methodology cannot be rigorously determined because Wright and Fink did not indicate the ages of subjects. They did state that ages of mongoloid and normal subjects were comparable and that normal subjects were drawn from a pædiatric clinic, suggesting that all were under 15 years of age. Most of our mongoloids were adolescents and young adults (mean age = 15·1 years). However, if age were the important variable, one would expect our normals to differ from theirs, since our controls were all 18 years of age or older. A test revealed no difference between the distribution of BAIB levels in the two control groups ($\chi^2 = 1{\cdot}43$, $P > 0{\cdot}25$), though the small size of our sample does not permit a very powerful test of the hypothesis. Whatever the causes, our results do not confirm the results of Wright and Fink.

Table 2. COMPARISON OF RESULTS FROM THIS WORK WITH THOSE OF WRIGHT AND FINK[7]

BAIB in mM/l.	Frequency Present work	Frequency Wright and Fink
0–0·14	18	21
0·15–0·49	13	29
0·50–1·70	2	25
1·80–9·00	0	12
Totals	33	87

Using one-dimensional chromatography of urine, Lundin and Gustavson[8] have reported an increased proportion of high excretors of BAIB among mongoloids. In duplicating their procedure, eluting the region corresponding to BAIB and column-chromatographing the eluate, we found the region of the paper containing the upper half of the BAIB spot to contain also tyrosine and urea, the respective approximate molar proportions being 8 : 1 : 27; the lower half contained BAIB and urea, in the proportions 1 : 56. Partially independent evidence that Lundin and Gustavson were measuring components other than BAIB is provided by the level of BAIB they designated as high excretion, namely, 10 per cent or more of the total optical density of the pattern being attributable to BAIB. Column chromatography of our highest BAIB excretor showed that the area of the BAIB peak was about 1/10 the combined areas of the peaks produced by glycine, alanine, lysine and urea alone. In the light of these findings, a comparison of our data with those of Lundin and Gustavson is obviously meaningless.

The fact that the column chromatographic method yields data on BAIB excretion which do not agree well with the results of previous paper chromatographic investigations suggests the need for re-examination of the level selected for discriminating high and low excretors before the hypothesis that the presumed recessive gene regulating BAIB excretion is on chromosome 21 can be tested. As will be shown elsewhere[11], making the assumptions that there is such a gene on chromosome 21, that it is absolutely linked to the centromere, that non-disjunction occurs in the first division, and that heterozygous mongoloids with a double dose of the recessive gene will

resemble disomic homozygotes (a dosage effect), there will be 12·7 per cent high excretors among mongoloids if the frequency of disomic high excretors is 5 per cent and 23·7 per cent if the frequency of disomic high excretors is 10 per cent. The expected excess of high excretors among mongoloids under these assumptions is considerably less than the 4–6-fold excesses previously reported[7,8]. Further, if these assumptions are not met, the excess will generally be smaller.

Taurine is considered to be derived from cysteine via cysteine sulphinic acid[15]. Its urinary excretion is highly variable and reflects primarily protein intake as evidenced by its lowered excretion under fasting conditions. Gartler, Dobzhansky and Berry[16] and others have found little evidence of heritability in the excretion rates of taurine, though the difference between mono- and di-zygotic twins was in the direction expected if genetic factors were involved. In the independent urine samples from the same individuals mentioned above, taurine excretion levels were 0·64, 1·00 and 0·87 mg/l. for the one mongoloid and 32·7 and 35·2 mg/l. for the other.

Table 1 provides the results obtained on taurine excretion from the present subjects. Because several values were under 1 mg, taurine is expressed in terms of the logarithm (taurine in mg/day or mg/l. + 1). Three subjects with exceedingly low excretion rates were excluded from the control group because they were on a taurine-deficient but nutritionally complete synthetic diet and one because he was fasting. No sex differences in taurine excretion were detected. The mean log for mongoloids was significantly lower than that for controls ($t = 5{\cdot}33$, $P < 0{\cdot}001$). As might be expected, taurine excretion was lower for younger subjects, but the difference between mongoloids and controls persisted when subjects less than 10 years of age were excluded ($t = 4{\cdot}90$, $P < 0{\cdot}001$), and when subjects less than 18 years of age were excluded ($t = 4{\cdot}77$, $P < 0{\cdot}001$). Though protein intake for these subjects was not rigorously established, the diet available to the mongoloids, based on an 1,800 calorie intake, includes 80 g protein, 80 g fat and 180 g carbohydrate. Subjects are served milk three times a day, meat twice a day and eggs once each day. Hence, it does not appear that the protein intake is low. The low heritability previously shown for taurine excretion and the large proportion of mongoloids with low excretion rates discourage the inference that a gene or genes regulating taurine metabolism is on chromosome 21. On the other hand, the absence of a theoretical genetic basis for calculating the expected proportion of low taurine excretors among mongoloids prevents testing such a hypothesis.

Other differences in amino-acid excretion patterns of some mongoloid subjects were observed and will be reported elsewhere[11], together with further details of the experiments reported here.

Addendum. Work under way at the time the foregoing paper was submitted has been completed[17] which establishes a theoretical genetic basis for the high frequency of low taurine excretors as well as for the high galactose-1-phosphate uridyl transferase activity[18], and high neutrophil alkaline phosphatase activity[19] among mongoloids. These striking differences are probably due to overdose effects, that is, to genes which when present in triple dose give rise to phenotypes different in quantity or kind from the effects of the same gene in double dose. With assumptions that crossing over and timing of non-disjunction are independent of parental genotype, it can be shown that the various trisomic genotypes occur in the proportions:

Genotype	Frequency
AAA	$(p^3 + 1/2\ p^2qK)\ (1-m) + mp^2$
AAA'	$(3p^2q + 1/2\ pqK(1-3p))\ (1-m) + mpq$
$AA'A'$	$(3pq^2 + 1/2\ pqK(1-3q))\ (1-m) + mpq$
$A'A'A'$	$(q^3 + 1/2\ pq^2K)\ (1-m) + mq^2$

where p = frequency of A, q = frequency of A', m = proportion of post-fertilization non-disjunction, and $K = c + 2t - 3ct$, where c = frequency of crossing over, and t = proportion of second division meiotic non-disjunction. The excess of high excretors of BAIB among mongoloids previously reported[7,8] is not compatible with any assumptions regarding dominance relationships in the proposed model and is also dubious for the reasons stated. In contrast, the low taurine-levels and reported enzyme differences[18,19] are compatible with overdose effects in the model described, though the few data presently available and the lack of knowledge of gene frequencies preclude rigorous tests.

We thank Dr. C. Nash Herndon for his advice. This work was supported in part by grant *AM*–08050 from the U.S. National Institutes of Health and by a grant from the United Medical Research Foundation of North Carolina.

EFFECTS OF ELECTRIC CURRENTS ON BONE *IN VIVO*

By Prof. C. ANDREW L. BASSETT* and ROBERT J. PAWLUK
Orthopædic Research Laboratories, Columbia University College of Physicians and Surgeons, New York
AND
ROBERT O. BECKER
Upstate Medical Center, State University of New York, and Veterans Administration Hospital, Syracuse, New York

It now seems evident that bone functions as a transducer, converting mechanical energy to electrical energy. This behaviour has been ascribed to solid state or semiconductor characteristics in bone by some observers[1–3], and to classic piezoelectric phenomena, such as those observed when quartz crystals are stressed, by others[4–6]. Regardless of the mechanism by which these electrical

* Career Scientist, Health Research Council of the City of New York.

potentials are produced, the question of how they function remains obscure. While it has been recognized for many centuries that bone structure adapts to functional demands[7], the immediate controlling factors have not been identified. In 1962 it was suggested that the stress-generated electrical phenomena were capable of directing the activity of bone cells and were responsible for the orientation and/or aggregation pattern of macromolecules in the extracellular space[1]. Subsequent work in these laboratories demonstrated that collagen fibrils were oriented by weak, direct, electric currents (1 μamp) as they were reconstituted from solution[2]. The pattern of fibril orientation which occurred near the cathode was field-dependent, and at right-angles to the field. The present investigation was initiated to determine the effects of similar low-level, direct electric currents on bone, *in vivo*.

Electric currents were developed in bone by implanting units consisting of 2 iridium–platinum electrodes, a battery and a resistor. Within the units a 1·4 V mercury cell battery was connected in series to a resistor with a value of $1{\cdot}5 \times 10^6$, $1{\cdot}5 \times 10^5$ or $1{\cdot}5 \times 10^4$ ohms, so that the approximate current yield would be 1 μamp (microampere), 10 μamp or 100 μamp respectively. All connexions between battery, resistor and platinum electrodes were made with silver-epoxy cement. The entire unit was finally 'potted' in epoxy and coated with RTV silicone prior to implantation (Fig. 1*a*). Two holes, 13 mm apart, were drilled in the lateral, middle portion of the femora of 18 adult dogs, through an otherwise intact periosteum. Battery packs were inserted so that the platinum electrodes projected through the cortex, and 3–4 mm into the medullary canal. Muscle, fascia and skin were closed over the packs. Non-active controls were implanted in the contralateral femora. Current was monitored *in situ* continuously for 30 min, with a Hewlet-Packard d.c. meter connected to a strip recorder.

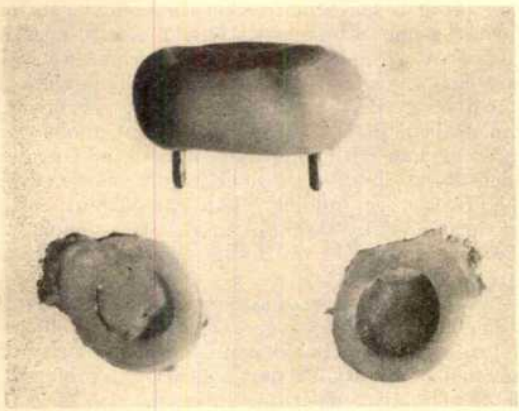

Fig. 1. (*a*) Silicone-encapsulated battery-resistor pack, with iridium–platinum electrodes which are 'plugged in' to holes drilled in femur so that tips of electrodes project 3–4 mm into medullary canal. (*b*) Cross-section of femur with 100-μamp pack in place for 14 days. Cathode left, anode right. Note the mass of intramedullary bone, nearly filling marrow cavity in specimen on left. The reaction about the anode, on the right, is approximately equal to that of the non-active control specimens

The results, depicted in Fig. 2, indicate that, most likely, as electrode polarization increases, resistance external to the pack increases and current falls. It seems reasonable to conclude that stability may be reached when the rate of gas production at the electrodes equals the rate of gas solution in the extracellular fluid. After 21 days in the animal, the 100-μamp packs were still delivering 3 μamp. When these animals were killed by the intravenous administration of an overdose of pentobarbital, the current fell rapidly to 2 μamp. This also suggests that current flow is dependent on the amount of gas being liberated and dissolved at the electrodes.

Cross and longitudinal sections of both femora were obtained following a perfusion of the hind quarters with 10 per cent neutral formalin, 14 and 21 days after operation. In the gross specimens, a mass of bone trabeculæ surrounded all platinum electrodes where they projected into the medullary canal. There was no difference between the amount of newly formed bone around cathode or anode of the active, 1-μamp packs and the inactive controls. Marked differences were observed, however, between controls and the specimens bearing the 10-μamp and 100-μamp packs. In both of these groups with active packs, massive production of new bone was noted around the cathode, while the reaction about the anode resembled that of the 2 inactive platinum electrodes in the controls (Fig. 1*b*). The result was the same, whether the cathode was proximal or distal to the anode. Frequently with the 100-μamp packs a dense, cathodal bone mass nearly filled the medullary canal. Bone production in the region of the negative electrodes had apparently reached a peak at about 2 weeks, since continuation of the stimulation for 21 days did not increase the trabecular masses. Although the differences were small, it appeared that animals with 100-μamp packs formed more bone at the cathode than did animals with 10 μamp packs.

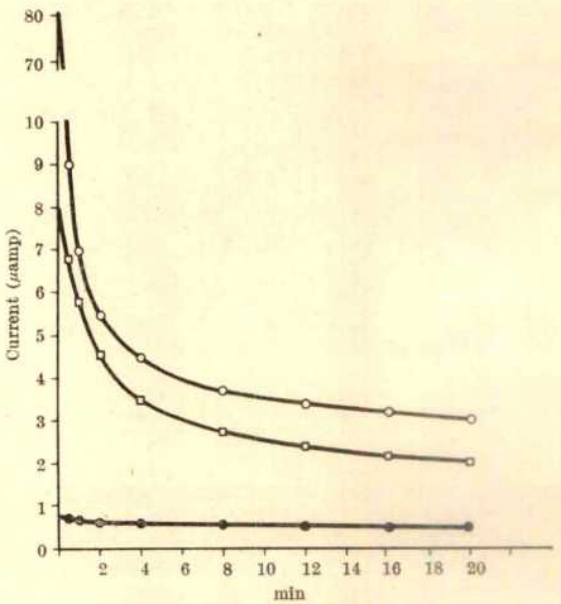

Fig. 2. Graph of current flowing in living bone after various intervals. Initial current values were 0·8, 8·0 and 80 μamp. ○, 100-μamp pack; □, 10-μamp pack; ●, 1-μamp pack

Microscopic examination of sections, prepared from specimens decalcified in formic acid, and embedded in paraffin, and stained with hæmatoxylin and eosin, paralleled the results listed here. There was bone formation about all active and control electrodes. While the reaction about control electrodes, cathodes and anodes was qualitatively similar, with minor exceptions, there was a greatly increased quantity of non-oriented, young, trabecular bone about the cathodes of all 10- and 100-μamp packs.

Osteogenic activity was judged by the number of osteoblasts on trabecular surfaces, the number of large lacunar spaces, and by the general cellularity. On the basis of these criteria, more bone was being formed about all control and active electrodes on the 14th than on the 21st post-operative day. At the cathodes of the 10- and 100-μamp packs, however, the picture at 14 days was one of florid osteogenesis. Many of these specimens contained microscopic fields which were extremely cellular

and in which the newly formed osseous matrix was poorly organized or non-existent (Fig. 3). In some areas, the tissue might have been mistaken for osteogenic sarcoma, had the cells appeared slightly more pleomorphic. Few of these histological characteristics were present in the cathode region of the 10 and 100 μamp packs at 21 days, and these were uniform fields of maturing fibre bone (Fig. 4). Osteoclasis was not observed at the anode. Multinucleated cells were frequently found on the trabeculæ and at some distance from them, but they were distributed uniformly throughout the areas of reaction. A sheet of brownish, homogeneous material, 30–40μ thick, possibly denatured protein, encased the active anode, but not the other electrodes. In the femoral cortex, between the cathode and anode of the 10 and 100 μamp packs, remodelling of osteones occurred and seemed to increase in magnitude between the 14th and 21st days. Bone resorption and deposition were evident along the course of the Haversian and Volkmann's canals in these specimens. Osteoblasts and osteoclasts did not appear to accumulate selectively in the region of the anode or cathode.

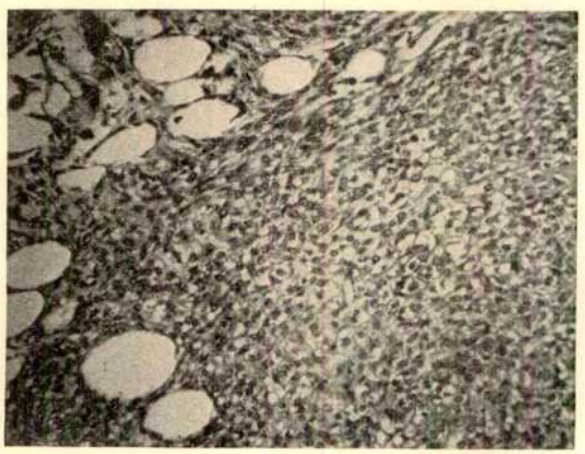

Fig. 3. Specimen 1(*b*), near cathode. Note marked cellularity, large vascular spaces and narrow 'seam' of osteoid at right of photomicrograph. (Hæmatoxylin and eosin, × 80)

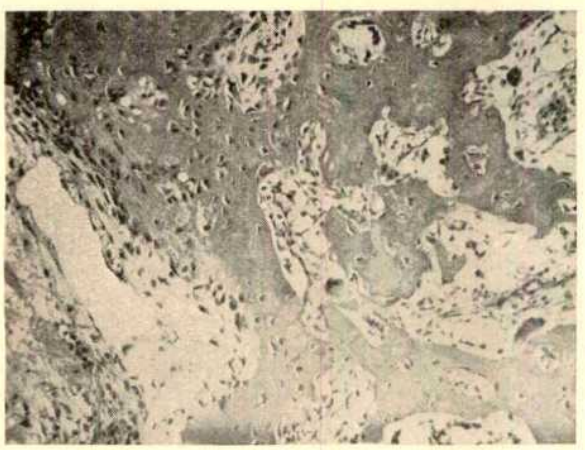

Fig. 4. Specimen 21 days after operation. Note fewer cells and more abundant extracellular matrix than are seen in Fig. 3. This picture was characteristic of the newly formed bone in most specimens with either active or non-active control packs. (Hæmatoxylin and eosin, × 80)

This work was begun without knowledge that investigators in Japan[9,10] had attempted similar experiments in 1956 and 1957, with results similar, in part, to those presented here. This present work, however, was undertaken as a test of the validity of a theoretical control system regulating bone structure and regeneration. The control system was proposed[2] as follows: mechanical deformation applied to the multiple apatite-collagen *pn* junctions in the bone matrix produces an electrical signal, which in turn stimulates differential cellular responses and causes the oriented deposition of newly formed collagen fibres to produce a structural change in the bone, enabling it better to resist the applied, deforming force. When the proposal was advanced in 1963, data were available to support each of its facets, with the exception of the relationship between electric currents and bone cell activity. Our results seem to indicate that such a relationship does, in fact, exist.

The massive osteogenesis occurring at the cathodes was probably not the result of electrophoretic action on collagen or mineral constituents. Had electrophoresis played a dominant part in the observations, a gradient effect might have been expected, with a greater or less amount of bone formed nearer the electrodes. Furthermore, on the basis of other studies (to be published), a preferred orientation of collagen fibres might also have been expected. Certainly, the mass of new bone was associated with an absolute increase in the number of young mesenchymal cells and osteoblasts. It is impossible to account for this degree of cellularity, unless more cells migrated to the region about the cathode, or the cells already present divided more frequently. Of the two possibilities, an increase in the mitotic rate seems more feasible, and the histological picture supports this. Furthermore, most cell membranes are negatively charged, and move towards the anode in electrophoretic chambers, under the influence of current densities vastly greater than the ones employed in this investigation[11,12]. In this connexion, it should be emphasized that while the current rating of packs before implantation ranged between 1 and 100 μamp, only 0·7 to slightly more than 3 μamp were actually delivered.

It was tempting to predict, on the basis of earlier studies[1,2], that bone formation on the concave surface of a deformed bone was related to its electro-negativity, while bone resorption on the convex surface was related to the relative positivity of that area. This work does not corroborate this hypothesis entirely. However, the experimental conditions, that is, direct continuous current, electrodes in line with long axis of bone and projecting into medullary canal, were deliberately chosen for simplicity. It is very unlikely that the current and field patterns produced by the implanted battery packs would ever be encountered in the living system in the natural course of events.

However, it seems that, under the influence of low level, direct electrical currents, bone formation mechanisms are affected in some way that depends on the polarity of the applied current, to produce new bone growth preferentially in regions of relative electro-negativity.

NEUTRALIZING ANTIBODY RESPONSES OF GUINEA-PIGS TO INACTIVATED RUBELLA VIRUS VACCINE

By Dr. JACK W. FRANKEL

Research Department, CIBA Pharmaceutical Co., Summit, New Jersey

A NUMBER of investigators have recently reported the isolation of rubella virus in tissue cultures inoculated with specimens from patients with clinically diagnosed rubella. Parkman, Buescher and Artenstein[1] observed that inoculation of primary African green monkey kidney cell monolayers with rubella virus rendered the cells resistant to super-infection with ECHO 11 virus. Sever, Schiff and Traub[2] used Coxsackie *A*-9 virus for challenge. Weller and Neva[3] noted specific cytopathogenic changes in cultures of primary human amnion cells infected with rubella virus. Utilizing these techniques, rubella virus isolations were afterwards reported by Veronelli, Maassab and Hennessy[4], Sigurdardottir, Givan, Rozee and Rhodes[5], Plotkin, Dudgeon and Ramsay[6], Lehmann and Ferris[7], Forbes, Bennett and Gray[8], Selzer[9] and Heggie and Robbins[10].

This article describes the frequency of isolation of rubella virus from naval recruits with clinically diagnosed disease and the neutralizing antibody responses of guinea-pigs following vaccination with non-viable rubella virus vaccine prepared from one of the rubella virus isolates.

Specimens were collected during April 1962 from naval recruits with clinically diagnosed rubella (lymphadenopathy, general malaise, nausea, headache and erythematous macular or maculopapular eruption persisting for 2–4 days) within 24 h after onset of rash. Control specimens were collected from some patients in the midst of the rubella outbreak with complaints other than rubella (that is, rubeola), and throat washings were obtained from a number of 'rubella-contacts' who failed to exhibit any clinical evidence of disease. The throat washings (in 0·5 per cent lactalbumin hydrolysate–Hanks's balanced salt mixture) were stored at −60° C in sealed glass ampules. Serum samples were collected at the same time and approximately 3 weeks later.

Rubella virus isolations were accomplished in culture tubes containing monolayers of African green monkey kidney cells. The monolayers were prepared, following treatment of kidneys with trypsin, with 2 per cent heat-inactivated 'Agamma' calf serum*–Medium 199 mixture containing SV_5 antiserum, and the monolayers, when confluent, were maintained with Medium 199. All media contained 1,000 units of penicillin and 1,000 μg of streptomycin per ml. No fewer than 10 cultures were inoculated with 0·1 ml. of throat washings and incubated on a roller apparatus at 36° C. After 7–9 days, a *p*H adjustment was made by the addition of small quantities of 2·4 per cent $NaHCO_3$. After 12–15 days, fluids were pooled and frozen at −60° C and 1·0 ml. of Medium 199 containing 100 TCD_{50} per 0·1 ml. of Coxsackie *A*-9 virus added to each tube. The cultures were incubated for an additional 7 days and resistance of the monolayers to super-infection with challenge virus was considered presumptive evidence for the presence of rubella virus. At least 3 sub-passages of pooled culture fluids were made before a specimen was considered not to contain rubella virus.

Rubella virus infectivity titrations were performed by the inoculation of 0·1 ml. of serial 0·5 $\log_{10}$ dilutions of rubella virus in Medium 199 to each of 4 culture tubes. After 12 days, the fluids were replaced with 1·0 ml. of Medium 199 containing 100 TCD_{50} per 0·1 ml. of Coxsackie *A*-9 virus. Infectivity titres (TCD_{50} per 0·1 ml.) were recorded 5 days later as the highest dilution of rubella virus rendering cells resistant to Coxsackie *A*-9 virus super-infection. Along with infectivity titrations, as with rubella virus isolations and sub-passages, uninoculated culture fluids were passed. Hæmadsorption tests with a variety of erythrocytes and animal and chicken embryonated egg inoculations were frequently made to exclude the presence of agents other than rubella virus.

Neutralizing antibody titres were determined by incubating 0·5 ml. quantities of serial ten-fold dilutions of rubella virus (diluted in 0·5 per cent 'Agamma' calf serum–Medium 199 mixture) with 0·5 ml. of serial two-fold dilutions of unheated serum for 90 min at room temperature. 0·2 ml. of mixture was then inoculated into each of 3 culture tubes and the monolayers incubated at 36° C for 11 days. After fluid removal, 1·0 ml. of Medium 199 containing 100 TCD_{50} per 0·1 ml. of Coxsackie *A*-9 virus was added to each tube. Five days later, neutralizing antibody titres were recorded as the highest (original) dilution of serum capable of suppressing the control rubella virus infectivity titre at least ten-fold ($10^{-4.1}$–$10^{-3.1}$ per 0·1 ml. in Table 1).

Table 1. Neutralizing Antibody Titres in Guinea-pigs to Rubella Virus Vaccine

* Intramuscular injection of 1·0 ml. vaccine.
† Serum (1 : 4) failed to neutralize Coxsackie *A*-9 virus.
‡ Geometric mean of neutralizing antibody titres.

The rubella virus vaccine was prepared as follows: 1-l. capacity bottles containing confluent African green monkey kidney cell monolayers maintained with 65 ml. of Medium 199 were inoculated with 1·5 ml. of undiluted rubella virus (isolate *GL*6, 3rd monkey kidney culture passage, $10^{2.3}$ TCD_{50} per 0·1 ml.) and incubated for 13 days at 36° C, during which time the *p*H was occasionally adjusted with dilute $NaHCO_3$. The cells and fluids were frozen in an alcohol–dry ice mixture, thawed once, pooled and centrifuged at 2,000 r.p.m. at 5° C for 30 min. The *p*H of the pool was adjusted to 7·2 and inactivation of virus infectivity ($10^{3.8}$ TCD_{50}/0·1 ml.) was directly performed with liquid ethylene oxide at a final concentration of 1 per cent for 1 h at 5° C. The ethylene oxide was completely volatilized during further incubation at 36° C for 14 h. The vaccine was stored at 5° C for the duration of the investigation. The vaccine probably did not contain any viable rubella virus or any other viruses since inoculation of monkey kidney cell cultures with the vaccine and subsequent challenge of some

* Obtained from Hyland Laboratories, Los Angeles, California.

cultures with 500–1,000 TCD_{50} per 0·1 ml. of Coxsackie *A*-9 virus failed to reveal the presence of such agents. Two additional sub-passages yielded similar results as did a single test performed in rabbit kidney cell monolayers according to the technique reported by McCarthy, Taylor-Robinson and Pillinger[11]. Suckling mice and chicken embryonated eggs were inoculated with the vaccine, also. Tests for detection of viable microbes other than viruses were similarly negative.

The results of virus isolation investigations indicate that the frequency of rubella virus isolation was greater from throat washings collected 1–12 rather than 13–24 h after rash onset. From 30 clinically diagnosed cases of rubella, 18 rubella virus isolates were obtained: 10/12 (83 per cent) from throat washings collected 1–12 h and 8/18 (44 per cent) from specimens collected 13–24 h following onset of rash. Rubella virus was recovered from 1 of 14 'rubella contacts' and rubeola virus from 2 individuals with illnesses clinically diagnosed as measles. Each rubella virus isolate was further characterized in that: (1) none was neutralized by homologous- or heterologous-acute phase serum samples but each was cross-neutralized by 3-week convalescent sera (antibody titres 1/32–1/512); (2) the infectivity of each isolate was neutralized by 4 pools of human γ-globulin† (antibody titres 1/128–>1/512); (3) each was neutralized by a standard reference rubella virus antiserum‡ (antibody titres 1/16–1/1,024); (4) all the convalescent but none of the acute phase serum samples neutralized a standard reference rubella virus preparation‡ (antibody titres 1/64–1/1,024). Various virus hyperimmune antisera failed to react with any of the isolates in neutralization and complement-fixation tests. Based on these results, the rubella virus isolates appeared to be antigenically similar to, or identical with, one another and the reference rubella virus preparation.

To determine whether the vaccine would induce the formation of neutralizing antibodies, 11 male guinea-pigs weighing 600–700 g were injected intramuscularly with 1·0 ml. (0·5 ml. injected into each of 2 sites) of vaccine and serum was collected at intervals noted in Table 1. Two additional animals as controls were inoculated with 1·0 ml. of normal tissue culture fluid treated with ethylene oxide. Neutralizing antibody titres were determined in a single neutralization test employing rubella virus isolate *GL*8 rather than *GL*6 used in the preparation of the vaccine. It can be seen from Table 1 that neither pre-vaccination sera nor serum specimens collected 1 week following a single injection of vaccine contained rubella virus antibodies. One week after a second injection of vaccine, neutralizing antibody titres were detected in 3 of 6 guinea-pig sera (antibody titres 1/32–1/64). Significantly higher titres (1/32–1/512) were found in serum samples collected 1 week after a third inoculation of vaccine (geometric mean 1/34) and these titres appeared to decline within 10 weeks (geometric mean 1/11). However, a single injection of vaccine at this 10-week interval resulted in an increase in the geometric mean of the neutralizing antibody titres to 1/60. Moreover, this additional inoculation resulted in the seroconversion of one guinea-pig (No. 6). Antibodies were not detected in undiluted serum samples collected from another (No. 3). None of the sera collected from immunized and control animals neutralized Coxsackie *A*-9 virus.

The results of these investigations indicate that rubella virus neutralizing antibodies appear in sera of guinea-pigs following immunization with rubella virus vaccine not containing detectable viable rubella virus. Since infection with rubella virus may result in serious congenital malformations, the results suggest that vaccination of susceptible human beings with non-viable rubella virus vaccine may induce the formation of antibodies protective against this virus infection.

RELATIONSHIP BETWEEN RADIATION DOSE AND GIANT CELLS IN THE SURVIVING CELL POPULATION OF MOUSE MARROW AS DETERMINED BY INTERFERENCE MICROSCOPY

By HUN LEE and Prof. VICTOR RICHARDS

Department of Surgery, Presbyterian Medical Center, San Francisco

WE have reported previously the dry mass distribution of the normal bone marrow cell population of the mouse[1] and the subsequent changes during the first 24-h post-irradiation period[2], and suggested that the dry mass changes might help to determine the degree of radiation injury of the marrow and the chances of survival of the patient. This article is the result of an investigation of the quantitative relationship between radiation doses and the changes in cellular dry mass of the giant cells in the surviving marrow cell population 24 h following irradiation. The changes, as we observed, are approximately proportional to the radiation dose; thus the information may be of value in the estimation of radiation injury to the marrow caused by a source known or unknown as to its strength.

LAF_1 male mice of approximately 20–33 g body-wt. and about 8–9 weeks of age were supplied by Jackson Memorial Laboratory. Each animal was exposed to a single dose of total-body X-irradiation (200 kVp, 20 m.amp. high-voltage layer, 1·35 mm copper) in an individual plastic container. Some of these doses, namely, 1,000 and 1,500 r., were composed of two successive exposures with an interval between them of no more than 10 min. Twenty-four hours after the irradiation, the animal was

killed in a glass jar with an overdose of ether. Slide preparations for interference microscopy were made from the femoral marrow cells suspended in normal saline. The techniques of slide preparation and interference microscopy were described in our previous publications[1,3,4].

Two thousand cells from 40 non-irradiated control animals and 1,000 cells from 20 irradiated animals for each of the following X-radiation doses were measured for their total cellular dry mass with the aid of an *A-O* interference microscope and a half-shade eyepiece. The doses tested were: 100, 200, 300, 400, 500, 600, 700, 800, 900, 1,000 and 1,500 r. Of 50 cells from each animal, 25 from each femur were measured. The megakaryocytes, which were too variable in size and often difficult to measure because of the difference in dry mass concentrations between cytoplasm and nucleus, coupled with the irregularity in the shape of the nucleus, and cells smaller than the mature neutrophiles (about 8–10μ in average diameter when flattened in the slide preparation), which include the erythrocytes, small lymphocytes and small nucleated erythrocytes, were excluded from measurement. The erythrocytes, the small lymphocytes and the small nucleated cells in the erythrocyte series were found without discernible change in dry mass following lethal irradiation in our previous experiments. The mature granulocytes, which also showed little or no change in dry mass, however, were included in our measurements because we needed a base line for calculating the percentages of giant cells. Except for the excluded cell types mentioned above, all the cells found in each microscopic field of a 100× objective were measured. By and large there were only a few cells in each field, as the cells must be well separated for interference microscopic measurements. To find 25 measurable cells from a single slide, it must have an average of 5–10 fields, thus for 1,000 cells as many as 200–400 microscopic fields were needed. This provided satisfactory compensation for the lack of uniform distribution of different types of cells in the marrow.

We chose to study the post-irradiation period at the 24-h level because we found that the maximum dry mass increase in the marrow cells was reached at the end of that period[2].

As we have already stated, our main interest in this work is the quantitative relationship between radiation doses and the changes in the giant cells of the surviving marrow cell population. The death of the giant cells which may occur at higher dose-levels, and their rate of death are, however, not included in our study. This relationship is three-fold: (1) the distribution of giant cells, of different dry mass values in the surviving population; (2) the changes in mean dry mass per cell of the surviving giant cell population; (3) the changes in percentages of giant cells in the surviving cell population, as related to radiation doses. A giant cell is arbitrarily defined as any cell which has a total dry mass of more than 110 relative units, with the exception of megakaryocytes which were excluded from our measurements. The line of demarcation was drawn at 110 relative units due to the fact that, with the exception of megakaryocytes, only 0·1 per cent of the normal marrow cells reached the dry mass level between 110 and 130 relative units among 2,000 cells measured in our non-irradiated control animals, and none was found beyond this limit. The demarcation line could more appropriately set at 130 relative units had it not been for the fact that the percentage of cells between 110 and 130 relative units in dry mass increased rapidly as the radiation dose increased even at the non-lethal levels where no evidence of cell death was found. These cells must be considered as radiation-induced giant cells as well as the cells with more than 130 relative units of dry mass.

Distribution of giant cells of different dry mass values in the surviving cell population. As aforementioned, in the non-irradiated controls we found only 0·1 per cent of cells which had a dry mass value between 110 and 130 units and none over 130 units. In the irradiated animals, the giant cells not only increased in number rapidly but also gradually expanded its ranges to higher values on the dry mass scale as the radiation dose increased. The percentages of giant cells with lower dry mass values were generally higher than those of the cells with higher dry mass values. The changes in the distribution of the giant cells are obviously related to the dose. For easy comparison, the distribution changes were illustrated in the histograms (Fig. 1).

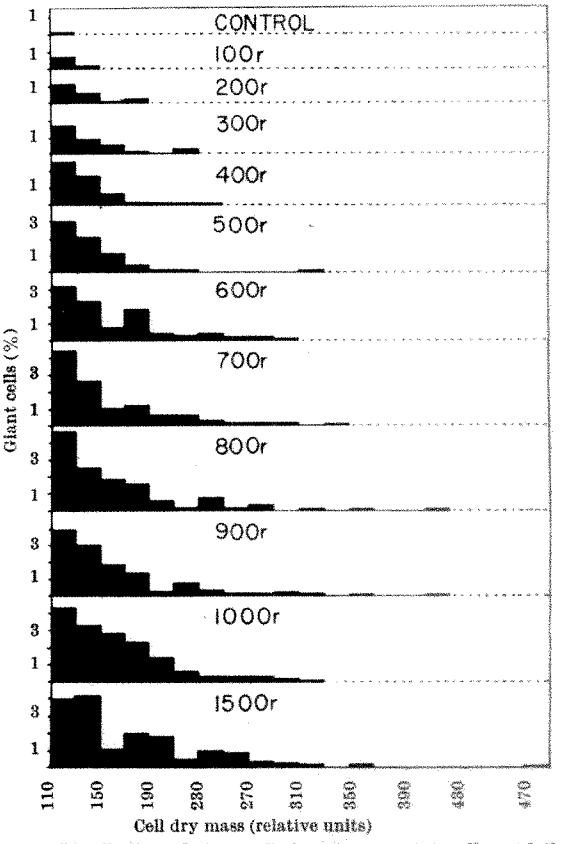

Fig. 1. Distribution of giant cells in mouse marrow cell population according to their dry mass values. Except for megakaryocytes, all the cells with more than 110 relative units in dry mass are considered as giant cells. The percentages of giant cells and their dry mass ranges increase with increasing radiation dose. The percentage of giant cells found in non-irradiated control animals is 0·1 per cent. Only the giant cells were presented in the histograms. The percentages of giant cells were calculated from 1,000 cells measured for each radiation dose tested and from 2,000 cells measured in the case of the non-irradiated control

Two factors contributed to the changes of giant cell distribution, namely, the increase in the number of giant cells and the increase in the dry mass of individual giant cells. The increase in number of the giant cells can be expressed as increase in percentage of the giant cells among the 1,000 cells measured from the surviving cell population for each dose, while the increase in dry mass of the individual giant cells can be expressed as an increase in mean dry mass per cell of the giant cell population.

Changes in mean dry mass per cell of the surviving giant cell population. From the fact that the giant cells showed a gradual spread towards the higher dry mass values in the increasing radiation doses as observed in the histograms (Fig. 1), one can almost predict that the mean dry mass of the giant cells will show a corresponding increase. When the mean dry mass of the giant cells for all the radiation doses as well as that of the non-irradiated control were calculated and plotted against the radiation doses in a curve, it became clear that the increase in mean dry mass per cell with the increasing radiation doses was approximately linear up to a limit—somewhere between 1,000 and 1,500 r. (Fig. 2). The linearity of the curve will probably improve with much larger cell samples

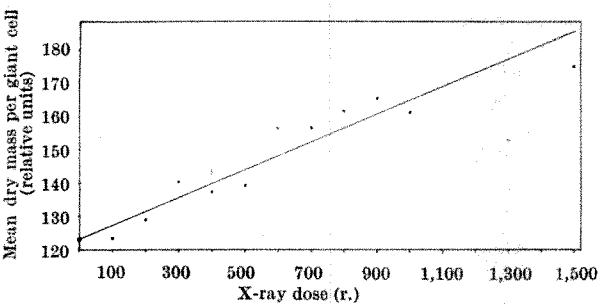

Fig. 2. Increase in mean dry mass per cell of the giant cell population of mouse bone marrow as plotted against increasing X-ray doses is approximately linear

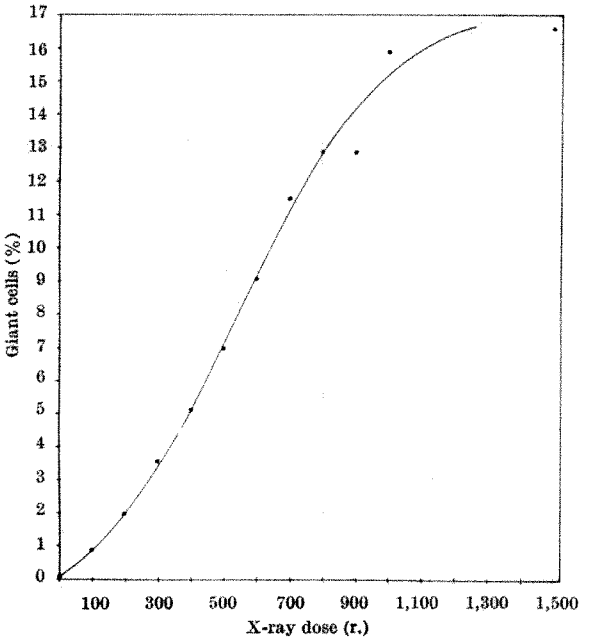

Fig. 3. Increase in the percentage of giant cells in the surviving marrow cell population of the mouse against the increasing X-ray doses results in a sigmoid curve. The middle portion of the curve between 400 r. and 800 r. is almost linear

measured. Thus the post-irradiational increase in mean dry mass per giant cell is also related to the dose.

Increase in percentages of giant cells in the surviving cell population. Another phenomenon related to the dose is the increase in percentages of giant cells in the surviving cell population which was demonstrated in both Puck's work[5] and ours. A gradual increase in the number of the giant cells as the radiation dose increased was clearly noticeable when the histograms of the giant cell distribution (Fig. 1) were compared. This gradual increase can be more clearly elucidated by plotting the percentages of giant cells of the non-irradiated control and of the irradiated animals against the radiation doses (Fig. 3). This results in a sigmoid curve. The middle portion of the curve from 400 to 800 r. is almost linear. The dose 400 r. is LD_2, very close to the non-lethal dose (LD_0), and the dose 800 r. coincides with LD_{100}. The increase of the giant cells is slow at the lower dose-levels but becomes faster at the 300-r. level; and a subsequent slowing down appeared at the last portion of the curve. This slowing down is probably due to the death of some giant cells at the higher dose-levels. The increase of the giant cells in the irradiated populations over that of the non-irradiated control is 52 times for 400 r., 129 times for 800 r. and 166 times for 1,500 r.

An increase in the size of cells following irradiation was observed in various organisms as well as mouse and human tumours in the late twenties through the early forties[6–9]. The appearance of radiation-induced giant cells in the animal bone marrow was first reported by Bloom in 1948 (ref. 10). The formation of the giant cells following irradiation was the result of mitotic inhibition without a corresponding inhibition in RNA and protein synthesis[11,12]. Puck found that, after X-irradiation, when the HeLa cells were plated, in tissue culture, the proportion of giant cells in the cells of the abortive colonies increased with the increase of the X-ray dose[5]. Cell death without any subsequent cell division following irradiation, however, occurred only at dose-levels above 600 r. Our results show that not only the percentage of giant cells in the surviving cell population increases with the increase of the radiation dose; the giant cell distribution pattern and the mean dry mass per giant cell are also related to the dose. The increase in percentages of giant cells seems to be the result of the fact that more cells are affected by a higher radiation dose in their mitotic process, while the increase in mean dry mass per giant cell can be explained by the increasing duration of mitotic inhibition of the higher radiation doses. It is a well-established fact that the duration of mitotic inhibition increases with increasing dose of irradiation[13]. The changes in the percentages of giant cells and the changes in the dry mass of the individual cells, together with the possibility of the death of some giant cells at higher dose-levels, contributed to the changes in the giant cell distribution.

Whether any radiation-induced death of the marrow cells in the sense of complete cessation of all the biological activities with subsequent disappearance from the population within 24 h following irradiation at dose-levels no greater than 600 r. may occur is open to question in the light of Puck's findings. If mammalian cells in tissue culture do not die without at least one or two cell divisions following direct exposure to radiation at the 600-r. level, one would tend to believe that marrow cells subjected to *in vivo* irradiation at levels of 600 r. will probably not die in statistically significant numbers. Thus cell death may have played little part in the changes we found in our results, at least not at the 600-r. level or below. At any rate, our concern is the relationship between the radiation doses and changes in the giant cells of the surviving cell population as an index to the degree of radiation-caused marrow injury. Whether or not any cell death might have occurred is of no significance.

These findings may have value in the estimation of the extent of radiation injury to the bone marrow and, accordingly, to the prognosis for a patient. Inasmuch as the response of individuals to a given dose of radiation differs greatly, knowledge of the dose a patient receives is helpful but far from being safe in permitting evaluation of the prognosis. A direct examination of the patient's response following the exposure is, therefore, of primary importance. This technique may offer possibilities as an aid in such investigations. The difficulty involved in the application of this technique for this type of study is that it is slow and tedious. With the information from our findings, we are at present exploring the possibilities of using much more rapid methods, such as a Coulter counter, for the measurement of corresponding changes in the size of the giant cells, and immersion refractometer for the measurement of the changes in cell dry mass concentrations at a populational level after irradiation of measured intensity.

CONTROL OF HÆMOGLOBIN A AND F SYNTHESIS: HÆMOGLOBIN FORMATION IN FŒTAL AND ADULT ERYTHROID CELLS

By DR. EDWARD R. BURKA and PROF. PAUL A. MARKS

Department of Medicine, Columbia University, College of Physicians and Surgeons, New York

THE work recorded here was designed to investigate the factors determining the rates of synthesis of fœtal and adult hæmoglobins. Examination of the mechanisms controlling the synthesis of hæmoglobin in human erythroid cells affords an opportunity for investigating certain aspects of cell differentiation. The hæmoglobin of human erythroid cells normally consists of a major type, hæmoglobin F ($\alpha_2\gamma_2$) in the fœtus, or hæmoglobin A ($\alpha_2\beta_2$) in the adult, and one or more minor components. Hæmoglobin A begins to replace hæmoglobin F as the major component during late fœtal development. In normal adults hæmoglobin F generally comprises less than 2 per cent of the total hæmoglobin[1]. In adults with certain types of thalassæmia, however, the proportion of hæmoglobin which is hæmoglobin F may exceed 40 per cent. Less striking elevations in hæmoglobin F concentration may occur in association with other types of hæmolytic anæmia. The α-globin chains in hæmoglobin F and adult hæmoglobin are probably identical in amino-acid composition[2].

Control mechanisms in protein synthesis may be exerted at various sites in the series of reactions involved in the translation of genetic information into the specific protein products. Previous investigations provided evidence that in thalassæmia there is a selective decrease in the capacity of polyribosomes to synthesize hæmoglobin A[3]. The rate of synthesis of hæmoglobin F in thalassæmic cells was found to be similar to that of cells from subjects with other hæmolytic anæmias not associated with impaired hæmoglobin A formation[4]. The synthesis of hæmoglobins A and F has now been further examined by determining the rate of formation of these proteins in fœtal reticulocytes and in cell populations from adults in which both hæmoglobins A and F are formed.

Ribosome content and amino-acid incorporation on ribosomes. It has been shown that ribosomes characterized by sedimentation coefficients greater than 100*S* (polyribosomes) are the site of protein synthesis in erythroid cells of adult subjects with thalassæmia and other types of hæmolytic anæmia[3]. The polyribosome content of reticulocytes from thalassæmic and non-thalassæmic persons is similar. In the present experiments, initial studies were designed to determine the content of ribosomes in reticulocytes of fœtal blood and to determine which ribosomes are active in protein synthesis in these cells. Fœtal blood was obtained from normal placentæ following full-term spontaneous delivery. The blood was collected in siliconized tubes containing 10 mg of dry heparin per 10 ml. of blood and immediately cooled in ice. The cells were recovered from the blood by centrifugation, re-suspended in 2 volumes of a modified Krebs-Ringer bicarbonate buffer[5] containing 6–10 μc. of ^{14}C-valine (20·3 μc./μmole) and ^{14}C-leucine (17·1 μc./μmole). Incubation was carried out with agitation under air at 37° for 80 min. Aliquots of the incubation suspension were removed at varying time-intervals from zero to 80 min for determination of radioactivity incorporated into the soluble protein[4]. In all studies the rate of incorporation of the ^{14}C-amino-acids into the soluble protein increased linearly during the entire period of incubation. Following the 80-min period of incubation, the cells were cooled in ice, separated by centrifugation and lysed, and ribosomes were recovered from the hæmolysate by the techniques described elsewhere[3]. The concentration of ribosomes was determined by absorbance at 260 mμ and the sedimentation characteristics analysed by sedimenting them through a 5–20 per cent linear sucrose density gradient[3]. The total amount of ribosomes and the proportion of the ribosomes with sedimentation coefficients in excess of 80*S* were estimated by analysis of the sucrose density gradient patterns.

In all cells, the incorporation of the radioactive amino-acids on the ribosomes was associated primarily with polyribosomes, ribosomes corresponding to sedimentation coefficients equal to or in excess of 110*S* (Fig. 1). Thus, in fœtal erythroid cells, as in rabbit reticulocytes[6–8] and human adult reticulocytes[3], protein synthesis proceeds primarily on polyribosomes.

The ribosomes recovered per unit of reticulocytes from the fœtal blood cells was 1·3 mg ± 0·7 mg/10^{10} reticulocytes. This value for ribosome content in reticulocytes is not significantly different from that found in cells of patients with thalassæmia major, sickle-cell anæmia, sickle-cell thalassæmia or acquired hæmolytic anæmia[3]. In fœtal erythroid cells, the proportion of the ribosomes which are polyribosomes was 37 ± 5 per cent, a value also in general agreement with that obtained for adult erythroid cells[3]. These findings suggest that differences between cord blood cells and adult blood cells with respect to the rates of synthesis of hæmoglobin A and hæmoglobin F do not reflect any gross differences in the content of polyribosomes.

Synthesis of hæmoglobins A and F in fœtal erythroid cells. Hæmoglobin A and hæmoglobin F were separated by chromatography of hæmolysates on 'Amberlite *IRC*-50' columns by the method of Allen, Schroeder and Balog[9]. In 20 chromatography runs, the average recovery of hæmoglobin was 97·6 ± 9·3 per cent, and of radioactivity, 90 ± 10·5 per cent. The homogeneity of the

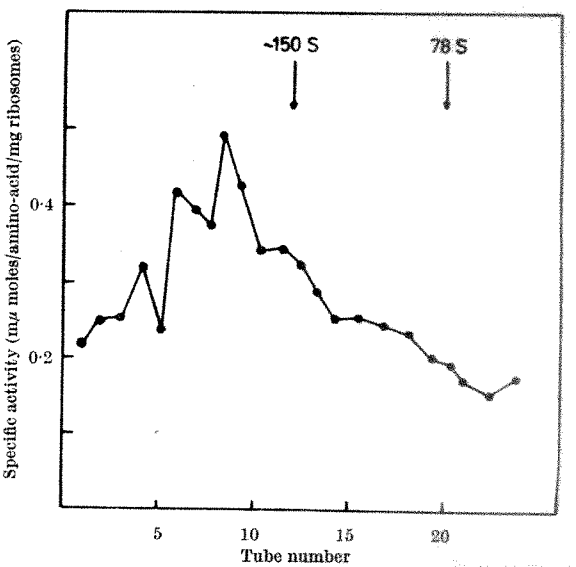

Fig. 1. The pattern of specific activity of ribosomes from fœtal blood cells labelled with ^{14}C-leucine and ^{14}C-valine. The ribosomes were layered on a 5–20 per cent linear sucrose density gradient. The sucrose was in a solution of $1·5 \times 10^{-3}$ M $MgCl_2$, 5×10^{-2} M KCl and 10^{-2} M *tris* HCl, *p*H 7·4. Centrifugation was in an *SW*-39 rotor at 39,000 r.p.m. for 40 min. The fractions of the sucrose gradient were collected and ribosome concentration and radioactivity determined as previously described[3]

fractions recovered from the column was evaluated by electrophoresis on starch gel. Fraction I contained, in addition to hæmoglobin F, non-hæmoglobin protein. The contaminating non-hæmoglobin protein was separated on DEAE cellulose[10] and never exceeded 5 per cent of the total counts incorporated into soluble protein. Fraction II included hæmoglobin A (or S) and A_2. The absence of hæmoglobin F in Fraction II was further documented by the following experiment. Hæmolysates were prepared from cord blood cells which had been labelled with ^{14}C-isoleucine. In human hæmoglobin, isoleucine is present only in the γ-peptide chain. The radioactivity in these hæmolysates was associated only with Fraction I[9] containing hæmoglobin F. There was no detectable ^{14}C-isoleucine in Fraction II containing hæmoglobin A.

The rate of incorporation of leucine and valine into total soluble protein by fœtal blood cells was similar to that observed for cells from patients with sickle-cell anæmia or other hæmolytic anæmias, and was markedly higher than that of cells from subjects with thalassæmia major (compare Table 1, col. 3, and Table 2, col. 4). In fœtal cells, hæmoglobin F accounted for, on the average, 90 per cent of the total hæmoglobin. However, in these cell populations hæmoglobin A was synthesized at a rate which averaged 28 per cent of that of hæmoglobin F. Thus, in each investigation of cord blood, the specific activity of hæmoglobin A was higher than that of hæmoglobin F. A ratio of specific activity of hæmoglobin A to specific activity of hæmoglobin F equal to one would be expected if the concentrations of the two hæmoglobins in cord blood was an accurate index of the capabilities of erythroid cells to form these proteins. The finding that the ratio of specific activities of hæmoglobin A–F is higher than one in cord blood is compatible with the concept that the capacity for hæmoglobin A synthesis increases during late fœtal development while the capacity for hæmoglobin F synthesis declines. At the time of birth, the major portion of the hæmoglobin in peripheral fœtal blood cells was formed at an earlier stage in fœtal development. This would account for the observation that, at birth, the ratio of the rates of synthesis of hæmoglobin A–F exceeds the ratio of the concentrations of hæmoglobins A–F.

Synthesis of hæmoglobins A and F in adult erythroid cells. Blood samples were obtained from patients with thalassæmia major, sickle-thalassæmia, sickle-cell anæmia and acquired hæmolytic anæmia. The rates of synthesis of hæmoglobin A and F by cells from these subjects were determined by methods indicated for the work on fœtal blood cells.

Peripheral erythroid cells from patients either homozygous or heterozygous for the thalassæmia gene, that is, patients with thalassæmia major or sickle-thalassæmia, synthesized protein at a markedly lower rate than cells from subjects with sickle-cell anæmia or acquired hæmolytic anæmia (Table 2). This decreased rate of protein synthesis in the presence of the thalassæmia gene was almost entirely due to a low rate of hæmoglobin A or S formation. The rate of hæmoglobin F synthesis in all adult groups was similar (Table 2).

It is clear from the results presented here that the capacity to form β-chains is not inversely related to the capacity to form γ-chains. Equally high rates of γ-chain or hæmoglobin F formation were observed in thalassæmia, with very low rates of β-chain or hæmoglobin A synthesis, as well as in other hæmolytic anæmias without impaired β-chain synthesis. Further, in fœtal cells, despite high rates of γ-chain formation, the rate of β-chain synthesis exceeded that of the cells from thalassæmic subjects. These data rule strongly against the concept[11] that β-globin synthesis, within a population of erythroid cells, is inversely related, in a specific fashion, to γ-globin synthesis.

If the relative rates of synthesis of hæmoglobins A and F remain constant during the maturation of erythroid cells, and if the survival of these two proteins in the peripheral blood are the same, the ratio of specific activities of hæmoglobin A–F would be equal to one. In studies with cells from subjects with sickle-cell anæmia or acquired hæmolytic anæmia, the average ratio of the specific activity of hæmoglobin A or S to the specific activity of hæmoglobin F was greater than one (Table 2). These results are in agreement with previous observations[4,12,13]. By contrast, in the patients with thalassæmia major or doubly heterozygous for thalassæmia and sickle hæmoglobin genes, the average ratio of the specific activity of hæmoglobin A or S to the specific activity of hæmoglobin F was lower than one (Table 2). Several mechanisms could account for the observed deviations from one in the ratio of specific activities of hæmoglobins A and F. Among these mechanisms are: (*a*) alterations in the relative rates of synthesis of messenger RNA (m-RNA) for different globins; (*b*) different rates of decay in the capacity of erythroid cells to form the different globins as these cells

*Hæmoglobin A and F concentrations are expressed as the proportion of the total hæmoglobin as determined by column chromatography according to the method of Allen *et al.*[9].
†Average value for 5 studies. *S.E.*, standard error.
‡Total protein synthesis is expressed as the mμmoles of leucine plus valine incorporated into protein in 80 min/mg of ribosomes recovered. The rate of incorporation is referred to ribosome content since synthetic activity of the peripheral red blood cells is more directly related to ribosome content than either the proportion of cells which are reticulocytes or the total number of erythroid cells[17]. The amount of hæmoglobin F and A synthesized was determined by the counts incorporated into the proteins separated by column chromatography on 'Amberlite *IRC*-50'[9]. The non-hæmoglobin proteins were separated by DEAE chromatography[10]. Differences between the sum of columns 4 and 5 and column 3 represent non-hæmoglobin proteins.

mature; (c) different survival times for hæmoglobin A and F in peripheral blood.

The finding that in fœtal cells the specific activity of A–F exceeds one is most probably explained, as has been previously suggested[11], by a conversion from synthesis of m-RNA for γ-chains to that of m-RNA for β-chains during late fœtal life. The increase in synthesis of hæmoglobin F in cells from subjects with certain hæmolytic anæmias may reflect a similar mechanism, namely, regulation at the level of DNA with an increase in the synthesis of m-RNA for γ-globin[11,14]. However, the present findings with cells from adult subjects can be explained by mechanisms regulating the amounts of hæmoglobins A and F formed which involve sites of control other than at the level of DNA.

In an earlier investigation[15] it was demonstrated that as erythroid cells mature, their capacity to synthesize hæmoglobin decreases, in association with a decay in polyribosome content. It is possible that the templates for different globins decay at different rates. It was previously suggested that the increased level of hæmoglobin F formation in hæmolytic anæmias might result from a decrease in the rate of decay in the capacity of erythroid cells to synthesize this protein as these cells mature under conditions of erythropoietic stress[4]. Such a change in the capacity to form hæmoglobin F could result from the fact that erythropoietic stress is associated with an altered pattern of maturation of erythroid cells, characterized by circulating reticulocytes being derived from early erythroid forms[16,17].

The observation that in reticulocytes from sickle-cell anæmia or acquired hæmolytic anæmia the ratio of the specific activities of hæmoglobin A–F exceeds one could result from a faster rate of decay in the capacity of erythroid cells to synthesize γ-globin (hæmoglobin F) than to synthesize β-globin (hæmoglobin A). A shorter survival of hæmoglobin A than F in the peripheral circulation could also result in a ratio of specific activities of hæmoglobin A–F of greater than one. Investigations of hæmoglobin turn-over in sickle-cell anæmia[18] and thalassæmia[19] demonstrated that hæmoglobin A or S survival is shorter than that of hæmoglobin F. However, a shorter survival of hæmoglobin A or S than F is not an adequate explanation of the findings in patients with the thalassæmia gene. In this work, the specific activity of hæmoglobin A was lower than the specific activity of hæmoglobin F. These findings can be explained by the hypothesis that the amount of a particular globin synthesized by erythroid cells reflects, in part, the relative rate of decay in the template for this protein as the cells mature. The presence of a thalassæmia gene may lead to a selective acceleration in the rate of decay in the template for β-globin.

The hypothesis that different rates of decay of globin templates is a factor controlling the rates of hæmoglobin A and F synthesis predicts that in normal subjects the capacity to form hæmoglobin F should decrease more rapidly than the capacity to form hæmoglobin A. According to this prediction it would be expected that in normal bone marrow the ratio of synthesis of hæmoglobin A–F would be less than the ratio of the concentration A–F in peripheral blood. In bone marrow cells of normal subjects, the ratio of the rate of synthesis of hæmoglobin A–F is less than the ratio of the concentration of A–F in peripheral blood[20,21].

The work recorded here provides evidence that in patients heterozygous or homozygous for the thalassæmia gene there is a marked selective decrease in hæmoglobin A formation. The defect in hæmoglobin A ($\alpha_2\beta_2$) synthesis in this group of patients appears to reflect a primary failure in β-globin synthesis. This is suggested by the finding that the rate of synthesis of hæmoglobin F ($\alpha_2\gamma_2$) is similar in cells from patients with a variety of hæmolytic anæmias with or without the thalassæmia gene. The capacity for hæmoglobin F synthesis in erythroid cells from these subjects is only a fraction of that of fœtal erythroid cells at birth. It is suggested that regulation at the level of the rate of decay in the templates for different globins may be important in the control of hæmoglobin A and F formation in erythroid cells of adult subjects. The conversion from hæmoglobin F to A synthesis in late fœtal life probably involves a different mechanism, such as control of the rates of synthesis of the different m-RNA's.

DEMONSTRATION OF SYNGENEIC PREFERENCE *IN VITRO*

By K. E. HELLSTRÖM, I. HELLSTRÖM and G. HAUGHTON

Institute for Tumour Biology, Karolinska Institutet Medical School, Stockholm

As a rule, tumours of homozygous origin take more frequently and after a shorter latency period when small cell numbers (usually below 10^6) are transplanted to syngeneic recipients than to various semi-isologous F_1 hybrid hosts[1–3]. This phenomenon has been termed 'syngeneic preference'[4]. It can be demonstrated with sarcomas[3] and carcinomas[3] as well as with lymphomas[1,2]. Probably analogous findings have been made with hæmatopoietic cells, transplanted to lethally irradiated hosts[5,6].

In an attempt to examine the mechanism of syngeneic preference, iso-antigenic variant sublines were used, isolated from a mouse lymphoma of *A/Sn* × *A.SW* F_1 hybrid origin by selective passage in one of the parental strains[1]. The variants were selectively compatible with the parental strain of selection and had irreversibly lost the

H-2 isoantigens specifically derived from the opposite parental strain[7]. When compared with the *A* × *A.SW* F_1 tumour line, from which they had been selected, in *A* × *A.SW* F_1 recipients, the variants grew more slowly[1]. However, in their compatible parental strain they grew faster than in the hybrid, and behaved in the same way as did the unselected line in the hybrids. The differential behaviour of the variants in homozygous versus F_1 hybrid animals was maintained when the mice had been pre-irradiated with 450–500 r. in order to decrease their immunological reactivity[1] and it did not increase after pretreating the mice with sub-limit doses of the variant cells or normal cells of the strain of variant selection[8]. Since the *A* and *A.SW* strains are co-isogenic resistant lines differing mainly at the *H*-2 locus, the decreased growth capacity of the variant cells in the F_1 hybrids could be tentatively attributed to their loss of *H*-2 antigens resulting in a difference between graft and host on their inoculation into F_1 hybrids.

Among conceivable mechanisms of syngeneic preference, one possibility is that exposure of the cells to foreign histocompatibility antigens may have a cytopathogenic or growth inhibitory effect[1]. This article describes experiments designed to test this possibility. Mouse tumour cells cultured *in vitro* were exposed to homogenates prepared from a foreign mouse strain or to antigenic extracts, prepared according to the technique of Haughton[9], similar to that described earlier by Davies[10].

Two methylcholanthrene - induced sarcomas were used: *MC57S* of *C57BL* origin, and *MACD* of *A/Sn* × *A.CA* F_1 hybrid origin. Both tumour lines had been maintained by serial transplantation in syngeneic hosts for 20–30 and 45–52 passages, respectively. Tissue cultures were prepared by methods described previously[11], which involved addition of penicillin (100 I.U./ml.) and streptomycin (100 μg/ml.) to the medium. Trypsinized cell suspensions were made from transplanted tumours to start primary cultures. Secondary cultures were made from these 2–4 days afterwards, when roller tubes were inoculated with $1{\cdot}5 \times 10^6$ cells in 1 ml. of medium, consisting of 10 per cent (v/v) heat-inactivated calf serum in Earle's salt solution, to which 0·5 per cent (w/v) lactalbumin hydrolysate had been added. When the cells had formed layers, 48 h after explantation, the medium was replaced by 1 ml. of a mixture of 2 per cent (v/v) heat-inactivated horse serum in Parker 199 solution, to which homogenates or antigenic extracts were added. The tubes were placed in a drum, rotated at a speed of 4 r.p.m. As a rule, the number of trypan-blue unstained cells in each tube was determined two days later for 2–6 tubes of each series, after the cells had been detached from the glass by versene treatment. The tubes were given code numbers, unknown to the person performing the counting.

The homogenates were prepared under sterile conditions from the spleens of *C57BL*, *A/Sn* or *A/Sn* × *C57BL* F_1 hybrid mice weighing about 20 g. Three spleens of each type were homogenized into 3 ml. of Earle's salt solution. In order to kill possibly surviving cells, the homogenates were frozen in dry ice and thawed four times, after which they were kept at +4° C and used within 2 weeks. The homogenates were added in 0·1-ml. volumes to the medium of the cultures, either undiluted or after 1 : 2, 1 : 3 or 1 : 10 dilution (Fig. 1). The antigenic extracts were prepared according to the technique of Haughton[9]. They contained 33, 25–50 and 30 antigenic units per mg, as defined by Haughton[9]. Extracts were made from the strain *A/Sn* carcinoma *TA*3, from *C57BL* spleen cells and from lymphoma *EL*4 of *C57BL* origin. Lyophilized antigenic extracts were sterilized by ultraviolet irradiation, and suspensions of 75-mg lyophilized antigenic extract were made in 8 ml. of Earle's salt solution, and were added in 0·1-ml. volumes to the cultures, either undiluted or after 1 : 2 or 1 : 10 dilution.

The results are presented in Figs. 1 and 2. Fig. 1 shows that cultures exposed to allogeneic homogenates contained regularly fewer trypan-blue unstained cells than control groups, exposed to syngeneic homogenates. Since all preparations were tested on *MACD* and *MC75S* cells as well, a non-specific toxic effect could not explain the results obtained. The two tumours examined were sensitive to about the same degree. In a few experiments (not included in Fig. 1) *MACD* and *MC57S* cultures were exposed to homogenates prepared from *A* × *C57BL* F_1 hybrids in a similar way as from *A* or *C57BL*. Cultures treated with these homogenates (allogeneic to both tumours) contained regularly fewer cells than cultures treated with syngeneic homogenates.

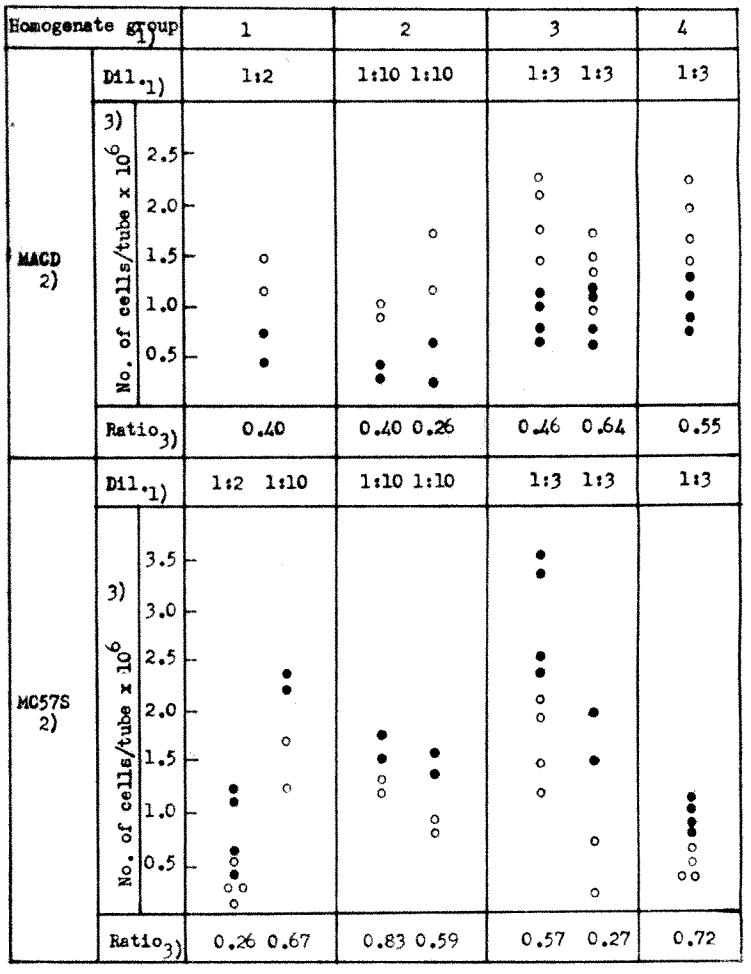

Fig. 1. Effect of allogeneic and syngeneic homogenates on cultured tumour cells. (1) Four different groups of homogenate were used, each group consisting of one sample of *A/Sn* and one sample of *C57BL* homogenate. The spleens of 3 *A/Sn* and 3 *C57BL* mice were homogenized into 3 ml. Earle's salt solution, after which the homogenates were diluted 1 : 2, 1 : 3 or 1 : 10. (2) *MACD* and *MC57S* are both methylcholanthrene-induced fibrosarcomas, of *A* × *A.CA* F_1 and *C57BL* origin, respectively. (3) The number of cells was determined two days after addition of the homogenates to the cultures, that is, 4 days after explantation. The cells were detached from the glass surfaces by versene. The number of trypan-blue unstained cells in millions per tube is shown for each tube counted. ○, Tube treated with *A/Sn* homogenate, ●, Tube treated with *C57BL* homogenate. The ratios $\frac{\text{cell No. with allogeneic homogenate}}{\text{cell No. with syngeneic homogenate}}$ were calculated

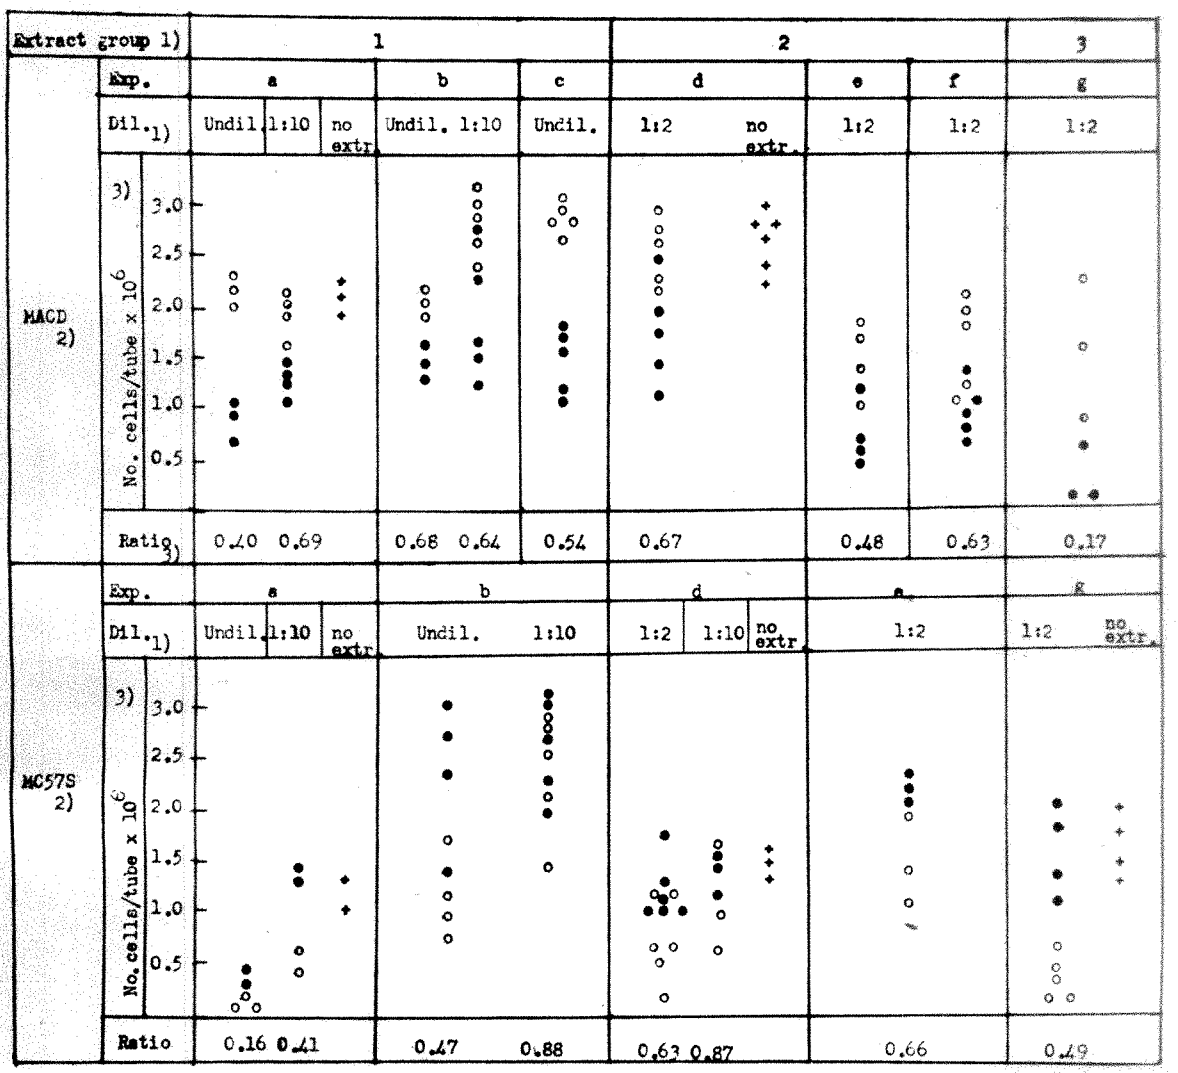

Fig. 2. Effect of antigenic extracts containing foreign *H*-2 isoantigens on cultured tumour cells. (1) Three different groups of antigenic extract were used, all containing one extract of *A/Sn* origin (from tumour *TA*3) and one extract of *C57BL* origin. In groups 1 and 3 the *C57BL* extract was prepared from spleen cells (preparations made on two different occasions), and in group 2 from ascites lymphoma *EL*4 of *C57BL* origin. The *TA*3 extract contained 33 antigenic units/mg, the *C57BL* spleen extracts 25–50 units/mg and the *EL*4 extract 30 units/mg, as defined by Haughton[9]. Cultures received 0·94 mg undiluted extract/tube. (2) See footnote 2 to Fig. 1. (3) See footnote 3 to Fig. 1. ○, Tube treated with *A/Sn* antigenic extract. ●, Tube treated with *C57BL* extract; +, no antigenic extract added

Confirmatory results were obtained with the antigenic extracts (Fig. 2): cultures exposed to allogeneic extracts contained fewer cells than cultures exposed to syngeneic extracts. There was no difference in the number of living cells between groups which received syngeneic extracts and those which did not receive any extract except in one experiment with *MC57S*, where cultures receiving undiluted *C57BL* extract contained fewer cells than untreated controls or cultures receiving *C57BL* extract diluted 1 : 10.

The findings presented in Figs. 1 and 2 concern cell numbers two days after addition of homogenate or antigenic extract. This interval was chosen for the majority of experiments, since cell layers often became detached from the glass surfaces at later intervals in untreated controls as well. A clear-cut difference was, however, already found between the cell numbers in experimental and control groups 36 h after the addition of the antigenic material and was maintained for 6–8 days, whereafter the majority of cells became detached from the glass surfaces.

Although it seems most likely that the inhibitory effect found with allogeneic homogenates and antigenic extracts is due to their content of foreign isoantigens, it remains to be definitely proved that the antigenicity, *per se*, is involved. Experiments performed with extracts and tumours from co-isogenic-resistant mouse strains, known to differ only at locus *H*-2, may help to elucidate this point. Furthermore, it may be worth attempting to neutralize the inhibitory effect of allogeneic antigenic extracts by specific isoantibodies.

It follows from the findings described that syngeneic preference, detected by transplantation of tumour cells into mice, is probably due to the exposure of the grafted cells to the foreign isoantigens of the host and not, for example, to recessive histocompatibility factors.

It may be postulated that syngeneic preference has a homeostatic function helping to maintain the genetic equipment of the somatic cells constant by eliminating cells which lack certain isoantigens (as a result of somatic mutation, for example). The present findings make it possible to approach this question by studying the interaction between cells and foreign isoantigens under well-defined conditions and to determine the effects of various amounts and various types of antigen added ('strong' and 'weak' histocompatibility antigens, tumour specific antigens). It will also be possible to investigate whether differences in sensitivity to the foreign isoantigens exist between dividing and non-dividing cells and whether the cellular sensitivity can be modified by various means.

This investigation also suggests that it may be possible to select *in vitro* for cells that have gained certain antigens, for example, by fusion[12], from populations where the majority of cells lack the same antigen. Such selection has

been successfully performed *in vivo* in model experiments, involving artificial mixtures of tumour cells of different genotypes[13]. Selection *in vitro* is an advantage since cells which do not grow progressively *in vivo* can also be studied.

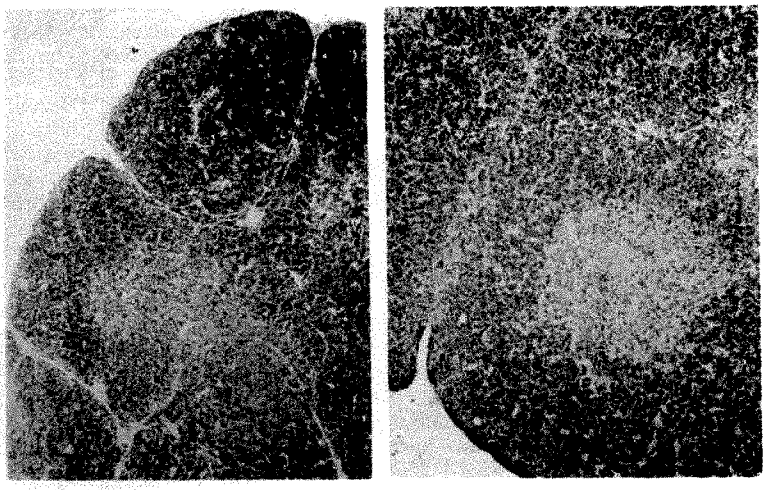
FAILURE TO RECONSTITUTE NEONATALLY THYMECTOMIZED MICE BY 'SUCCESSFUL' RAT THYMUS TRANSPLANTATION

By Dr. EDMOND J. YUNIS*, Prof. CARLOS MARTINEZ† and Prof. ROBERT A. GOOD‡

Departments of Physiology and Laboratory Medicine and the Pediatric Research Laboratories of the Variety Club Heart Hospital, University of Minnesota, Minneapolis

THE immunological deficit and growth failure of neonatally thymectomized mice may be prevented by several procedures performed within the first three weeks of life: grafting of syngeneic or allogeneic thymus[1,2]; injection of adult syngeneic spleen or lymph node cells[2–4]; injection of new-born or adult allogeneic or syngeneic thymus cells[5,6], and intraperitoneal implantation of 'Millipore' chambers containing thymic tissue[7,8]. This last group of investigations confirmed the existence of a subcellular, humoral, and presumably hormonal, factor in the mouse thymus which permits development of the peripheral lymphoid tissues and immunological competence. Such a factor had been suggested by the findings of Miller[1] and Dalmasso *et al.*[2] that the lymphoid cells of the spleens of neonatally thymectomized mice grafted with allogeneic thymus were largely of host origin, as determined by the *T6* marker[1] and histocompatibility characteristics[2]. Significant restoration of lymphoid tissue structure and immunological function in neonatally thymectomized rats by thymus tissue contained in 'Millipore' membranes has also been reported recently[9].



The work to be reported here was designed to ascertain whether xenogeneic thymus grafts can be successfully accomplished and prevent the growth failure and immunological deficiency of neonatally thymectomized mice. These experiments stemmed directly from the preliminary observations of Dalmasso *et al.*[2] that rat thymus grafts may take in neonatally thymectomized mice but do not seem to reconstitute the capacity of the spleen cells of the animals to exercise a graft versus host reaction.

Mice of the *C3H* strain of both sexes were thymectomized within 24 h after birth by the method routinely performed in this laboratory[10]. One group was not treated further; three others received thymus grafts, either one lobe of thymus from new-born albino rats of the Holtzman line, an entire new-born syngeneic thymus, or an entire new-born hemi-allogeneic $(A \times C3H)F_1$ thymus. All grafts were cut part way through in two or three places and placed into the subcutaneous tissue of the back. Eight rat-thymus-grafted mice were killed 5, 10, 15 and 20 days after grafting for microscopic evaluation of the graft. Lymphocyte counts were done at 4–5 weeks of age for animals in all the groups. At 5–6 weeks of age, several rat-thymus-grafted and syngeneic-thymus-grafted mice were killed, the subcutaneous tissues of the back examined both grossly and microscopically for presence of thymus graft, and the capacity of their spleen cells to exercise graft versus host reactions in F_1 hybrid recipients was compared with that of intact *C3H* mice and ungrafted neonatally thymectomized animals. Two additional rat-thymus-grafted mice were splenectomized at 40 days of age, the thymus grafts removed, and the animals followed until death. The assay of graft versus host reactivity of Simonsen was used[11]: it involves administration of 30 million spleen cells to 8-day-old mice hybrid to the host histocompatibility characteristic. Splenomegaly is assessed 8 days later by determination of the relative spleen weight (mg/100 g body-wt.) and finally calculation of the spleen index, the mean relative spleen weight of the experimental group divided by the mean relative spleen weight of hybrids of the same litters receiving syngeneic cells (negative controls). An index of 1·30 or more is, in these laboratories, considered indicative of significant graft versus host activity. The remaining animals were weighed every third day. All mice dying of wasting disease, killed for the Simonsen assays, or surviving at 120 days were

Fig. 1. Portion of a rat-thymus graft removed from a neonatally thymectomized *C3H* mouse five days after placement. There is some depletion of the cellular elements (compare with Fig. 2), although not so much as has been observed in mouse thymus grafts in some studies

A *B*

Fig. 2. Comparison of a rat thymus graft, removed from a neonatally thymectomized *C3H* mouse 24 days after placement (*A*), with a normal rat thymus of the same age (*B*). The two show comparable cellularity, and the essential structure of the normal thymus seems to be present in the graft

autopsied. The retrosternal areas of all neonatally thymectomized animals were examined for thymic remnants under the dissecting microscope, and the soft tissues of the mediastinum sectioned for microscopic study. Mice found to be incompletely thymectomized are not included in this report. In all thymus-grafted animals the graft found in the subcutaneous tissue of the back was examined grossly and microscopically.

These experiments confirm the earlier preliminary finding that neonatally thymectomized mice regularly accept rat thymus grafts, just as they sometimes accept rat skin[3]. The successful grafts included all eight of the animals killed 5–20 days after grafting, four of the five splenectomized or killed at 5–6 weeks for graft versus host assays, and eight of the 12 dying of wasting disease. At 5 and 10 days, the grafts showed some necrosis and some loss of lymphoid elements or both (Fig. 1), similar to that described by others[12,13] in sequential investigations of thymus grafts. After 10 days and up to 39 days, the vascularized rat thymus grafts had epithelium, Hassall's corpuscles, approximately normal numbers of lymphoid elements, and even organization into cortex and medulla (Fig. 2). Morphologically they were very similar in appearance to the successful syngeneic and hemi-allogeneic thymus grafts examined. Chromosome analyses of the grafts were not carried out, and the relative proportion of rat and mouse lymphocytes in the repopulated grafts was not determined.

Despite the apparent success of the rat thymus grafts, early mortality was as characteristic of neonatally thymectomized mice receiving thymus grafts from new-born rats as it was of untreated neonatally thymectomized mice. These results contrast with the high percentage of survival at 120 days of the neonatally thymectomized mice grafted with new-born syngeneic or hemi-allogeneic thymus (Table 1). Fig. 3 shows the growth curve, age at death, and graft status of each of the rat-thymus-grafted animals. Despite the presence of the well-vascularized, normal-appearing rat thymus graft in most of these animals, they all developed weight loss, diarrhœa, hunched appearance, and ruffled fur, the typical post-thymectomy wasting syndrome, and succumbed between 29 and 66 days of life. For comparison, mean body-weights of neonatally thymectomized mice are given in the figure, as are comparable data for neonatally thymectomized mice receiving hemi-allogeneic thymus grafts. Fig. 4 shows that the transplantation of new-born rat thymus did not restore the numbers of circulating lymphocytes of neonatally thymectomized mice toward normal. By contrast, studies in our laboratories[14] and elsewhere[3] have shown restoration of circulating lymphocyte levels as a regular consequence of early transplants of syngeneic or allogeneic thymus.

Recorded in Table 2 are investigations indicating that ungrafted or rat-thymus-grafted neonatally thymectomized mice do not develop immunological competence, as assessed by the graft versus host reaction of Simonsen. By contrast, intact mice or syngeneic thymus-grafted neonatally thymectomized animals had spleen cells with

Table 1. Effect of Thymus Grafts from New-born Mice and Rats on the Longevity of Neonatally Thymectomized *C3H* Mice

Thymus graft donor	Survival rate at 120 days
None	0/24*
New-born *C3H* mice	7/8
New-born $(A \times C3H)F_1$ hybrids	5/6
New-born rat	0/12*

* All animals in these groups had died before 85 days of age.

Table 2. Graft-versus-host Assay of Spleen Cells from Neonatally Thymectomized Mice receiving Syngeneic and Xenogeneic Thymus Grafts

Recipient	Thymus graft donor	Test litters	Spleen indices*
Intact *C3H*	None	$(C3H \times DBA/2)F_1$	1·85, 2·40, 3·40, 3·80, 4·20
Neonatally thymectomized *C3H*	New-born *C3H*	$(C3H \times DBA/2)F_1$	1·14, 1·51, 2·28, 2·86, 3·20
Neonatally thymectomized *C3H*	New-born rat	$(C3H \times DBA/2)F_1$	0·85, 0·89, 1·03, 1·14, 1·28
Neonatally thymectomized *C3H*	None	$(C3H \times DBA/2)F_1$	0·82, 0·98, 0·99, 1·03, 1·03, 1·09, 1·15, 1·17, 1·32

* The spleen index is calculated by dividing the relative spleen weight (mg/100 g/body wt.) of the test animals by the mean relative spleen weight of the negative controls.

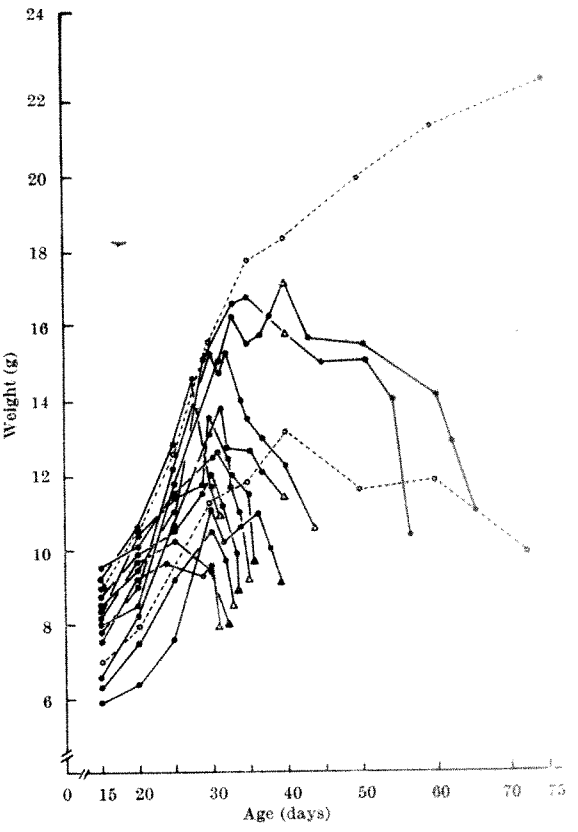

Fig. 3. Weight curves of neonatally thymectomized *C3H* mice bearing rat thymus grafts (solid lines): an open triangle indicates a vascularized thymus graft at autopsy or biopsy, a solid triangle a rejected graft. The lower broken line represents the mean weights of neonatally thymectomized mice not receiving grafts; the upper broken line represents the mean weights of neonatally thymectomized mice receiving hemi-allogeneic $(A \times C3H)F_1$ grafts. None of the rat-thymus-grafted mice escaped the wasting syndrome

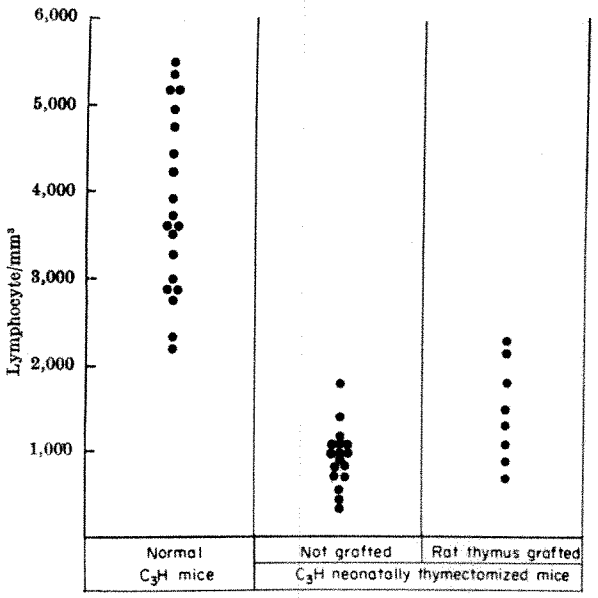

Fig. 4. Lymphocyte counts, at 4–5 weeks of age, of rat-thymus-grafted neonatally thymectomized *C3H* mice compared with those of normal animals and untreated neonatally thymectomized mice of the same strain

vigorous capacity to produce splenomegaly after intraperitoneal injection into appropriate 8-day-old hybrid mice.

The lack of effect of the 'successful' rat thymus grafts on the wasting disease, lymphoid tissue depletion, and immunological deficit of neonatally thymectomized mice suggests that the thymic hormone(s) may be proteins and may operate through mechanisms demanding species specificity. There is, however, a precedent for a thymic effect on lymphopoiesis across species barriers in the finding that extracts of human thymus produce a lymphocytosis in baby mice[15].

It is possible, of course, that quantitative factors are involved in our results, and that the effect of the rat thymus graft in these animals was below the sensitivity of the assay technique used. In the present experiments the rat thymus grafts were at least as large and, from a morphological point of view, as successful as the mouse thymus grafts, but the possibility exists that a larger number of rat thymus grafts, or even rat thymus grafts in different locations, might provide evidence of reconstitution. It may also be that immunological processes insufficient to result in morphological rejection of the graft could inhibit production of a hormonal factor by the rat thymus stroma in the mouse.

Whatever the explanation, our observations indicate clearly that rat thymus grafts can regularly be apparently successful in neonatally thymectomized mice and yet fail to give evidence of significant physiological or immunological effects on neonatally thymectomized mice.

We thank Mr. K. Sjodin for performing the thymectomies in the neonatal mice.

GENERALIZED HOVERING-FLIGHT CORRELATION FOR INSECTS

By Prof. G. HOUGHTON
School of Engineering and Mines, University of Pittsburgh, Pennsylvania

It has been proposed[1–4] that the three major forces on a fluttering wing-body system are gravitation, air acceleration and aerodynamic lift such that the resultant produces body oscillation superposed on continuous directional motion. Under hovering conditions digitally computed flight trajectories have shown[3,4] that, for four insects and a bird, the aerodynamic lift arising from wing flutter represents on average 25 per cent of the force needed to cancel gravity, the remaining 75 per cent being generated by air acceleration resulting from the non-uniform wing motion (wave-form); while the aerodynamic lift contribution is not small, it is by no means enough to balance gravity, an observation that explains why most of the earlier theories based on aerodynamic lift considerations alone were inadequate to explain the phenomenon of insect and bird flight. Furthermore, the average experimental accuracy of most insect flight data[5–7] of value in the context of the present analysis is of the order of ± 25 per cent, as estimated by Weis-Fogh and Jensen[8], the aerodynamic lift contribution being, therefore, of the same magnitude as the experimental error, so that for purposes of simplicity it would seem feasible, within this error, to approximate the body velocity $u(t)$ by only two terms, one due to gravity, $-gt$, and the other due to non-uniform air acceleration as follows:

$$u(t) \approx -gt - (\gamma\varphi/M)\int_0^t P_{\tau\tau}(k, \omega\tau + \varepsilon)\cos[\varphi P(k, \omega\tau)]\mathrm{d}\tau \quad (1)$$

where

$$\gamma = 8\rho(1 + \varkappa)\varphi S m_2 \quad (2)$$

$$m_2 = (1/S)\int_0^L r^2 W(r)\mathrm{d}r \quad (3)$$

$$S = \int_0^L W(r)\mathrm{d}r \quad (4)$$

The periodic wave-form $P(k, \omega\tau)$ of overall angular frequency, ω, can be simulated by two half sinusoids of different frequencies either joined at their bases (S-wave-form) or at their peaks (Z-wave-form), the ratio of the highest to the lowest frequency being the duration factor k—because of inertial and viscous effects the air acceleration force may lag behind the wing motion by a phase angle ε as shown in equation (1). In this connexion digital computations have shown[4] that the integral air acceleration term of equation (1) is the sum of two parts, one of which increases linearly with time and can be represented by $(\mu\gamma\varphi/M)(\omega_U^2 - \omega_D^2)t$, the remaining part being a smooth oscillation simulated by $-(\gamma\varphi\omega^2/M)\int_0^t \cos(\omega\tau + \varepsilon)$

$\cos(\varphi \cos \omega\tau)d\tau$ so that equation (1) can be replaced by the following functional approximation:

$$u(t) \approx [-g + (\mu\gamma\varphi/M)(\omega_U^2 - \omega_D^2)]t - (\gamma\varphi\omega^2/M)\int_0^t \cos(\omega\tau + \varepsilon)\cos(\varphi\cos\omega\tau)d\tau \quad (5)$$

where μ is an empirical constant, the value of which must be adjusted to fit the particular air acceleration term under consideration, it being possible to obtain fits within 5 per cent using just the one constant.

According to relation (5) the effect of gravity can be nullified by setting the coefficient of t equal to zero, while motion away from Earth can be obtained by making the same coefficient positive, so that using expression (2) for the acceleration factor γ and remembering that $\omega_U = (k + 1)\omega/2$ and $\omega_D = (k + 1)\omega/2k$, these being the upstroke and downstroke frequencies respectively with $k = \omega_U/\omega_D$, then the criterion for levitation or antigravity motion is:

$$-Mg + 8\rho(1 + k)\mu\omega^2\varphi^2 KSm_2 \geqslant 0 \quad (6)$$

where $K(k) = (k - 1)(k + 1)^3/4k^2$; $k > 1$

In criterion (6) $\varkappa$ is the coefficient of virtual mass for the air displaced by the wings when acting as paddles, the digitally computed flight trajectories for a bird, locust, moth, fly and bee having shown[3] that $1 + \varkappa = 2{\cdot}3 \pm 0{\cdot}7$ with a Z-wave-form at $\varepsilon = -3\pi/4$—similar calculations[4] under the same hovering conditions have revealed that the dimensionless constant μ must have values of 0·125, 0·056, 0·099, 0·047 and 0·096 respectively to approximate the acceleration term for the same bird, locust, moth, fly and bee, the overall average being $\mu = 0{\cdot}085 \pm 0{\cdot}026$, no trend with either animal size or wing frequency being detectable for either $\varkappa$ or μ. The average deviations of $\pm 0{\cdot}7$ and $\pm 0{\cdot}026$ respectively for the dimensionless coefficients $1 + \varkappa$ and μ correspond to variations of ± 30 per cent from the mean, this average deviation being the same magnitude as the average experimental error (± 25 per cent) in measuring the wing frequency ω and the angular half amplitude φ—that the use of mean values for $\varkappa$ and μ is quite reasonable is justified by the final correlation in Fig. 1 of the extensive insect data of Table 1, the theoretical line based on criterion (6) roughly bisecting the experimental points, thereby lending statistical significance to the use of fixed values of $\varkappa$ and μ. Before inequality (6) can be applied to the quantitative behaviour of insects and birds, it is first necessary to generalize, if possible, the position of the second wing moment m_2, which takes into consideration possible variations in wing geometry and size—since previous workers did not foresee any need for taking into account wing shape, except qualitatively, such geometrical data are not available in the literature.

However, I have made geometric measurements on the wings of a variety of insects including bees, wasps, flies, flying beetles, moths and butterflies and have found the second moment defined by relation (3) to be remarkably consistent in that it can be located with respect to the overall length of the wing L by the simple relationship $m_2 = (0{\cdot}36 \pm 0{\cdot}03)L^2$, the deviation being the average. While not used in the present analysis, it is also interesting to note that the first wing moment, $m_1 = (1/S)\int_0^L rW(r)dr$, which locates the centre of mass or centroid of the wing, can be similarly generalized by the relation $m_1 = (0{\cdot}54 \pm 0{\cdot}03)L$. The consistency with which m_1 and m_2 may be simply predicted for a wide range of insects indicates that the first and second wing moments are either inherently insensitive parameters or that a process of evolution has standardized them at aerodynamically optimum values, regardless of wing size and shape. The procedure for

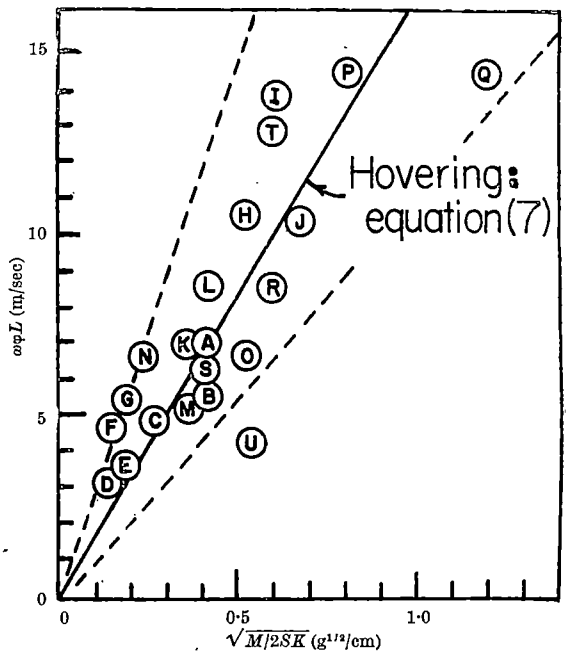

Fig. 1. Correlation of the insect results from Table 1 by hovering (equation 7). The broken lines define the experimental error and the letters denote particular insects in Table 1

* Angular amplitude adopted by Osborne (ref. 6). † Duration factor indicated by computer calculations.

determining the wing geometry was to trace carefully the outline of the wing on transparent graph paper so that, after drawing a straight line from the root of the wing to the tip, corresponding values of the chord length $W(r)$ as a function of distance r from the root could be taken and graphically integrated to obtain m_1 and m_2; in effect such a procedure transforms the asymmetric wings found in Nature into their axially symmetric equivalents of the same area S as defined by expression (4). Thus, using the generalizations that $\varkappa = 1{\cdot}3$, $\mu = 0{\cdot}085$ and $m_2 = 0{\cdot}36L^2$, inequality (6) is readily transformed into the following hovering-flight criterion:

$$\omega\varphi \geqslant \omega_c\varphi_c = \frac{1{\cdot}33}{L}\sqrt{\frac{Mg}{K\rho S}} \qquad (7)$$

According to criterion (7), if the product of wing frequency and angular half amplitude exceeds a certain critical value $\omega_c\varphi_c$ then the fluttering wing-body system will rise against gravity, while $\omega\varphi = \omega_c\varphi_c$ corresponds to hovering and $\omega\varphi < \omega_c\varphi_c$ to fall.

Criterion (7) predicts that, as the wing loading (mass per unit area, $M/2S$) increases, the frequency ω must in general increase, since there are limitations on increases in the stroke half-angle φ. Table 1 summarizes the insect data of Magnan[5] as supplemented by Osborne[6] and Sotavalta[7], and it is interesting to note that the insect orders can be roughly arranged in a sequence of ascending wing loadings with corresponding ascending wing frequencies as follows: Lepidoptera (moths and butterflies) $\lesssim$ Neuroptera (lacewings and snake flies) $\lesssim$ Diptera (flies and mosquitoes) $\lesssim$ Hymenoptera (bees and wasps)—the Coleoptera (flying beetles) appear to be an exception presumably because of the high stroke angles and because the wing loadings of Table 1 and Fig. 1 do not include the area of the stationary wing covers or elytra which could contribute somewhat to the lift by being immersed in the velocity field created by the fluttering membranous wings, the area of the latter only being used as the basis for the present calculations. Although not shown in Table 1 because the duration factors were not available, most of the Lepidoptera reported by Osborne[6] exhibited wing frequencies of 10–12 c/s with correspondingly low wing loadings of 0·007–0·013 g/cm^2.

Another interesting observation from critical relation (7) is that, as the air density ρ decreases with increasing altitude, the insect or bird should increase either its flapping frequency or stroke angle to attain the same gravitational stability. The results of Chadwick[9–11] and Williams[9] for insects show that, although ω and φ in fact increase as ρ decreases, a rigorous analysis of density effects is obscured by small compensations in numerous other parameters. Furthermore, since the single wing area S will be a function of the wing length L, then criterion (7) predicts that the wing frequency is proportional to $L^{-3/2}$ if the width parameter for the wings is held constant and proportional to L^{-1} if the total wing surface is invariant. Previous models for insect flight behaviour based on considerations of wind forces or wing mass indicate that the beat frequency may vary as $L^{-1/2}$ (refs. 12 and 13), $L^{-2/3}$ (ref. 7) and L^{-1} (refs. 14 and 15). The inverse relationship between wing frequency and wing length is supported by the careful experimentation of Weis-Fogh[16] on the swarming desert locust—he found that ω was proportional to $L^{-2/3}$, it being pointed out by Weis-Fogh and Jensen[8] that the somewhat crude methods of estimating the length parameter do not permit a distinction to be made between powers of L in the range $-0{\cdot}5$ to $-1{\cdot}0$. In the experiments of Weis-Fogh and Jensen, L was taken as the geometric average of the fore-wing length and the length of the hind femur.

In order to test the validity of criterion (7) for the insect data of Magnan[5], Osborne[6] and Sotavalta[7] in Table 1, Fig. 1 has been constructed using the wing-tip velocity $\omega\varphi L$ as the ordinate and the group $\sqrt{M/2SK}$ as the abscissa. The 'hovering line' that divides the field into rising and falling regions corresponds to the critical hovering relation $\omega\varphi L = \omega_c\varphi_c L = \sqrt{1{\cdot}8Mg/K\rho S}$ with $\rho = 1{\cdot}25 \times 10^{-3}g/$ cm^3 and $g = 981$ cm/sec^2. Clearly the hovering line passes symmetrically through the data, the scatter on either side being probably due to experimental variations of ω, φ and k, since, according to Weis-Fogh and Jensen[8], the experimental error in ω and φ is on average about ± 25 per cent for the data of Magnan[5]—the possible effects of such experimental errors are shown by the broken lines in Fig. 1 which provide an error band for the hovering line. The more recent frequency data of Sotavalta deviate from the earlier measurements of Magnan by on average 22 per cent, the largest deviation being 80 per cent, so that whenever two frequencies are available in Table 1 the mean has been used in constructing Fig. 1. Furthermore, the duration factor k is only reported to the nearest $\pm 0{\cdot}1$, so that when all possible causes of deviations are taken into consideration it would seem that the correlation predicts the values and trends reasonably well, particularly for a natural phenomenon of this kind. There is also some reason to believe that the k factors of Magnan[5] might have an experimental error in excess of $\pm 0{\cdot}1$ since attempts to simulate the vertical flight of the stag beetle (*Lucanus cervus*) on the digital computer indicate that k should be at least 1·4 and not 1·0 as reported by Osborne[6]; the value of 1·4 would also agree better with the values of 1·3–1·5 reported for the other flying beetles in Table 1. That the deviations and scatter of the data in Fig. 1 are probably due mostly to random experimental errors is also indicated by the distribution of the 21 experimental points around the hovering line, 13 insects rising and 8 falling.

Another more concise, but perhaps less pictorial, method of specifying the gravitational stability of insects would be in terms of the dimensionless number N generated from criterion (7) such that $N = \omega^2\varphi^2L^2K\rho S/Mg \geqslant 1{\cdot}8 \approx 2$; for $N > 2$ the fluttering wing-body system will climb, hovering corresponding to $N = 2$, and fall to $N < 2$. Such critical dimensionless numbers are common in fluid mechanics usage—for example, the critical Reynolds number of 2,000 corresponds to the ratio of the fluid inertia to viscous friction that must be exceeded before laminar flow in pipes may become turbulent. In the present instance the dimensionless number N denotes the ratio of the kinetic energy per unit volume dissipated by non-uniform air motion ($\frac{1}{2}\rho\omega^2\varphi^2L^2K$) to the gravitational force per unit wing area ($Mg/2S$).

In conclusion—while criterion (7) correlates, within experimental error, the values and trends observed for a wide range of insect flight behaviour, the results reveal a need for more exact experimentation on both insects and birds along the lines of the classic work of Weis-Fogh[8,16] and Jensen[8,17] on the desert locust, particularly with a theory in view, so that all the pertinent flight parameters are determined simultaneously and precisely.

I thank R. L. Houghton for supplying the insect specimens needed to determine the generalized wing geometries.

PHYSICS

Solar Radiation on Inclined Surfaces

CALCULATION of the probable intensity of solar radiation on a surface which is inclined to the horizontal and at any attitude or azimuth relative to the Sun's meridian is frequently necessary in solar engineering research. The usual practice has been to perform such a calculation by separating the direct component of insolation and the diffuse component of sky radiation and to combine these according to the geometry of the system[1]. The assumption is made that the sky radiation is uniformly distributed from all directions, but this is known not to be the case for bright Sun or cloudless conditions, when the diffuse radiation is more intense in the vicinity of the Sun[2]. Hence the normal procedure as already described here is not valid except for surfaces which are horizontal.

The work recorded here is based on the results of four years' continuous recording of the solar radiation received by surfaces at various attitudes and has the object of unifying the method of presentation of the data for bright Sun conditions*. The total radiation received by a surface at any attitude may then be calculated directly in terms of the total radiation received by a horizontal surface at the same instant. Briefly, the system of unification is based in the first instance on the resolution of the direct radiation from the Sun into components that are respectively perpendicular and parallel to the inclined surface, only the former being effective. Hence equation (1) is derived for these simplified conditions, and this is afterwards modified to allow for the diffuse radiation component.

$$\Phi I = \left(\frac{I_i}{I_h} - \cos\theta_H\right)\frac{\tan a}{\sin\theta_H} = \cos A_r \qquad (1)$$

where I = intensity of direct radiation; D = diffuse radiation; E = total radiation = $I + D$. The suffix i added to the foregoing symbols refers to intensities on an inclined surface, the suffix h to a horizontal surface. θ_H = angle of inclination of the surface to the horizontal; a = solar altitude above horizon; A_r = relative azimuth of surface, that is, the angle between the facing direction of the surface and the Sun's meridian.

The relationship shown by equation (1) when plotted graphically gives the 'ideal radiation characteristic line', which is universally valid for all conditions, except zenith Sun, if the diffuse component of radiation is ignored. As shown in Fig. 1, ΦI plotted against cos A_r gives a straight line of slope unity provided a is greater than θ_H. If a is less than θ_H, the relationship becomes a horizontal line at the relative azimuth angle at which the Sun's rays graze the surface; this is at $A_r = 90°$ or cos $A_r = 0$ for $\theta_H = 90°$ (vertical surfaces) or in general when cos $A_r = -\tan a/\tan\theta_H$.

If the terms for total radiation, namely, direct plus diffuse components, are substituted for the direct radiation in equation (1), then the data show that the conditions may be represented by equation (2) here, that is, there is still a straight-line relationship between ΦE and cos A_r, but the characteristic lines do not pass through the point 0,0 and have a slope less than unity.

$$\Phi E = \left(\frac{E_i}{E_h} - \cos\theta_H\right)\frac{\tan a}{\sin\theta_H} = C + M\cos A_r \qquad (2)$$

* The expression bright Sun conditions implies that the vicinity of the Sun is free from cloud, that the total cloud does not exceed 3/10, and that there is an absence of haze. Perfectly cloudless conditions are so rare that there would be a paucity of data and the periods of application would be limited.

The constant C is the value of ΦE when cos $A_r = 0$ and M is the slope of the characteristic lines; the deviation of these from the ideal is determined by the quality

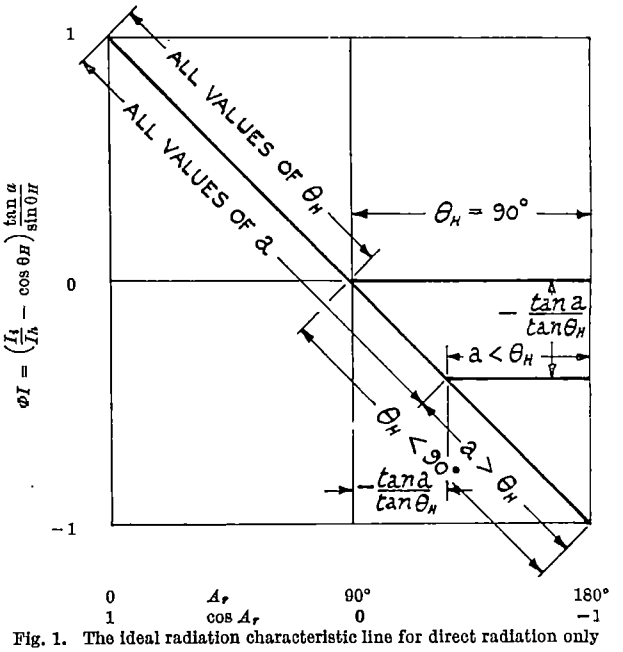

Fig. 1. The ideal radiation characteristic line for direct radiation only

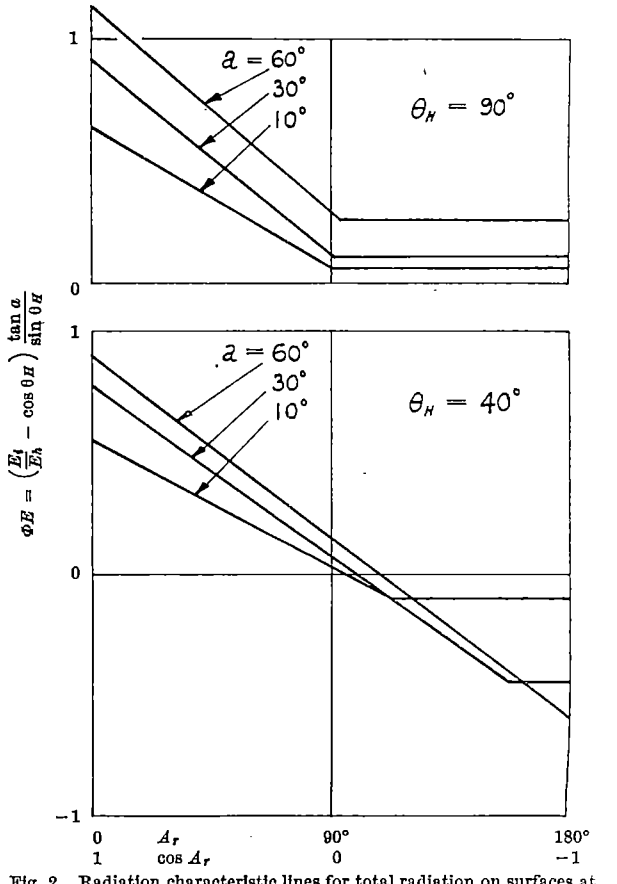

Fig. 2. Radiation characteristic lines for total radiation on surfaces at 90° and 40° to the horizontal and for various solar altitudes

of the radiation, that is, the relative magnitudes of the direct and diffuse components or of the ratio D_h/E_h. If it is assumed that for a given locality and season of the year the quality of the radiation is predominantly a function of the solar altitude α, then this latter factor is a convenient parameter on which to base a system of characteristic lines for a given value of θ_H. Typical characteristic lines are shown for $\theta_H = 90°$ and $\theta_H = 40°$ in Fig. 2. An analysis of the theory shows that if the diffuse component of radiation were uniformly distributed the slope M of the characteristic lines would be $(1 - D_h/E_h)$, but as the distribution is not uniform $(1 - D_h/E_h)$ is slightly smaller than M. The total radiation on a steeply inclined surface also includes some radiation from the heated surface of the ground, but this ceases to be appreciable when the angle of inclination θ_H is below 60°.

It is intended to publish charts or tabulated values of the constants C and M for various solar altitudes throughout the yearly cycle in the London area, which will enable the values of E_t/E_h to be calculated for any surface. The primary object of this communication, however, is to promote interest in the research in other countries and to stimulate the determination of similar data which will extend knowledge of the availability of solar radiation.

Electron Temperature in a Laser-heated Plasma

When a high-power laser beam is focused on to a material target, a small inertially confined plasma is generated near the target surface. Theoretical work by Basov and Krokhin[1,2], verified by Dawson[3], suggests that very hot plasmas ($\sim 10^7$ °K) can ultimately be produced in this way. A spectroscopic investigation of plasmas generated by a small Q-switched ruby laser has already been reported[4]. Further experiments have now been carried out using a larger Q-switched neodymium glass laser, and an estimate of the electron temperature attained in a carbon plasma is reported in this communication. Other results will be described in detail elsewhere.

The peak power density at the focus of the neodymium glass laser beam was about 10^{11} W cm^{-2}. The output wave-length was 10,600 Å. Each laser pulse lasted about 1 μsec and consisted of three spikes. The energy in a pulse was about 1 joule. The focused beam broke down atmospheric air, so the target was placed in a vacuum. The plasma formed by the laser beam was imaged on the entrance slit of a Hilger medium spectrograph. When a graphite target was used, a single laser pulse was sufficient to produce a spectrogram on which lines of the CI, II, III, IV and V spectra were identified.

Kaufman and Williams[5,6] have pointed out that under certain conditions the specific intensities of lines from atoms of the HeI isoelectronic sequence give a useful indication of the plasma electron temperature even when thermodynamic equilibrium is absent and the electron and ion densities are only very approximately known. A number of assumptions must be made whose validity will be discussed in a later paper. In particular, a Maxwellian distribution of electron velocities is assumed. The expression given by these authors for the specific intensity, I, divided by the product of the number densities of electrons, n_e, and of quadruply ionized carbon atoms in the ground state, n_t, has been evaluated for the observed CV transition $2s^3S_1$–$2p^3P_2$ at 2270·91 Å and is plotted as a function of the electron temperature, T_e, in Fig. 1.

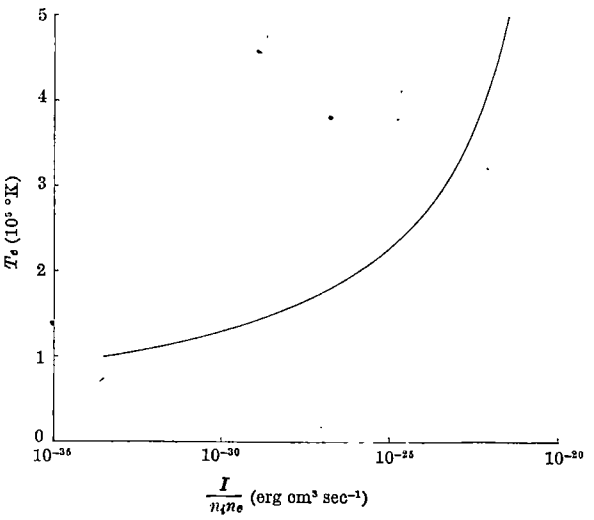

Fig. 1

Taking into account geometrical considerations, the observed blackening of the spectrographic plate indicates that the specific intensity of this CV line was at least 3×10^{11} erg cm^{-3} sec^{-1}. An extreme upper limit of 10^{21} cm^{-3} for n_t is obtained from the volume and density of the graphite removed from the target by the laser pulse, and the volume of luminous plasma emitting CV light. The corresponding maximum electron density is 6×10^{21} cm^{-3}, because the carbon plasma was very pure. Thus $I/(n_t n_e) \geq 5 \times 10^{-32}$ erg cm^3 sec^{-1}. From Fig. 1, the lower limit for the peak electron temperature is therefore $1{\cdot}1 \times 10^5$ °K. As may be seen from Fig. 1, at this temperature large errors in density or intensity estimates produce only small errors in the derived temperature. Nevertheless, as the true densities may well be orders of magnitude lower than the values used in the calculation the true electron temperature is probably somewhat higher.

Saturation Characteristics of a Spherical Ionization Chamber and a Determination of Boag's Constant for Air

Thomson and Rutherford's[1] initial investigations of the saturation characteristics of a parallel plate ionization chamber were followed by theoretical treatments by Thomson[2], Mie[3], Seeliger[4] and others. More recently, Boag and Wilson[5] have shown by dimensional analysis that the collection efficiency, f (that is, the ratio of the measured current, i, to the ideal saturation current, i_s), is a function of $d^2q^{\frac{1}{2}}V^{-1}$ where d is the distance between the plates, q is the rate of ionization and V is the applied voltage. Through the introduction of certain assumptions, they derived the following equation for the generalized saturation characteristic:

$$i_s = i\left[1 + \frac{i}{i_s} \cdot \frac{1}{6} \cdot \frac{\alpha/e}{k_1 k_2} \cdot \frac{d^4 q}{V^2}\right] \qquad (1)$$

or $$f = 1 - \frac{1}{6} f^2 \xi^2$$

where $$\xi = m\left(\frac{d^2 q^{\frac{1}{2}}}{V}\right) = \sqrt{\frac{\alpha}{e k_1 k_2}}\left(\frac{d^2 q^{\frac{1}{2}}}{V}\right)$$

k_1 and k_2 are the mobilities of the positive and negative ions respectively (that is, it is assumed that the current carried by electrons is negligible); α is the recombination coefficient; e is the charge per ion; m is Boag's constant.

Greening[6] has surveyed experimental data and concluded that, while equation (1) was valid very near saturation, Mie's theory[3], as simplified for the case of air, is true at least down to $f = 0{\cdot}7\left(i \cdot e \frac{i}{i_s} > 0{\cdot}7\right)$ and gives an equation for the generalized saturation characteristic:

$$i_s = i\left[1 + \frac{1}{6}\frac{\alpha/e}{\left(\frac{k_1 + k_2}{6}\right)\left(k_1 k_2\right)^{\frac{1}{2}}} \cdot \frac{d^4 q}{V^2}\right] \qquad (2)$$

or $$f = 1 - \frac{1}{6} f \xi^2$$

Although in equation (2) m is defined as:

$$m^2 = \frac{\alpha/e}{\left(\frac{k_1 + k_2}{2}\right)\left(k_1 k_2\right)^{\frac{1}{2}}}$$

it differs numerically from the definition given with equation (1) by only 0·5 per cent. Greening also obtained from his survey a value for m of 36·7 ± 2·2, which was higher than an earlier suggestion[5]. Boag[7] has shown theoretically that both equations (1) and (2) can be extended to a spherical ionization chamber provided the electrode separation $(a-b)$ is modified by a geometric factor, K_{SPH}:

$$(a-b)\, K_{SPH} = (a-b)\sqrt{\frac{1}{3}\left(\frac{a}{b} + 1 + \frac{b}{a}\right)}$$

where a and b are the radii of the outer and inner electrodes, respectively. Notwithstanding this, he points out that Mie's theory (equation (2)) may not necessarily be valid down to $f = 0{\cdot}7$ for spherical geometry.

A spherical ionization chamber has been constructed of copper with the radii of the inner and outer electrodes 3·13 cm and 5·08 cm, respectively, and irradiated in the γ-ray fields from a 2,000-c. cobalt-60 unit and a 1,000-c. cæsium-137 unit.

The wall thickness of the outer electrode, 2·64 mm of copper, was sufficient to establish electron equilibrium. The polarizing voltage was supplied by dry batteries and the current measured on a vibrating reed electrometer. A voltage calibration of the electrometer was obtained by means of a standard cell together with a potential divider. The input resistors were calibrated by a capacity leak method.

The experimental saturation characteristics obtained at two different exposure rates from the two radiation sources are shown in Fig. 1. Measurements made at other exposure rates lay on the same curve. The value of Boag's constant resulting from Greening's survey, 36·7, was used to calculate the generalized saturation characteristic from Boag's theory (Fig. 1, *B*) and Mie's theory (Fig. 1, *M*). The agreement at different exposure rates and different γ-ray energies confirms Boag's theoretical deduction that the generalized saturation curve derived for a parallel-plate chamber can be applied to a spherical ionization chamber, provided an appropriate geometric constant is introduced.

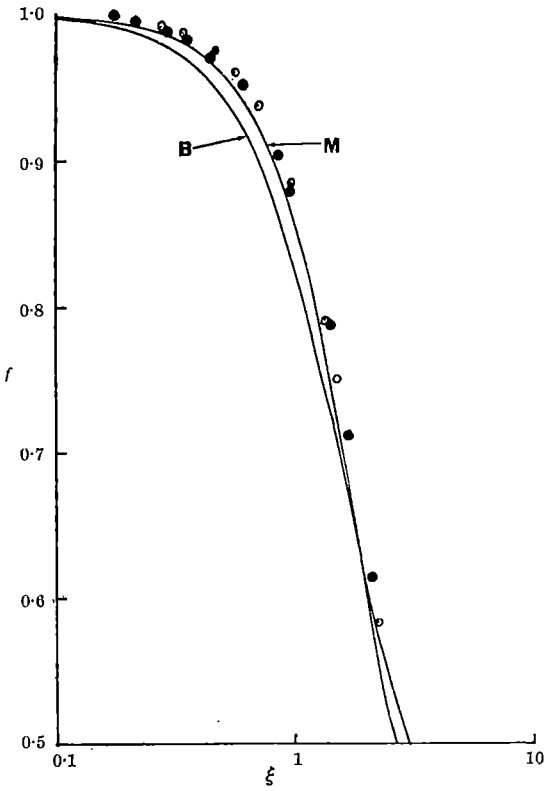

Fig. 1. The generalized saturation characteristics of a spherical ionization chamber. *M*, Mie's theory; *B*, Boag's theory; ○, Experiment, cobalt-60 γ-rays, q, 1·28 E.S.U./cm³ sec; ●, Experiment, cæsium-137 γ-rays, q, 0·51 E.S.U./cm³ sec

The experimental results tend to coincide more closely with Mie's theory. In fact, when the value of Boag's constant, which is derived later, is used to calculate the theories, the experimental points are superimposed on the curve representing Mie's theory. However, a better way of examining the validity of the two equations is to plot f against f^2/V^2, which according to Boag's theory should be a straight line, and also against f/V^2, which according to Mie's theory should be a straight line. This is done for one set of measurements in Fig. 2, where it will be observed that the plot of f against f^2/V^2 exhibits a distinct curvature, while the plot of f against f/V^2 lies on a straight line. The same results were obtained with the other sets of measurements. This concurs with Greening's finding that Boag's theory is valid only very near saturation, but Mie's theory is valid over a wider range. In addition, it is noted in Fig. 2, and in other measurements not presented here, that the straight line for the plot of f against f/V^2 is maintained down to at least $f = 0{\cdot}7$. This suggests that

^{60}Co	0·76	33·8
^{137}Cs	0·51	33·7
^{137}Cs	0·047	34·8

the generalized saturation curve derived from Mie's theory is valid for currents greater than 0·7 of the saturation current for spherical ionization chambers, as well as for parallel-plate ionization chambers. As the slope of the straight line in Fig. 2 is $-\frac{m^2d^4q}{6}$ (see equation (2)) Boag's constant can be determined from these data. This has been done for the two sets of measurements represented in Fig. 1 and also for the other two sets of measurements. The rate of ionization, q, and the calculated value of Boag's constant are listed in Table 1. The mean value obtained for Boag's constant was 34·2.

We thank Mr. D. E. A. Jones for allowing us to use the radiation facilities at Mount Vernon Hospital, Northwood, and Prof. J. F. Fowler and Mr. J. Yarwood for their advice. Dr. J. W. Boag kindly let us see the text of his chapter on "Ionization Chambers" prior to its publication in *Radiation Dosimetry*.

Forward Scattering of Light from a Laboratory Plasma

The scattering of electromagnetic radiation by a plasma in thermal equilibrium has been investigated by several authors[1–3] following the remarkable result of Bowles[4], who found that the spectrum of the radiation back-scattered from the ionosphere has a breadth comparable to the Doppler shift at the thermal velocity even though the electrons do the scattering. Rosenbluth and Rostoker[5] have extended those calculations to certain non-equilibrium cases. These calculations all show that the form and breadth of the spectrum of the scattered radiation are determined principally by the parameter defined as follows:

$$\alpha = \lambda/(4\pi\ \lambda_D \sin\theta/2)$$

where λ is the wave-length of the incident radiation, λ_D the Debye length of the plasma and θ the scattering angle measured with respect to the forward direction. If $\alpha \ll 1$ the electrons scatter as independent particles and the resulting spectrum is gaussian with a half-breadth given by the Doppler shift corresponding to the electron thermal velocity. If $\alpha > 1$ the spectrum is dominated by collective effects and consists of a central peak broadened at the Doppler shift corresponding to the ion thermal velocity which, however, is gaussian in shape only for large frequency shifts and has two weak maxima at the half-breadth positions and two electron satellites at $\pm\omega_p$, the electron plasma frequency. These electron satellites each contain only $1/\alpha^2$ of the total scattered energy.

Since λ_D for a typical θ-pinch plasma is of the same order as the wave-length of the ruby emission, if α is to be greater than unity the scattering angle must be less than $(2\pi)^{-1}$. This communication reports the first results obtained on a laboratory plasma for scattering at angles sufficiently small for collective effects to be dominant as contrasted with other work[6–10] at large angles.

Fig. 1 shows the experimental arrangement. Light from a Q-switched ruby laser is sent down the axis of a θ-pinch discharge and caught in a light trap beyond. The laser emits a single pulse of 20-nsec duration and a power of either 1·5 or 15 MW depending on the temperature of the ruby.

The light scattered at angles round 3° is collected from the entire azimuth and length of the plasma by the combination of a lens, axicon, and focal plane stop. The light then passes through an interference filter and a Fabry–Perot etalon. The etalon is followed by a lens-axicon combination which for a given wave-length shrinks one of the circular interference fringes to a point so that it can pass through a focal-plane stop to a photomultiplier (RCA 7265). The spectrum is scanned by displacing the axicon. (This method of scanning is described in detail in an article to be published in *Applied Optics*.) A second photomultiplier monitors the total signal to correct for variations in the laser output. The fraction of light scattered at all wave-lengths was $\sim 10^{-12}$.

The θ-pinch consisted of a coil 7 cm diam. × 16 cm long. The condenser bank was 4 μF charged to 36 kV. The period of the discharge was 4·8 μsec and all measurements were made 3·7 μsec after initiation. Hydrogen was used throughout at a pressure of 200μ.

The electron spectrum is taken with the etalon set for a free spectral range of 30 Å and the laser operated at a power of 15 MW. Fig. 2 shows a spectrum taken over two orders. The dispersion is, of course, quadratic and the wing toward the short wave-lengths is an instrumental effect. It is noted that the photoelectric signal is always enhanced in the presence of plasma within the instrumental breadth of the etalon. Outside the signal falls to the level of the noise except at certain points to the short-wave-length side of the main peak where a large enhancement is noted in the presence of plasma. The arrows show the corresponding point on the long-wave-length side where a small enhancement is noted. It would seem that the short wave-length electron satellite is much stronger than the long wave-length one.

The ion spectrum is taken with the etalon adjusted for a free spectral range of 0·8 Å. The laser is refrigerated to emit a narrow line. The resulting power is 1·5 MW. Fig. 3 shows the results. It is seen that the maximum of the ion peak is shifted toward shorter wave-lengths. The results are very sporadic in the neighbourhood of the maximum emission wave-length of the laser, as the latter was found to shift frequency from shot to shot. These variations are

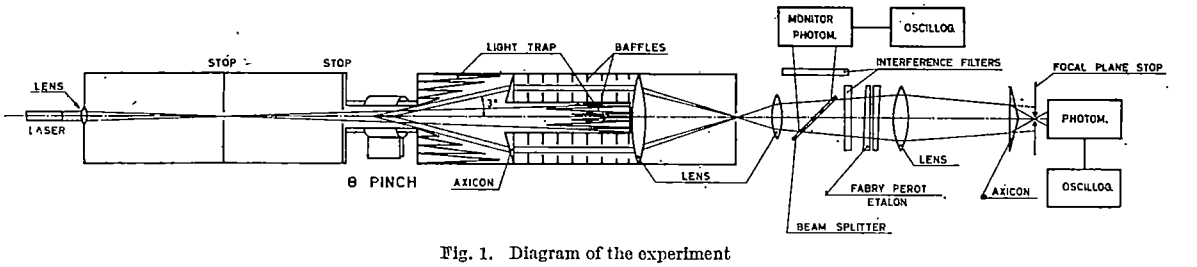

Fig. 1. Diagram of the experiment

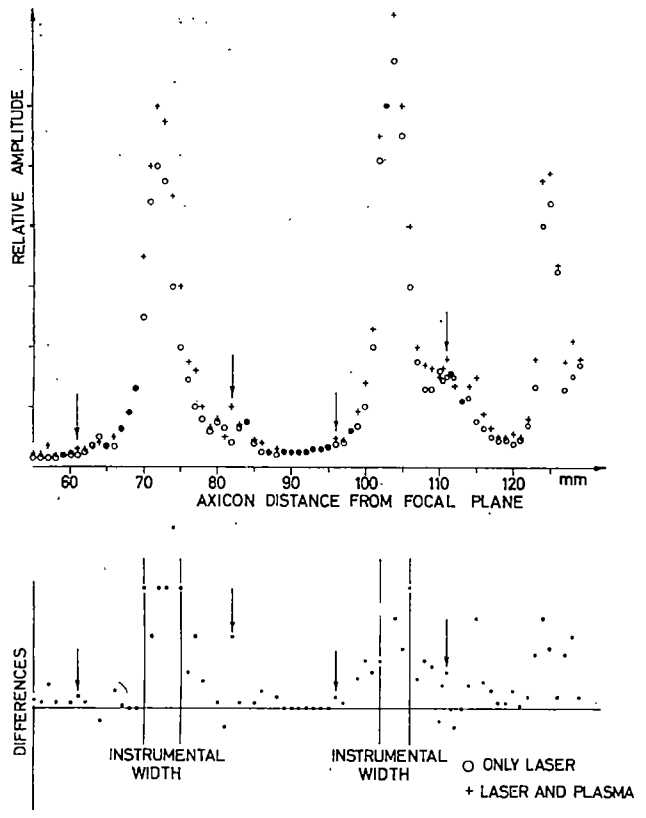

Fig. 2. Spectrum of scattered light at low-resolution etalon free spectral range 30 Å

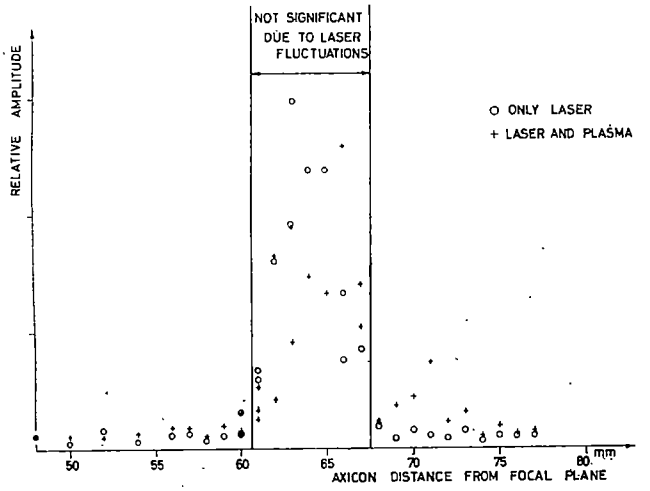

Fig. 3. Spectrum of scattered light at high-resolution etalon-free spectral range 0·8 Å

not sufficient to give a false indication of the displaced ion peak, however, because with the axicon set to accept such a large frequency shift the large-amplitude signal occurred only in the presence of plasma.

If one neglects any thermal correction to the electron satellites the resulting electron density from the frequency shift is $3{\cdot}2 \times 10^{15}/cm^3$. This agrees with the value of $2{\cdot}4 \times 10^{15}/cm^3$ deduced from the total scattered intensity. Setting the displacement of the ion peak equal to the ion thermal Doppler shift gives an ion temperature of 70 eV. If we assume the electron temperature is equal to the ion temperature the resulting value of α for our scattering angle of 3° is ~ 2. Except for the asymmetries toward shorter wave-lengths these data are consistent with the theory and the expected behaviour of a small θ-pinch. The asymmetry in the ion peak can be attributed to an electron drift velocity relative to the ions of the order of the thermal velocity according to the previously cited work of Rosenbluth and Rostoker. Such a drift could also account for the enhancement of the short wave-length electron satellite.

We thank Prof. Brunelli, director of the Laboratorio Gas Ionizzati, and other staff members of the laboratory for their advice. We also thank R. Marchetti and M. Baldascini for carrying out the measurements. One of the authors (J. K.) was a Euratom Research Fellow during 1961–63.

Attenuating Blast Waves produced by an Instantaneous Release of Thermal Energy

It has been observed that, when an explosive charge of TNT is intimately surrounded by a light crushable porous solid of large surface area and high heat capacity, the subsequent blast wave is rapidly attenuated. The mechanism of attenuation is hazarded as mainly heat transfer. The crushable nature of the surrounding porous solid (no elasticity–zero velocity of sound) would prevent immediate transmission of the blast wave energy and allow time for multiple reflexions, hence heat transfer and therefore attenuation, as gas flow is established through the porous solid.

Although a large number of materials would be suitable as the attenuating medium, initial experimentation has been confined to exfoliated mica, that is, vermiculite. The advantages of this material are its almost insignificant cost and its chemical inertness.

Experience has indicated that the use of vermiculite is a very convenient laboratory tool. A charge of TNT weighing 1/3 lb. can be detonated at the centre of a simple wooden box (4 ft. × 4 ft. × 4 ft.), filled with vermiculite, with complete safety. In fact very little audible signal is received outside the box.

Extrapolation emphasizes the possibility of obscuring the detonation of some 1,000 tons of TNT in a pile of vermiculite of the order of 100 ft. in height. The attenuating mechanism becomes more effective the higher the temperature of the explosive source.

GEOLOGY

Gibbsite in Altered Granitic Rock in North Wales

My attention was directed by the Nature Conservancy's chief warden for Snowdonia, Mr. Evan Roberts, to an unusual form of rock weathering on the ridge of Y Llymllwyd, which projects into Nant Ffrancon between Cwm Cywion and Cwm Coch. These are two well-developed late-glacial corries. The rock in question is exposed over an area of about 100 sq. m. in a col on the crest of the ridge at approximately 750 m (2,450 ft.), *O.D.*, grid reference *SH* 631609.

Sections show a thin greyish-white surface horizon overlying white loose material, sandy in initial texture but easily crushed and earthy. This becomes more compact and massive at about 25–30 cm, in the form of soft altered rock to a known depth of 1·5 m. This soft rock retains a recognizable original fabric.

Williams[1] showed that granophyric intrusions probably of Llandeilo age, behaving generally as laccoliths, occurred in the area. These intrusions include the Bwlch-y-Cywion granite, which outcrops over an area of about 2·4 km × 0·4–0·8 km. This intrusion includes four lithological variants identified by Williams of which the most extensive, a microporphyritic granite, occupies the ridge of Y Llymllwyd. This rock, greyish-white or pinkish in colour, consists of a ground-mass of interlocking quartz and alkali felspars, mainly orthoclase, containing small tabular felspar phenocrysts and flakes and patches of biotite and chlorite. The felspars are partly decomposed to sericite and paragonite, but there is no reference to areas of deep weathering or decomposition. The complete chemical analysis of this rock[1] includes figures for SiO_2 and Al_2O_3 of 74·23 and 13·39 per cent respectively.

Examination of the clay fraction of the 0–25 cm horizon showed it to be composed of gibbsite (Al_2O_3 $3H_2O$) as the only crystalline component. X-ray powder photographs (Philips 114·6-mm cameras) give a strong pattern almost identical with that given by Rooksby[2] or on the American Society for Testing Materials (A.S.T.M.) data card 7–324. Differential thermal analysis (Netzsch equipment) gives a curve of the general type published for gibbsite[3] although peak positions are not identical to those of published data (which are themselves variable). The differential thermal analysis curve indicated that no substantial amount of any other clay mineral was present with the gibbsite except possibly allophane, evidenced by a small endotherm and exotherm at 160° C and 910° C respectively. The probability of some amorphous mineral of allophane type being present is shown by a semi-quantitative X-ray spectrographic analysis which gave aluminium as dominant, with silicon present to the order of 10–15 per cent SiO_2. Calcium, potassium, manganese and iron are present only as trace amounts. 44–75μ size-fractions from the same 0–25 cm horizon contain the order of 50 per cent SiO_2.

An occurrence of gibbsite as the dominant product of alteration or weathering of a granitic rock is believed to be unique in Britain. Gibbsite has, in Britain, been previously recorded in Tertiary bauxitic weathering products in the Antrim inter-basaltic horizon[4], in the Ayrshire bauxitic clays derived by contemporaneous weathering of Carboniferous lavas[5], and, associated with allophane, in segregations in chalk[6] at Clifton Hill, Brighton. The implications of this record from North Wales are of geological interest if it results from hydrothermal alteration and of wider interest if, as is presently believed, the gibbsite is a relic product of sub-aerial weathering. Work, in collaboration with Dr. D. A. Jenkins, University College of North Wales, Bangor, is continuing on the field relationships, petrography and chemistry of this clay, its parent rock and the 'weathered' zone with which it is associated.

Grand Banks Earthquake of 1929 and the 'Instantaneous' Cable Failures

The Grand Banks earthquake and the associated disturbances have received attention from all students of marine geology, particularly since the publication of the classical interpretation of the submarine cable failures by Heezen and Ewing[1]. In their recent publication, "Grand Banks Slump", Heezen and Drake[2] have attributed the virtually instantaneous cable failures around the epicentre of the earthquake to an initial slump, triggered by the shock. In their original interpretation, Heezen and Ewing attributed the later, systematic cable failures for a period of 13 h 17 min to the action of the turbidity current dislodged by the initial shock. The cause behind the almost instantaneous failure of six cables lying 150–1,800 fathoms on the continental slope, however, remained unexplained at that time. The original authors attributed these, rather vaguely, to "initial ground motion, or almost instantaneous slumps and slides".

The 'epicentral area' of this earthquake was about 30 miles in radius[2], and the instantaneous damage within this area was obviously due to the initial shock, ground movements and slumping. The fact which remained unexplained was that the southernmost cable, which broke instantaneously, lay but 10 miles away from the cable which broke 59 min later. Apparently, therefore, the almost instantaneous breaks were caused by a phenomenon somewhat different from and faster than the turbidity current which damaged the other cables at progressively increasing times from the 59th minute of the shock.

Heezen and Drake have suggested an initial slumping to explain the 'instantaneous' cable breaks. Gravitational slumping in the area is indicated by a reflexion seismic profile which shows irregular and curved sub-bottom horizon dips.

The idea of initial slumping supported by Drake's reflexion profile seems to be quite a plausible solution for part of the problem. From Fig. 1 of Heezen and Drake, however, it appears that the farthest cable which broke 'instantaneously' lay at a distance of about 60 miles from the epicentre. Considering the extensive area which, according to Heezen and Drake, was 'instantaneously' affected by a gravity slumping, I have been wondering if the almost instantaneous cable breaks outside the epicentral area could be attributed to some phenomenon faster than the postulated gravity slumping.

Surface wave disturbances in experimental seismograms are quite commonly experienced by the explosion seismologists. Travelling along the free solid-surface with about nine-tenths the velocity of the shear wave, these waves (particularly Rayleigh or the so-called 'ground roll') progressively hit the geophones at successively greater distances from the explosion. A similar phenomenon of elastic wave propagation might explain at least a part of the cable failures outside the 'epicentral area'.

Specific data on the shear wave velocity in underwater sediments are rather meagre. The available information from experimental studies on sediment cores by Sutton, Berckhemer and Nafe[3] roughly suggests a compressional wave velocity of 1·5–1·8 km/sec (or a mean velocity of about 1·65 km/sec) near the water-sediment interface. The corresponding shear wave velocity derived from velocity–porosity relations[4] is about 0·6 km/sec. Travelling along the free surface of the sediment the corresponding Rayleigh wave would traverse a distance of 60 miles in about 2·98 min. The distance of 30 miles from the edge of the 'epicentral area' to the farthest cable which broke almost instantaneously will be covered in only about 1·49 min—a rather small time-interval compared with the next cable break 59 min after the shock. Effects of the compressional and shear waves within this zone would, of course, be still faster (0·49 and 1·34 min, respectively). In view of the dispersive nature of the Rayleigh wave these velocity computations might be modified to some extent.

It is interesting to note in this connexion the earlier observation by Officer (in Nafe and Drake[4]) that the topmost part of the sediment near the water-sediment interface might have slightly lower velocity than the velocity of water for frequencies of about 100 c/s.

As regards the feasibility of large-scale damage in unconsolidated sediments by elastic wave propagation, the instrumental observations by Gutenberg (in Swain[5]) on the so-called "jelley theory" which indicates that displacements in unconsolidated medium may be two to ten times greater than displacements from similar shocks in solid rocks, are worth noting.

These observations are recorded not as alternative suggestions to the idea of initial gravity slumping in the area which has been confirmed by Drake's reflexion profile. This is only an attempt to indicate the possible specific mechanism which might be responsible for: (1) the initial gravity slumping within and around the 'epicentral area'; (2) the almost instantaneous cable breaks in an extensive area outside the epicentral zone where gravity slumping at the instant of the earthquake seems to be a rather remote possibility.

CHEMISTRY

Isotope Effects in the Infra-red Spectra of some Carbon-14-labelled Acids, an Ester and Sodium Salt

ISOTOPE shifts in the infra-red have been reported for a number of compounds containing deuterium, nitrogen-15 and oxygen-18, for example, the work of Pinchas *et al.*[1,2], but little has been published on carbon-13- or carbon-14-labelled compounds. George[3] has examined the spectrum of 1-^{13}C-propene-1, and Karabatsos[4,5] some ^{13}C-di-iso-propyl ketones and 2,2-dimethyl propionic acid; as regards carbon-14 compounds, only the spectra of carbon dioxide and barium carbonate appear to have been reported hitherto.

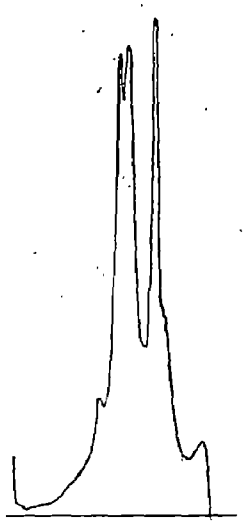

Fig. 1. Palmitic acid-1-^{14}C
μ: 5·68, 5·83, 5·90, 6·11, 6·20
cm^{-1}: 1,760, 1,715, 1,695, 1,637, 1,613 (*sh*)

This communication reports the spectra of some carbon-14 acids, an ester and sodium salt labelled at high specific activity in the 1-position.

The spectra were obtained on a Grubb-Parsons *G.S.*3 double-beam spectrophotometer from carbon tetrachloride solutions of the compounds, with the exception of sodium formate which was incorporated into a potassium bromide disk. The activities and radiochemical purities determined either by thin-layer chromatography, paper chromatography, or dilution analysis as appropriate were as shown.

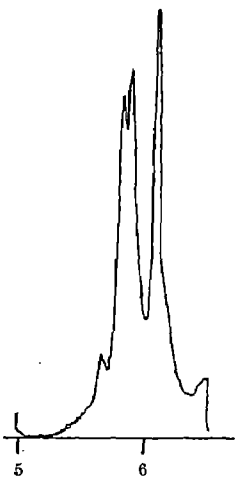

Fig. 2. Stearic acid-1-^{14}C
μ: 5·68, 5·83, 5·90, 6·11, 6·20
cm^{-1}: 1,760, 1,715, 1,695, 1,637, 1,613

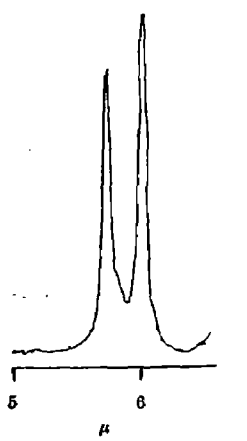

Fig. 3. Methyl stearate-1-^{14}C
C=O(^{13}C), 5·74μ, 1,742 cm^{-1}; C=O(^{14}C), 6·02μ, 1,661 cm^{-1}

It will be seen that the spectrum of the methyl stearate shows an additional peak at 1,661 cm^{-1} corresponding to ^{14}C=O stretching, and at a frequency close to that calculated. Similarly in the spectrum of sodium formate each of the peaks from 1,667 cm^{-1} to 741 cm^{-1} is also split. It is possible to detect ^{14}C–H stretching as a weak shoulder at approximately 3,260 cm^{-1}. However, it is worth noting that the free acids exhibit instead of the expected effects a complex band system, the origin of which is as yet unexplained.

Table 1

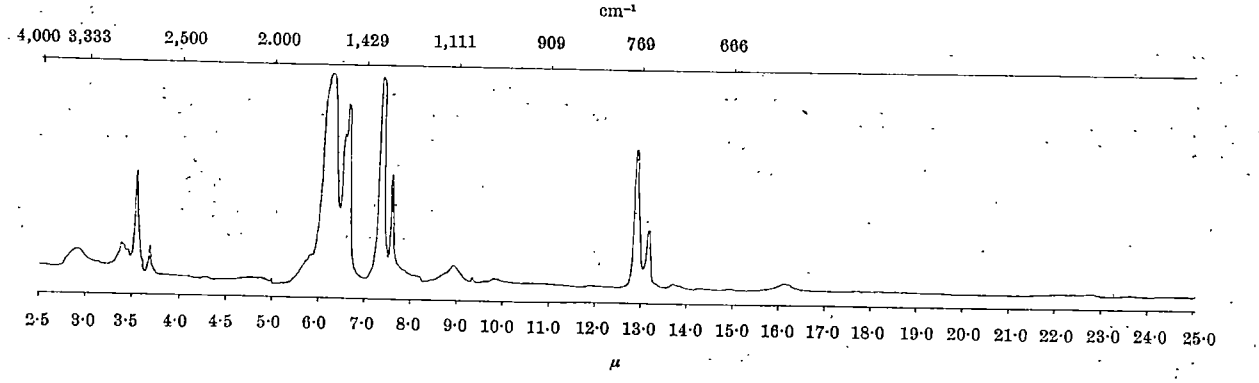

Fig. 4. Sodium formate-^{14}C

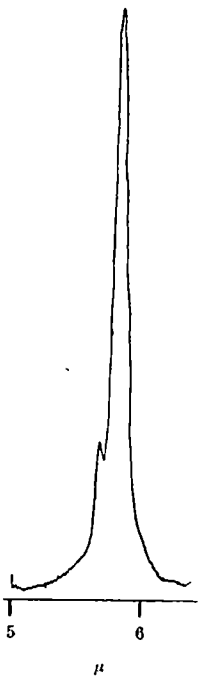

Fig. 5. Palmitic acid (inactive)
5·68μ, 1,760 cm⁻¹; 5·82μ, 1,718 cm⁻¹

We would like to direct attention to possible errors due to isotope shifts which might arise in purity determination of carbon-14-labelled compounds by infra-red spectrometry. Unsaturated fatty acids having multiple unconjugated double bands may be cited as an example, in this case absorption due to $^{14}C=O$ could easily be confused with the strong band arising from small amounts of conjugated impurities. The spectrum of a molecule generally labelled at high specific activity might well be so altered as to be unrecognizable as that of the same compound unlabelled. It is suggested that in such instances the evidence of infra-red spectrometry alone should not be accepted as a criterion of purity and recourse should be made to methods of assay independent of isotope effects.

A Sensitive Chemical Actinometer for Ultra-violet Radiation

The most widely used chemical actinometer for ultra-violet radiation is based on the photochemical decomposition of oxalic acid in solutions of oxalic acid and uranyl oxalate, and subsequent titration with hot potassium permanganate[1]. This actinometer requires relatively large volumes of solution, and since the ultimate sensitivity depends on the titration difference before and after irradiation, ultra-violet sources of low dose-rate require relatively long exposure times. Actinometers in which the products of photolysis are directly determined are capable of greater sensitivity, depending on the sensitivity of the method used for analysis. Direct spectrophotometry, with high absorption of the photolysis products, introduces problems of inner filters and non-linearity of response. Parker[2] has devised a chemical actinometer with high sensitivity which depends on the decomposition of potassium ferrioxalate, spectrophotometric determination of the ferrous ion formed by the addition of phenanthroline and buffer solution, and subsequent measurement of absorption at 5100 Å. However, even dim electric light produces rapid decomposition of the potassium ferrioxalate, and all manipulations must be performed in a dark room.

Fluorometry is inherently about 20,000 times more sensitive than colorimetry for measuring concentrations of substances, although fluorescence is not so universal a process as absorption, because of competing quenching processes which tend to decrease the yield of fluorescence.

During the course of our investigation of the benzoic acid dosimeter for ionizing radiation of Armstrong and Grant[3], we found that ultra-violet irradiation in the region below 300 mμ of aqueous solutions of benzoic acid caused the formation of fluorescent products[4]. A large fluorescence reading is obtained which is linear with dose, even for prolonged irradiation doses. No significant change is observed in the ultra-violet absorption spectrum of the benzoic acid as a result of irradiation (except for a small increase for very long irradiation times), thus assuring that a constant fraction of actinic light is absorbed during the photochemical reaction, as is seen in Fig. 1. The fluorescence production is extremely sensitive; doses of the order of 1×10^{-7} N quanta/cm^2 of 254 mμ radiation are easily detected. We estimate the minimum detectable amount of energy at this wavelength, with a 1×10^{-3} M benzoic acid solution at pH 12 irradiated in air, to be of the order of 2×10^{-8} N quanta/cm^2. This is much lower than can be measured with the uranyl oxalate actinometer, though it is not more sensitive than the Parker actinometer. The principal advantage of this actinometer, besides its sensitivity and stability in room illumination, is the fact that only small volumes (2–3 ml.) are required, and that measurements can be made directly with no further manipulations, if the irradi-

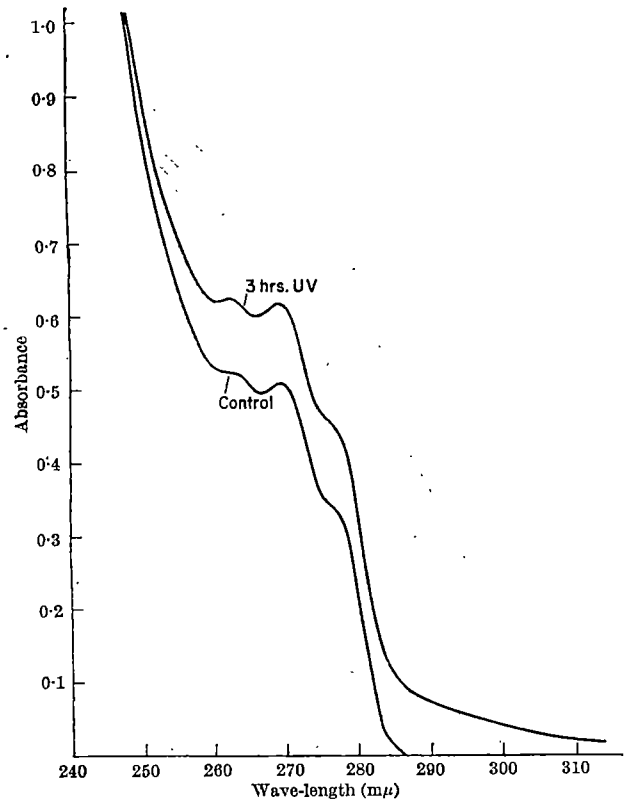

Fig. 1. Ultra-violet absorption spectra of actinometer solution before and after irradiation with germicidal lamp ($1{\cdot}4 \times 10^{-7}$ $Nh\nu$/min/cm^2). Solution is 1×10^{-3} M benzoic acid brought to *p*H 12 with NaOH. This dose increases the fluorescence intensity from nine arbitrary fluorometer units to 1,010 units

ation is carried out in a fluorometer cuvette. Fluorescence was determined with a standard fluorometer (Photovolt Corporation, New York, Model 520 *M*), using a Hanovia S-4 mercury lamp, fitted with an *RCA* 931-*A* photomultiplier tube. A primary filter (Corning 754 in conjunction with Wratten 34*A*) isolated the band with a maximum at 320 mμ for excitation, while a Baird-Atomic *A*-11 dielectric interference filter was used to isolate the 295 mμ band for shorter wave-length excitation. A secondary filter (Balzer 434-11-*B*-40) passed the fluorescent light with peak transmission at 405 mμ. The fluorometer was standardized before use by setting the fluorescence response to zero fluorometer units with distilled water, and to 1,000 fluorometer units with a solution of 6×10^{-6} molar *ortho*-hydroxy benzoic acid (salicylic acid) made alkaline to *p*H 12 with NaOH. Monohydroxy and dihydroxy benzoic acids have maximum fluorescence in alkaline solution where they are maximally ionized.

The fluorescent response of a 1×10^{-3} M benzoic acid solution was measured at different *p*H values against ultra-violet dose using a Mineralight 2537*SL* lamp, emitting primarily 254 mμ radiation at a dose-rate of $1{\cdot}4 \times 10^{-7}$ $Nh\nu$/min/cm^2, at a distance of 7·0 cm. Maximum fluorescence response to radiation was obtained at *p*H 12, similar to the response with ionizing radiation. These irradiations were carried out in air, with no bubbling or agitation. A slightly enhanced fluorescence response was noted if the irradiations were carried out under oxygen bubbling conditions, and the fluorescence response was slightly decreased under nitrogen bubbling conditions. The fluorescence is a linear function of dose for as long as 3 h duration. Curve *B*, in Fig. 2, shows the linear response of fluorescence intensity for doses of only several min duration. At 254 mμ, the fraction of light absorbed in a 1 cm cell containing 1×10^{-3} M benzoic acid at *p*H 12 is 75 per cent.

In an investigation designed to increase further the sensitivity of this actinometer. it was found that the addition of various compounds which are well-known radiation protective agents, namely, cysteine, cysteamine, glucose, and chloro-mercuri-benzoic acid, enhanced the fluorescence response by a factor of between 2 and 11 depending on the additive. For example, the addition of cysteamine (1×10^{-3} mole/litre) increased the fluorescence response by a factor of about 10, as shown in curve *A* of Fig. 2. The mechanism of this enhancement of sensitization is unknown at present; it cannot be due to increased absorption of light, since cysteamine at this concentration has an absorbance at 254 mμ of only 0·12, nor can it be due to fluorescent species formed by the photolysis of cysteamine, since control solutions of cysteamine at *p*H 12, similarly irradiated, developed no fluorescence.

From the data of Table 1 we can see that the ratio of arbitrary fluorometer units, F_{295}/F_{320}, found for peroxide-treated benzoic acid is very similar to that of ultra-violet irradiated benzoic acid.

Table 1. Comparison of Fluorescence Intensity at *p*H 12 with 320 mμ and 295 mμ Excitation

	Solution	Arbitrary fluorometer units F_{320}	F_{295}	F_{295}/F_{320}
a	Benzoic acid (1×10^{-3} M)	9	45	4·7
b	*ortho* Hydroxy-benzoic acid (6×10^{-6} M)	1,000	5,900	5·9
c	*meta* ,, ,, ,, ,,	2,120	6,850	3·2
d	*para* ,, ,, ,, ,,	20	75	3·7
e	Equal mixture of *b*, *c*, and *d*	1,040	4,275	4·1
f	H_2O_2 (2×10^{-3} M)-treated benzoic acid	1,020	4,350	4·3
g	NaOCl (2×10^{-3} M)-treated benzoic acid	0	0	—
h	Ultra-violet irradiated benzoic acid	1,000	4,500	4·5
i	4,000 rads from cobalt-60 gamma-rays	1,101	4,140	3·7

The activation process is due to the absorption of ultra-violet quanta, and subsequent photolysis of the type:

$$RH + h\nu \longrightarrow R\cdot + H\cdot$$

These radicals react readily with oxygen to form organic peroxides which may afterwards decompose with the formation of hydroxy-benzoic acid, similar to the action of hydrogen peroxide. However, the powerful oxidizing agent sodium hypochlorite does not cause any fluorescence in benzoic acid. We have calculated the quantum yield of hydroxy-benzoic acid production at *p*H 12 to be 0·081, assuming the fluorescence is due to an equi-molar ratio of hydroxy-benzoic acids. From the ultra-violet absorption spectra of benzoic acid at different *p*H values, the fraction of light absorbed and the quantum efficiency of isomer production at each *p*H can be calculated. The larger quantum yield at *p*H 12 may reflect the alkali-catalysed cleavage of peroxides, rather than differences in light absorption or ionization.

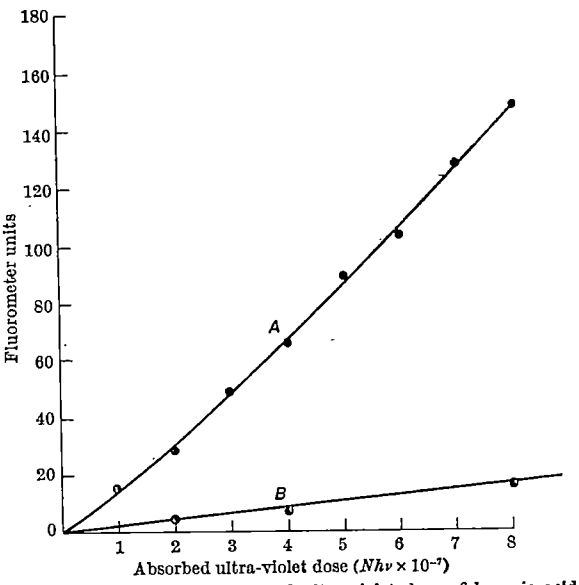

Fig. 2. Fluorescence intensity and ultra-violet dose of benzoic acid actinometer. Curve *A*: 1×10^{-3} M benzoic acid at *p*H 12 plus 1×10^{-3} M cysteamine. Curve *B*: 1×10^{-3} M benzoic acid at *p*H 12. Excitation is with 320 mμ band

Because this system does not absorb light at wavelengths above 300 mμ, excitation with the 320 mμ band in the fluorometer has no actinic effect on the benzoic acid. Only the products of photolysis, presumably the hydroxy isomers of benzoic acid, absorb at this wave-length and emit fluorescent radiation. Our system is more convenient and rapid in use than other conventional chemical actinometers.

Intermolecular Potential Energy Functions for Simple Molecules

THE development of an intermolecular potential energy function for simple molecules based solely on an investigation of properties arising from two-body interactions[1] may prove more valuable than the alternative approach which considers also the properties of solids[2]. The latter approach involves the assumption of the pair-wise additivity of potential energy, the validity of which must be regarded as unproven. Unfortunately, the second virial coefficient, which is the most convenient two-body property to analyse, is not capable of defining a unique potential energy function[3]. However, recent low-temperature data provide a valuable test of the adequacy of potential energy functions and illustrate clearly the failure of many widely-used potentials[4]. Although some evidence points to a more complex form of the potential function, it seems appropriate to examine first simple two-term functions of the $(n–6)$ type, which may be written:

$$U(r) = \varepsilon\left[\left(\frac{6}{n-6}\right)\left(\frac{r_m}{r}\right)^n - \left(\frac{n}{n-6}\right)\left(\frac{r_m}{r}\right)^6\right]$$

when r_m is the separation of the molecular centres at the potential minimum. The collision diameter σ is related to r_m by:

$$\sigma = r_m\left(\frac{6}{n}\right)^{\frac{1}{n-6}}$$

An analysis of the second virial coefficients of a number of simple gases shows that, as expected, many potentials of this type are capable of interpreting the experimental data for relatively high temperatures. However, analysis of the low-temperature results leads to the definite conclusion that, of the $(n–6)$ potentials, only those with n in the range $16 \leqslant n \leqslant 20$ are acceptable. (It is of interest to note that the shape of the (16–6) potential is similar to that of the Kihara function as applied to the inert gases[5]). This is illustrated for the very-low-temperature ranges in Fig. 1. Further evidence in favour of such values of n may be obtained from investigations of the transport properties of gases. It has been shown that an $(n–6)$ potential with $n > 12$ is superior to the traditional (12–6) potential when applied to such properties[6], and a quantitative investigation is in progress. Of the potentials we have considered, the (18–6) potential has previously been used to interpret the properties of globular molecules and found to be as good as the (28–7) potential which was expressly developed for this purpose[7].

On the basis of all the foregoing considerations we conclude that the (18–6) potential will provide a much more useful basis for the description of second virial coefficients and the transport properties of gases than any of the simple potential functions[11] in general use.

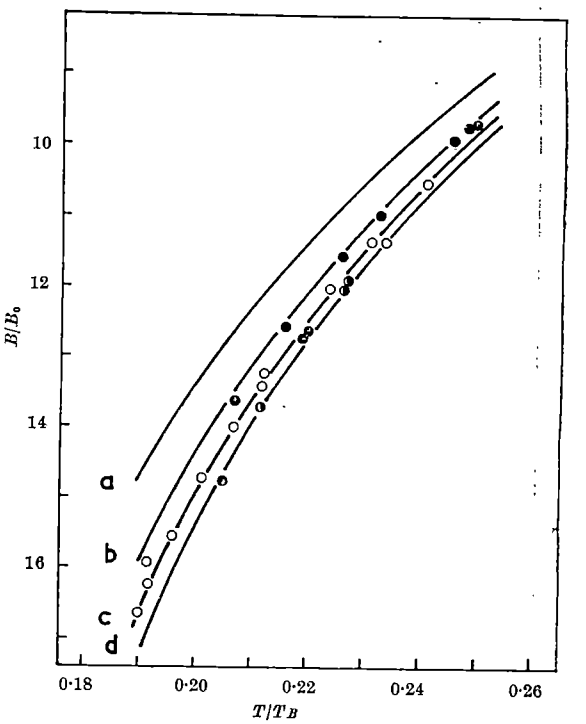

Fig. 1. The second virial coefficients at low reduced temperatures. The reduction procedure used was based on the Boyle temperature of the gases, $T_B.B_0$ is defined as the second virial coefficient at $T = 0{\cdot}7\ T_B$. Results are available for three classical gases in this region: ●, argon, refs. 4, 8, 9; ○, krypton, refs. 4, 10; ◑, oxygen, ref. 8. The solid curves *a*, *b*, *c* and *d* represent the theoretical values for $(n–6)$ potentials when n has the values 12, 16, 18, 20, respectively

We have calculated values of the reduced third virial coefficient over a range of reduced temperatures on the basis of the (18–6) potential by direct numerical integration, making the assumption of pair-wise additivity of the potential energy. The results are given in Table 1

Table 1. REDUCED THIRD VIRIAL COEFFICIENT FOR THE (18–6) POTENTIAL

T^*	C^*	$\Delta C^*/a^*$
0·7	−0·640	—
0·9	+0·513	—
1·0	+0·572	8·71
1·2	+0·535	5·73
1·5	+0·448	3·69
2·0	+0·373	2·27
3·0	+0·339	1·28
5·0	+0·338	0·69

$T^* = kT/\varepsilon$, $C^* = C/b_0^2$ where $b_0 = \frac{2\pi}{3}N\sigma^3$. $a^* = a/\sigma^3$ where a is the polarizability. $\Delta C^*/a^*$ is correction factor for non-additivity.

and are accurate to better than 0·5 per cent. A comparison with the rather uncertain experimental data shows the agreement to be reasonable, but in no way superior to that given by the (12–6) potential. However, if correction is made for non-additivity of the potential energy[12], the agreement is considerably improved.

Negative Ion Formation in the Atomic Oxygen – Acetylene Reaction

PREVIOUSLY[1,2] we have reported on the production of positive chemi-ions in low-pressure atomic oxygen–acetylene reactions. Now we have also observed large concentrations (estimated as 10^{11}–10^{12} c.c.$^{-1}$) of negative ions in this system and have concluded that they are formed predominantly by electron attachment processes. This medium thus offers a much-needed new opportunity for the examination of electron attachment and charge transfer phenomena and the reactions of negative ions with positive ions and neutral species. Both the 'natural' ions of the reaction environment and those ions formed in the presence of additives can be investigated.

The same mass spectrometer atomic-diffusion flame apparatus used for positive-ion studies was used in this investigation after electronic modifications for negative-ion operation[3]. An atomic oxygen stream, produced in a side tube by subjecting a 96 per cent helium–4 per cent oxygen mixture to a 2,450-Mc/s, 125-W microwave discharge, diffused into the central portion of a 12-in.-diam. 'Pyrex' cross through which C_2H_2 flowed. The resulting reaction zone was oxygen-atom rich in the early stages of the reaction (near the O-atom inlet) and hydrocarbon rich farther downstream. The reaction pressures were 1–10 torr and the temperature varied from a maximum of 700° K near the centre of the reaction zone to near room temperature far out in the 'Pyrex' cross.

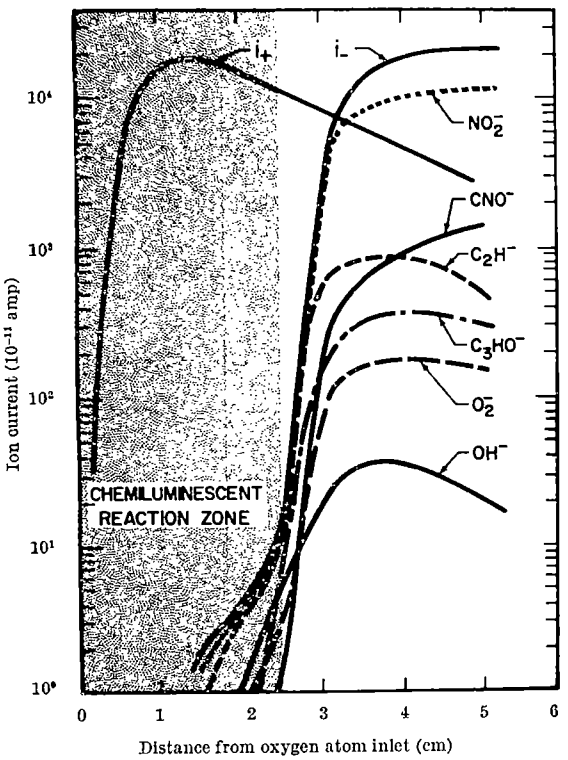

Fig. 1. Ion profiles. The magnitude of individual currents is not directly comparable to that of total current. i_+ and i_- indicate total positive and negative ion currents, respectively. C_2H_2 flow, 17·0 c.c. (S.T.P.) sec^{-1}; helium flow, 14·5 c.c. (S.T.P.) sec^{-1}; oxygen flow, 0·6 c.c. (S.T.P.) sec^{-1}

The negative ions observed include masses 16, 17, 24, 25, 26, 32, 42, 46, 49, 53 and 59. The hydrogen content of these ions has been determined in experiments where C_2H_2 was replaced with C_2D_2. Masses 17, 25, 53 and 59 all contain one hydrogen atom apiece; mass 49 may be a mixture of two species, having one and five hydrogen atoms, respectively. The other ions contain no hydrogen. Commensurate with these results, the ions observed have been tentatively designated as the following: O^-, OH^-, C_2^-, C_2H^-, CN^-, O_2^-, CNO^-, NO_2^-, C_4H^- (and possibly $CH_5O_2^-$), C_3HO^- and $HCNO_2^-$. The presence of nitrogen-containing ions in large relative concentrations is indicative of the well-known high electron affinities of their parent compounds, which are present as impurities only. Addition of halocarbons to the acetylene stream results in atomic halogen ions becoming dominant; addition of SO_2 yields large quantities of SO_2^- (or S_2^-) and some S^-.

Some individual ion current profiles are shown in Fig. 1, together with total positive and negative ion current profiles; the magnitude of individual currents is not directly comparable to that of total currents. The maxima in these total ion current profiles are approximately equal, but their relative magnitude in the luminous zone indicates that the negative charge carriers there are mainly electrons. Negative ions become important charge carriers only in the gases surrounding the reaction zone, indicating that they are formed predominantly by attachment processes. Concentrations of O^-, C_2^- and CN^- were too small, relative to OH^- and C_2H^-, respectively, to allow us to take meaningful profiles. Masses 49 and 59 are present in maximum concentrations comparable to O_2^- and C_3HO^-, respectively. Large relative concentrations of heavier ions up to at least mass 130 have also been observed. Little effort has been given thus far to identification of these ions because of poor mass spectrometer resolving power at higher mass numbers. These heavier ion species, however, maximize further from the O-atom inlet than do most of the lighter ion species. They are, therefore, thought to be the products of ion-clustering processes.

It is interesting to compare the results obtained here to those obtained in low (1–10 torr)[3] and atmospheric pressure[4] C_2H_2-O_2 combustion flames. The low-pressure combustion shows relatively small negative-ion to positive-ion ratios and a preponderance of lighter ions. The atmospheric pressure flames behave much like the present system, which shows that both electron attachment and ion clustering are favoured by lower temperatures and higher pressures. The same observation with regard to clustering can be made for the positive ions in these three systems[2,5].

Fite and Rutherford[6], working with afterglows in atmospheric gases, reported the presence of significant quantities of CO_3^- and (NO_2^-·H_2O), due to carbon and water impurities. There are no detectable quantities of these ions in the present system, notwithstanding the presence of carbon, NO_2^-, and at least some H_2O; water has been found to be a minor reaction product[7], and its presence here is also substantiated by the observation of an H_3O^+ peak[1,2].

A new mass spectrometer is being built to examine the discussed processes in further detail in electrical discharge flow systems of the Wood-Bonhoeffer type[1,2].

Preferential Adsorption of Long-chain Normal Paraffins on MoS_2, WS_2 and Graphite from *n*-Heptane

I REPORTED recently that cast iron[1] and graphite[2] adsorb preferentially long-chain normal paraffins from hydrocarbon solvents such as *n*-heptane or benzene. It was thought that the adsorption is relevant to effective lubrication of sliding surfaces of cast iron and graphite by mineral oils. Adsorbed films of hydrocarbons are most likely to reduce the extent to which the rubbing surfaces come into contact, under a given pressure, which would result in less transfer of solid material across the interface and, therefore, a reduced rate of wear.

It was reported in the literature that films of MoS_2 and WS_2 deposited on steel surfaces reduce their wear rates when lubricated by mineral oils[3]. These two sulphides were examined, therefore, in the flow micro-calorimeter to discover whether they also have the property of preferentially adsorbing long-chain paraffins from low-boiling solvents. The flow calorimeter used has already been described[2]. The solvent in which the adsorption was examined was *n*-heptane purified by percolation through silica gel and alumina. *n*-Heptane percolated through a bed of MoS_2 or WS_2 in the calorimeter cell and μg quantities of dotriacontane were injected into *n*-heptane. Contact between dotriacontane and graphite was accompanied by a heat effect registered by a potentiometric recorder.

MoS_2 and WS_2 used in the experiments were commercially available materials. Examination by X-ray diffraction showed that these disulphides have a high degree of crystallinity, the diffraction patterns corresponding to those of MoS_2 and WS_2. Some weak unidentified lines were present in the WS_2 pattern. The Brumauer–Emmett–Teller surface areas of the disulphides were 8·3 and 2·2 m^2/g respectively. The amount of the disulphides placed in the calorimeter was 0·15 g. Results of the preferential adsorption experiments are illustrated in Figs. 1 and 2.

It can be seen that as the amount of *n*-C_{32} that comes into contact with the disulphides increases from 2 to 40 μg the heat effects increase. This increase is approximately linear for WS_2. For MoS_2 the heat effects per unit weight of solute decrease with the amount injected. Thus, although for 2-μg quantities of *n*-C_{32} the heat effects are very similar for both MoS_2 and WS_2, the heat effects produced when 40 μg of *n*-C_{32} come into contact with the disulphides are higher for WS_2 than they are for MoS_2. These results are obtained in spite of the fact that the surface area of MoS_2 is four times that of WS_2. Thus in the calorimeter cell the total Brumauer–Emmett–Teller area available for the adsorption of *n*-C_{32} is 1·25 m^2 for MoS_2 and 0·32 m^2 for WS_2. (If all this area was available for adsorption and the adsorbed molecules lay flat on the surface, a monolayer would be formed by 75 μg of dotriacontane on WS_2.)

In separate experiments it was established that up to 40 μg of dotriacontane was adsorbed almost completely on 0·15 g of both disulphides when injected into *n*-heptane percolating through the solids. This made it possible to estimate heats of adsorption of dotriacontane on the disulphides from *n*-heptane. The results are given in Table 1. It can be seen that the heats of adsorption on MoS_2 are somewhat lower than those on WS_2. The difference is, however, small in comparison with that between the heat adsorption on graphite and WS_2 or MoS_2, the latter heats being about one-third of the heat of adsorption on graphite. This indicates that dotriacontane adheres to graphite surfaces more strongly than it does to the surfaces of the disulphides.

Table 1. Heat of Adsorption of n-Dotriacontane from *n*-Heptane on Some Solid Lubricants

Solute adsorbed (μg)	Heat of adsorption (kcal/mol)		
	Graphite	MoS_2	WS_2
2	50	12·3	12·3
10	36	10·0	12·0
20	34	10·1	12·4
40	—	7·9	12·3

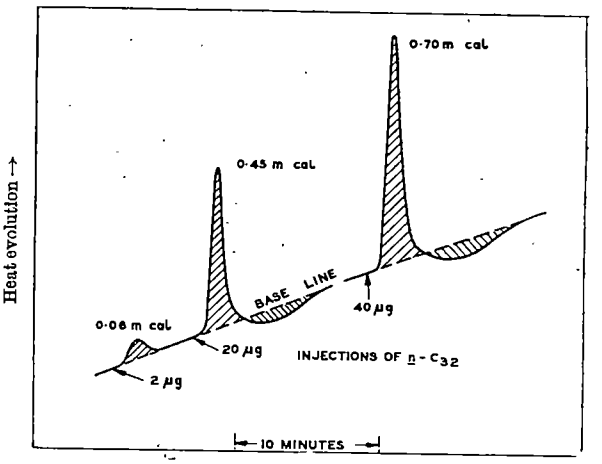

Fig. 1. Adsorption of *n*-C_{32} on MoS_2

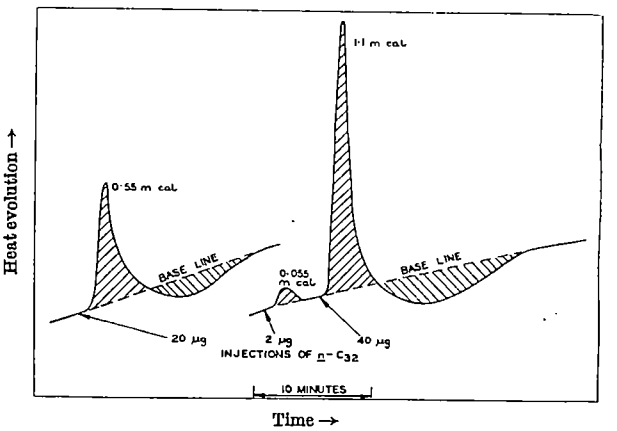

Fig. 2. Adsorption of *n*-C_{32} on WS_2

In view of the observed specific adsorption properties of graphite, MoS_2 and WS_2 and, also, the fact that these solids are reported to increase the load-carrying capacity of metal surfaces on which they are deposited, it is possible that the relatively strong tendency of long-chain hydrocarbons to adhere to the surfaces of these layered solids is an essential factor in increasing their load-carrying capacity.

It was shown by various investigations[4] that adsorption of long-chain compounds on metal surfaces in sliding contact decreases their wear and friction. This leads me to postulate that the value of graphite, MoS_2 and WS_2 in their performance as solid lubricants depends in part on their property of adsorbing tenaciously compounds with long normal hydrocarbon chains, which are usually present in mineral oils. The adsorbed hydrocarbons may be expected to reduce the frequency of solid-to-solid contact, in much the same way as the adsorption of stearic acid reduces the contacts of steel surfaces on which it is adsorbed.

3-Methylxanthosine

In view of the present-day interest in methylated purines as minor components of RNA and DNA[1], and their possible role in mutagenesis, carcinogenesis[2] and protein synthesis[3], the preparation of *N*-methylated purine nucleosides and nucleotides has attracted increased attention[4–6]. One of the aims of these investigations is to find the reactive sites of the purine bases toward alkylating agents.

With regard to methylation of xanthosine, Bredereck, Haas and Martini[7] recorded the synthesis of 1,3-dimethylxanthosine. Jones and Robins[5] prepared the 7-methyl derivative, indicating the reactivity of the N_7 position. We wish to report evidence for the formation of small amounts of 3-methylxanthosine, among other products, by the reaction of xanthosine with diazomethane. The structure of this compound was demonstrated by hydrolysis to 3-methylxanthine and D-ribose, which were identified by ultra-violet spectra and paper chromatography.

A chilled solution of diazomethane (5·5 mmole in all) in *N*,*N*-dimethylacetamide was added gradually, with stirring in the cold, to a suspension of 500 mg xanthosine in 1 ml. of the same solvent. The resulting clear solution was added to 50 ml. of cold chloroform. A precipitate formed, which was washed with cold chloroform and dried *in vacuo* (234 mg crude product).

Chromatography of an aqueous solution of the precipitate (25 mg) on a 'Dowex-1-acetate' (×8,200 mesh) column (2·5 × 66 cm) was carried out by developing and eluting with water. Collection of fractions (4·5 ml., 0·5 ml./min) began immediately after charging the column. The profile of the recorded absorbance at 260 mμ exhibited three peaks. The third peak, comprising fractions 113–150 (maximum at fraction 124), contained the presumed 3-methylxanthosine. Fraction 130 showed the absorption characteristics indicated in Fig. 1. The spectrum is similar to that reported by Pfleiderer and Nübel[8] for 3,9-dimethylxanthine, in analogy to the similarity of the spectra of xanthosine and 9-methylxanthine[8].

Hydrolysis of adjacent fraction 129, by acidifying to *p*H 1 with hydrochloric acid and heating for 2 h at 100°,

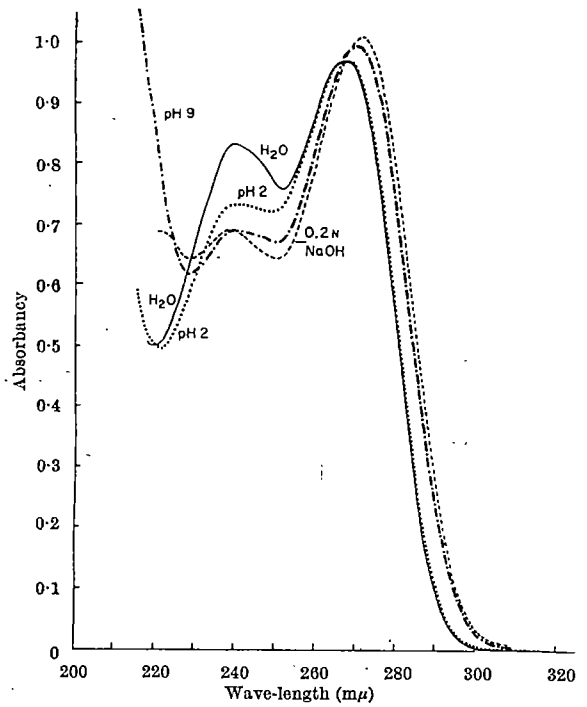

Fig. 1. Ultra-violet spectrum of 3-methylxanthosine (Fraction 130), maxima and minima (mμ): In H_2O, λ_{max} 239, 267, λ_{min} 220, 252; *p*H 2, λ_{max} 240 (*sh*), 267, λ_{min} 222, 251; *p*H 9, λ_{max} 240, 271 λ_{min} 228, 251; 0·2 N NaOH, λ_{max} 238, 272, λ_{min} 228, 250

Table 1. Comparison of Ultra-violet Spectra of Hydrolysed Fraction 129 with that of Authentic 3-Methylxanthine

	Hydrolysate (mμ) Max.	Min.	Authentic sample (mμ) Max.	Min.
*p*H 1	269	243	270	242
*p*H 9	271	245	272	245
0·2 N NaOH	273	235 (inflex)	273	235 (inflex)
		248		248

revealed an ultra-violet spectrum corresponding to that of authentic 3-methylxanthine (Table 1). The identity of the hydrolysate with 3-methylxanthine was further confirmed by R_F values in paper chromatograms. The summit of the third peak, which comprised a pool of fractions 120–128 containing the purest material, was concentrated to dryness *in vacuo* at room temperature. Half the dry material was hydrolysed in 0·1 N hydrochloric acid by heating for 2 h at 100°. The hydrolysate was concentrated *in vacuo* to a small volume, applied to Whatman No. 1 paper, and chromatographed in the following solvent systems: (I) ascending: *n*-butanol/acetic acid/water = 12 : 3 : 5 (v/v)[9]; (II) descending: *n*-butanol/*N*,*N*-dimethylacetamide/water = 2 : 1 : 1 (v/v); (III) descending: *n*-butanol/5 N acetic acid = 2 : 1 (v/v)[8] (Table 2).

The identity of the chromatographic spots obtained from the hydrolysate with 3-methylxanthine was again confirmed by the ultra-violet spectrum of the spot extract. Only one sugar spot was obtained from the hydrolysate, which was located with silver nitrate dipping reagent[9], and found to be identical with D-ribose (Table 2).

Table 2. Comparison of R_F Values of 3-Methylxanthosine Hydrolysate, 3-Methylxanthine, Xanthosine and D-Ribose in Three Solvents

R_F values	Solvents I	II	III
Authentic 3-methylxanthine	0·42	0·57	0·43
3-Methylxanthine in hydrolysate	0·43	0·55	0·44
Xanthosine	0·22	0·38	
1,3-Dimethylxanthine			0·67
Authentic D-ribose	0·33		0·28
D-Ribose in hydrolysate	0·33		0·29

Concentration of the eluate pool of fractions 120–128 was associated with considerable hydrolysis, reflected in a complete change of the ultra-violet spectrum and the appearance of spots on paper chromatograms indicating the presence of 3-methylxanthine and D-ribose.

We thank Miss Gertrude B. Elion, of Burroughs Wellcome Research Laboratories, Tuckahoe, New York, for supplying us with samples of methylated xanthines. This work was supported by U.S. Public Health Service grant *A*–162.

BIOCHEMISTRY

Effect of Amitosis on the Distribution of Human Lactic Acid Dehydrogenase Isozymes

The lactic acid dehydrogenase (LDH) of mammalian tissues exists as five isozymes[1] which have different charges, structures and biochemical properties[2]. The pattern of isozyme distribution in embryonic and adult

Table 1. Distribution of LDH Isozymes in Various Human Tissues at Different Stages of Development

Tissue	Age	Isozyme distribution* I	II	III	IV	V
Ideal binomial distribution		6·25	25	37·5	25	6·25
Skeletal muscle	Embryo	8	28	36	21	8
	Adult	3	4	7·5	9·5	76
Heart muscle	Embryo	7	27	39	19	10
	Adult	60	30	5	3	2
Œsophagus muscle	Embryo	8	22	30	25	14
	Adult	5	18	40	24	13

* Values are the percentage isozyme activity related to the total LDH activity in the tissue homogenate (ref. 5). At pH 8·6 isozyme I shows the fastest migration to the anode and isozyme V the slowest.

tissues indicates that the fertilized ovum also contains five isozymes[5] which are identical to those of all other tissues[3,4]. In embryonic tissue isozyme III is the most abundant, but with cell differentiation the relative amount of isozyme III decreases (Table 1). There exists a parallel between the shift in isozyme distribution and the increase in cell nuclei population of human heart muscle. This increase (in the last phase through amitosis) comes to an end in the left heart muscle about six months after birth but is not finished even after one year in the right heart muscle[6,8]. It was, therefore, thought that the final distribution of isozymes would be achieved earlier in the muscle of the left heart ventricle than in the muscle of the right.

The heart muscle from the right and the left ventricles of human embryos and babies was obtained approximately 10–20 h *post mortem*. The methods for the extraction of LDH, the electrophoretic separation of the isozymes and the measurement of their activities were as previously described[5]. The results (Table 2) show a constant isozyme distribution during the mitotic phase, but during the amitotic phase the isozymes in the left heart muscle approach their final distribution sooner than those of the right. Human skeletal muscle has a similar shift in isozyme distribution during the post-mitotic phase (Table 1).

Table 2. Distribution of LDH Isozymes in Heart Muscle of Human Fœtuses and Babies*

	Length (cm)	Ventricle	Isozyme distribution I	II	III	IV	V	B/A†
Mitosis	15	Right	3	19	43	28	7	0·95
		Left	5	23	36	30	5	0·93
	23	Right	5	21	43	26	5	0·95
		Left	7	25	38	23	7	1·02
	33	Right	10	28	39	21	2	1·26
		Left	10	28	44	15	3	1·3
Post-mitosis	46	Right	12	28	42	15	3	1·36
		Left	12	40	39	8	1	1·74
	47·5	Right	16	56	23	4	1	2·4
		Left	38	40	17	4	1	3·4

	60 years	Right	64	30	5	1	0	8·3
		Left	62	33	3·1	1·3	0·6	7·8

* Values are the percentage isozymes related to the total LDH activity and are the mean of 3 determinations. Lengths are from the crown of head to the heel in cm.

† Values are the result given by dividing the sum of sub-units *B* by the sum of sub-units *A*.

Each isozyme of the LDH is a tetramer. There are two types of monomers, *A* and *B*, the combinations of which result in the five isozymes (4*A*; 3*A*, 1*B*; 2*A*, 2*B*; 1*A*, 3*B*; 4*B*)[10,11]. Therefore, there must be at least two gene loci. A binomial distribution of isozymes would be expected if the monomers *A* and *B* were synthesized to the same extent. This was found to be the case for mitotic tissues (Table 1). During the post-mitotic phase more of the extreme isozymes (I and II or IV and V) are produced[9]. This could be explained by an increased synthesis of *A* or *B*. The cells are polyploid since the chromosomes multiply before the amitosis[7]. If more *A* or *B* gene loci were produced then the shift in isozyme distribution would be explicable.

Amitosis occurs only in highly differentiated, specialized cells. This should lead to an increase in efficiency[6,7]. In tissues which function *in vivo* under relatively aerobic conditions there is a preponderance of isozymes I and II and a preponderance of IV and V in relatively anaerobic tissues. For example, in skeletal muscle isozymes IV and V catalyse the production of large amounts of lactic acid under high pyruvate concentrations whereby isozymes I and II are inhibited through large amounts of lactic acid[3]. In heart muscle the synthesis of lactic acid is optimal under low pyruvate concentrations since isozymes I and II have a higher affinity for pyruvate than IV and V. It thus appears that the metabolism controls enzyme synthesis to ensure optimal utilization of available metabolites. This control could be achieved by changes in the polyploid state of the chromosomes during the post-mitotic phase[12].

This work was carried out in the Medizinische Poliklinik der Universität Mainz.

A Cryostat Method for the Extraction of Soluble Tissue Components

Established techniques used to release the intracellular components of tissues either into solution or suspension include homogenization[1,2], mincing[3], crushing[4], and ultrasonic vibration[5]. The degree of difficulty in producing tissue homogenates varies for different tissues. In the case of cellular tissues containing little connective tissue almost complete cell disruption can be obtained with any of these techniques. Hogeboom *et al.*[6] have shown that in unfiltered rat liver homogenates they were able to find only 7×10^6 intact cells/g liver as compared with 268×10^6 free nuclei. However, as the proportion of connective tissue increases, so does the work necessary to produce the same degree of cell disruption, and loss of labile cell contents generally follows as a result of prolonged exposure of the biological material to adverse physical conditions.

Perhaps the most widely used technique involves the use of a Potter–Elvehjem homogenizer[1]. There are many disadvantages to this technique, and the main ones are as follows: (*a*) Homogenization is carried out by a shearing force applied to the material for some time. The length of time necessary for complete homogenization is dependent on the type of tissue and this can lead to incomplete and non-reproducible degrees of cell membrane disruption. (*b*) Despite external cooling of the tube, the shearing force must result in localized heating which may in turn produce denaturation of the tissue components. (*c*) In order to allow the full shearing forces to develop it is necessary to reduce the viscosity of the suspension being homogenized by the addition of buffer, the volume of buffer required depending on the physical nature of the tissue. The concentration of the extract is therefore determined to some extent by the nature of the tissue.

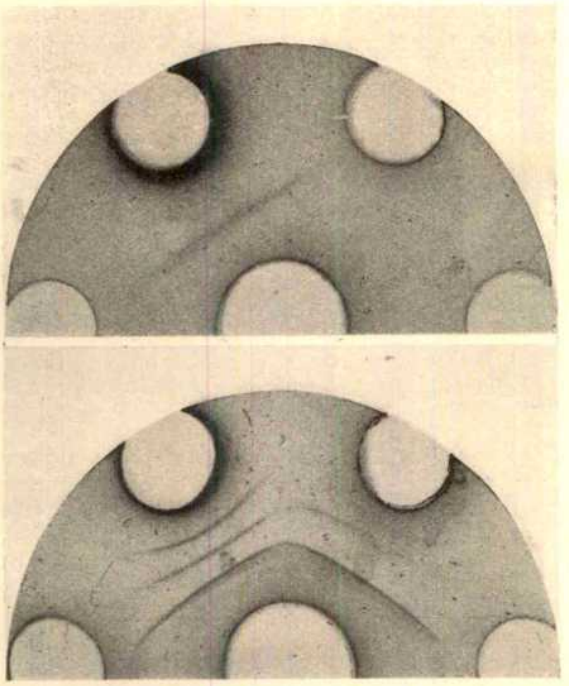

Fig. 1. Agar-gel diffusion plates of antitissue antiserum versus tissue extracts showing (*A*) an additional component, and (*B*) an increased concentration of components in the cryostat extracts. Central wells, antitissue antiserum; upper left hand well, cryostat extract; upper right hand well, Potter extract

In order to compare extracts from different tissues it is often necessary to concentrate them first—a process which can again lead to varying degrees of protein denaturation. Because of the viscosity effect one is restricted to the use of aqueous eluants and the use of organic or organic-aqueous solvents for the elution of specific cell components is precluded.

Some of these disadvantages are obviously common to the other techniques.

A very elegant steel block homogenizer, operating at temperatures below 0° C and using the freezing point depression occurring at high pressures, has been described by Ludvigsen[7]. Unfortunately the apparatus appears to be costly and its operation fairly complicated.

As a result of our preliminary attempts to use the established methods to isolate the soluble components from tissues, including human tumours, it became evident that the yields of cell components varied considerably according to the amount of connective tissue present. This made valid comparisons of the antigenic components from different specimens extremely difficult. In order to overcome this difficulty, a slicing technique, involving the use of a refrigerated microtome, has been developed which produces a degree of cell disruption at least equivalent to that of the homogenates produced by more conventional methods. The degree of cell disruption obtained was reproducible for a wide variety of tissues.

A block of the tissue, approximately 1 c.c., was frozen on to the chuck of a Cambridge rocking microtome using solid carbon dioxide. 5-μ sections of the tissue were then cut, either in a deep-freeze cabinet at −20° C or in a Bright's cryostat and collected into weighed pots. If required, sections were taken for histological or histochemical examination. After re-weighing, the pots containing the sections were stored at −20° C until required. The sectioned tissue was eluted with normal saline buffered with phosphate, *p*H 7·6 (3 ml./g sliced tissue). The slurry of tissue and buffer was either agitated gently for 3 h on a rotary mixer or left to stand overnight at 2° C. The suspension was then centrifuged at 15,000*g* for 15 min to pack down the cell debris and the clear supernatant pipetted off. The supernatants were stored at −20° C until required.

A comparison was made of the proteins present in the extracts from equal samples of the same tissues obtained by use of the cryostat, the Craigie Mincer[3], and the Potter homogenizer respectively. The extracts were adjusted to equal volumes and examined by starch-gel electrophoresis, agar-gel immunoelectrophoresis and Ouchterlony gel-diffusion technique.

Very little difference was found between the extracts prepared by the Potter homogenizer and the tissue mincer; but the cryostat extracts showed additional protein components or an increased quantity of proteins (Fig. 1). Similar extraction efficiency has been obtained with a variety of tissues, in particular human tumours.

In order to compare the degree of cell disruption produced by the Potter and cryostat techniques, smears were prepared from the tissue residues after homogenization. These smears, after fixing in Schaudinn's fluid and staining with hæmalum and eosin, were examined microscopically for the presence or absence of both free nuclei and intact cells.

Intact cells and clumps of cells were invariably present in all the Potter residues examined, while the cryostat residues only occasionally contained a few nuclei or intact cells (Fig. 2).

The advantages of this technique are summarized as follows: (*a*) Maximum cell membrane disruption was achieved. (*b*) Temperatures below 0° C were used for the homogenization. (*c*) No eluant was added until after homogenization and no restriction was made as to choice of eluant. (*d*) The homogenate could be stored. (*e*) The method required only readily available apparatus. This technique has been used with success in this laboratory for the past two years. The use of a tissue slicer for

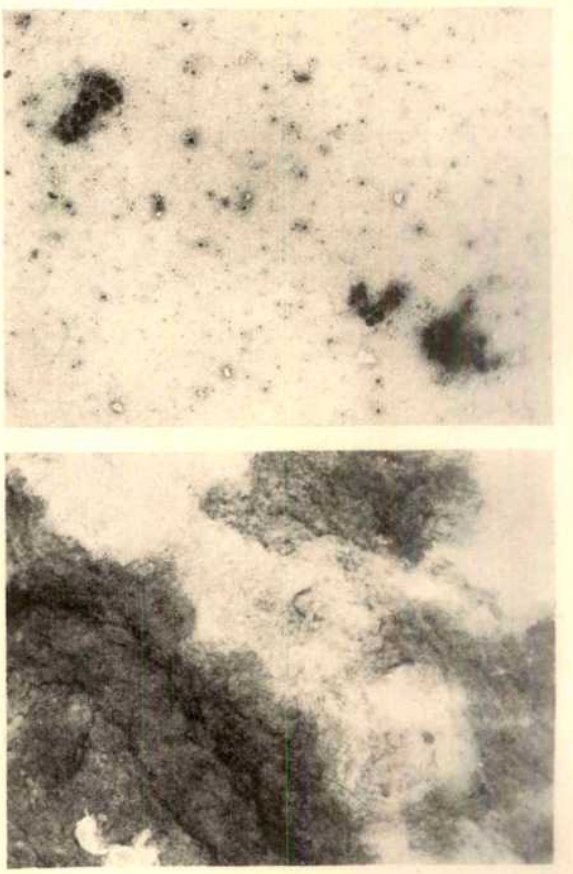

Fig. 2. Photomicrographs of tissue residue smears. (× *c.* 100.) *A*, After Potter homogenization, showing intact cells; *B*, after cryostat method, showing mainly acellular debris

tissue homogenization has been reported previously[4,8], but in this case the cells were not disrupted by sectioning but by freeze drying the slices and then bursting the cells by immersion in buffer.

Detection of Enzymes in Agar Electropherograms

To demonstrate the proteolytic enzymes in an electropherogram, Uriel *et al.*[1,2] dipped an electropherogram into a substrate solution of an appropriate *p*H and, after an incubation period of some hours, the electropherogram was stained with amido black. Light spots indicated the presence of proteolytic enzymes. In their immunological work, Raunio and Gabriel[3] used a second slide covered with substrate in agar to find the precipitation lines that had proteolytic activity. Here, too, the disappearance of substrate through enzymatic activity is demonstrated by staining the protein. With these publications in mind, we developed a simple and rapid method for localizing enzymatic activities in agar electropherograms.

We carried out the electrophoresis of a protein extract on a microscope slide. The substrate solution in 1 per cent agar was poured on to a second slide. After electrophoresis the slide with the agar substrate gel was placed, with the gel layer down, on to the electropherogram. After an incubation time of 5–20 min, at 37° C, the two slides were separated and the remaining substrate was precipitated by an appropriate fixing agent. Transparent spots indicated where enzymatic activity had occurred.

The advantage of precipitating rather than staining the substrate lies in the possibility of constantly observing the process. A short fixation only precipitates the uppermost layer of the substrate gel and thus reveals even very slight activity. On the other hand, the narrowing of the transparent spots after a long fixation time allows a more exact localization of the stronger enzymatic activities.

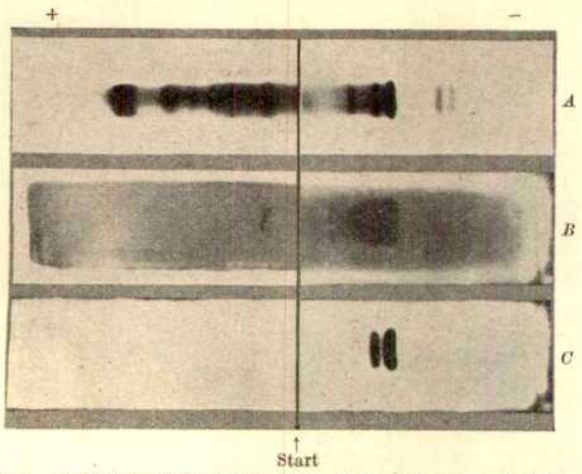

Fig. 1. *A*, The stained electropherogram of rat pancreas extract electrophoresis on microscope slides, covered with 2 ml. 1 per cent agarose in veronal buffer *p*H 8·6 ($\mu = 0{\cdot}033$), 35 min, 18 m.amp (approx. 20 V/cm); *B*, the substrate slide, after 5 min fixation in ethanol-acetic acid; *C*, the substrate slide, after 30 min fixation

This method can be used for the demonstration of several enzymes. It has been applied to the localization of amylase in electropherograms of a rat pancreas extract. The extract was obtained by grinding rat pancreas with sand under 0·14 M NaCl in a mortar. The extract was concentrated and subjected to electrophoresis on agarose[4] in a veronal buffer, *p*H 8·6.

For the substrate slide, 1 ml. 1 per cent hydrolysed starch in 1 per cent agar in the same buffer was used and after 15 min incubation at 37° C the starch was precipitated by immersing the slide in 70 per cent ethanol containing 5 per cent AcOH.

The presence of amylase activity is betrayed by the transparent spots on a milky white background, as seen in Fig. 1.

Three components with amylase activity could be distinguished in the rat pancreas extract. One of them occurred in such a low concentration that its effect was only visible after a short fixation time. The transparent spot disappeared after a prolonged fixation time.

This method, which can easily be adapted to the detection of other enzymes because of its flexibility, has helped us to locate proteolytic enzymes and nucleases. In the latter case, we used 0·5 N HCl as the precipitant.

A New Mould D-Amino-acid Oxidase

D-amino-acid oxidase has been found in mammalian tissues[1], bacteria[2,3] and moulds[4–7], and the enzyme has been used for many purposes, such as the determination of D-amino-acids, the optical resolution of DL-amino-acids and the preparation of α-keto acids.

On D-amino-acid oxidase from moulds, the constitutive existence of its activity has been reported in *Neurospora crassa* by Horowitz[4], in *Neurospora sitophila* by Burton[5] and in *Penicillium chrysogenum* by Emerson *et al.*[6]. Besides these reports, adaptive formation of D-glutamic acid oxidase activity, which also exhibits some activity towards D-aspartic acid in *Aspergillus ustus*, was reported by Mizushima *et al.*[7].

We also investigated extensively the D-amino-acid oxidase activity in moulds and found that an enzyme activity, which is highly active towards a wide variety of D-amino-acids, was formed in *Aspergillus flavus* and *parasiticus*.

The screening experiment of the moulds which could utilize D-amino-acids was carried out first. To the basal medium containing 2 per cent glucose, 0·2 per cent K_2HPO_4 and 0·1 per cent $MgSO_4 \cdot 7H_2O$, was added D-methionine, D-phenylalanine, D-tryptophan or D-valine as a sole source of nitrogen at a final concentration of 0·5 per cent. 43 typical strains of moulds were cultured with shaking at 30° for 3–6 days in test-tubes containing the foregoing screening media. Most of the tested moulds grew by utilizing the D-amino-acids.

Oxidase activity towards several D-amino-acids of the 8 strains, which showed better growth among those tested, was measured by a Warburg manometer. As a result, *Aspergillus flavus* and *parasiticus* were found to show the highest activities.

Thus with these two moulds, cultural conditions for the formation of D-amino-acid oxidase were investigated. Cultures of the moulds were prepared in 500-ml. shaking flasks containing 100 ml. of the respective media prepared by supplementing 0·2 per cent L-, D-, or DL-

amino-acids to Czapek medium, *S*–9 medium (2 per cent glucose, 2 per cent corn steep liquor, *p*H 5·0), and *S*–10 medium (2 per cent glucose, 2·5 per cent 'Pharmamedia' (Traders' Protein Division, Traders' Oil Mill Co., Fort Worth, Texas), *p*H 5·0). After 3–4 days culture at 30° on a reciprocal shaker, the mycelia were collected, homogenized, extracted with water, and the supernatant solution was used as cell-free extracts for the assay of oxidase activity.

Table 1. Effect of D-Amino-acids and DL-Amino-acids on the Production of D-Amino-acid Oxidases

D-Asp	0·8	0
Gly	0·4	0·3
L-Amino-acids	0	0

Conditions of enzyme assay were the same as described in Table 1.
*Uptake of oxygen *μ*l./h/mg of dry mycelia.
†*A. flavus* grown on *S*–9 medium containing DL-alanine.
‡*A. parasiticus* grown on Czapek medium containing D-valine.

As shown in Table 1, higher D-amino-acid oxidase activity was observed in the media containing D- or DL-amino-acids, although the activity was scarcely detected in the case of no addition or the addition of L-amino-acids. In *S*–9 medium, however, some activity was formed without the addition of D-amino-acids. This may be due to the presence of partially racemized amino-acids and/or glycine in corn steep liquor. The results suggest that the D-amino-acid oxidases of *Aspergillus flavus* and *parasiticus* are a kind of adaptive enzyme.

Using the cell-free extracts of *Aspergillus flavus* and of *Aspergillus parasiticus*, oxidative activities towards a number of D- and L-amino-acids were measured manometrically to compare their specificities.

As shown in Table 2, both preparations showed similar specificity. The D-isomers of neutral and basic amino-acids are readily oxidized, while acidic amino-acids and glycine are oxidized slowly or not at all. None of the L-isomers of all tested amino-acids was susceptible.

Judging from its higher activity, inducible nature and substrate specificity, the present enzyme activity appears to be quite different from any other previously known D-amino-acid oxidases from moulds[4–7] (summarized in Table 3).

Several enzymatic properties were examined with the enzyme from *Aspergillus flavus*. Although optimum *p*H varies to some extent according to the amino-acids and buffer solutions, it is situated at 8·0–9·5 in most cases. Reaction velocity attains its maximum at 47° C, and beyond this point the velocity decreases rapidly. The activity is inhibited by heavy metal ions, Ag^+ and Cu^{++}, monoiodoacetic acid, potassium cyanide and 2,4-dinitrophenol. The Michaelis constant is $2{\cdot}1 \times 10^{-3}$ M for D-valine, $2{\cdot}2 \times 10^{-3}$ M for D-phenylalanine, $4{\cdot}8 \times 10^{-3}$ M for D-lysine and $1{\cdot}1 \times 10^{-3}$ M for D-glutamine.

A Selective Reagent for the Study of Base Sequence in Nucleic Acids

Some time ago, we proposed an electron microscopic procedure for the determination of the sequence of bases in nucleic acids[1]. This method requires that electron-dense, base-specific groups be attached to the nucleic acid molecule. On examination in the electron microscope, the visible electron-dense groups indicate the positions of those bases to which they are specifically attached.

It was shown that 8-amino-1,3,6-naphthalenetrisulphonic acid can be attached to DNA by a diazocoupling

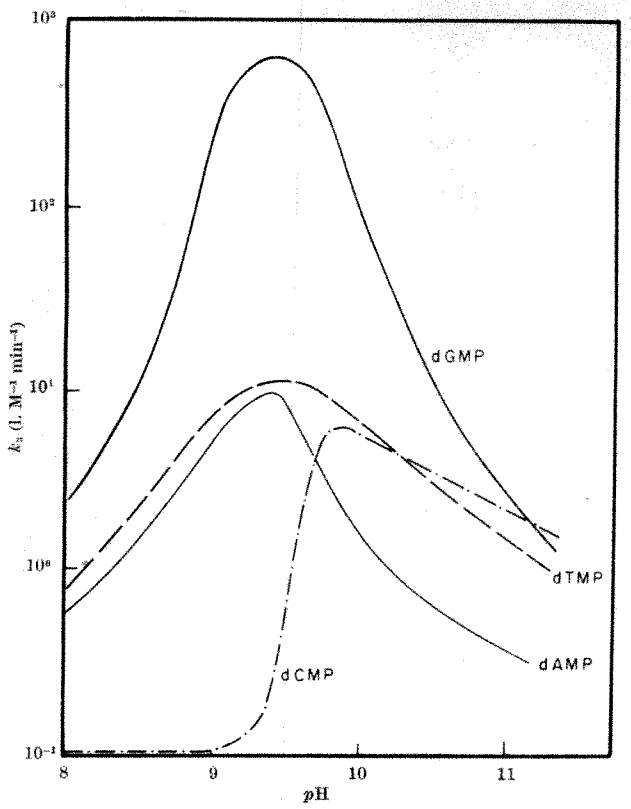

Fig. 1. Rate constants of reaction of diazotized 2-amino-1,4-benzenedisulphonic acid with the deoxyribonucleotides between *p*H 8 and 11

reaction and that, after staining with uranyl salts, it is detectable in the electron microscope. Here we report our results on the chemical specificity of a similar though somewhat smaller marker: diazotized 2-amino-1,4-benzenedisulphonic acid. The reactions of this reagent with the deoxynucleotides were investigated in aqueous solution at *p*H values from 7 to 11. The rate of coupling was inferred from the rate of disappearance of diazonium salt in the presence of the nucleotide. The concentration of unused diazonium salt was determined colorimetrically on addition of excess β-naphthol. Assuming second-order kinetics for the reactions, rate constants were calculated for all the nucleotides. These are given in Fig. 1.

It is clear that at *p*H 9 the reaction is highly *G* specific.

A fuller report of this work will be published elsewhere. This work was supported by National Institutes of Health grant *RG* 08968. We thank Dr. F. H. White for his assistance.

Beta-Galactosidase of *Helix pomatia*

The digestive juice of *Helix pomatia* contains a remarkable number of enzymes; many of them are carbohydrases, and they include an enzyme that hydrolyses lactose or β-methyl-galactoside[1,2]. This communication describes the properties and activities of the enzyme that hydrolyses *o*-nitrophenyl-β-D-galactopyranoside (ONPG).

Digestive juice was stored at 2° C with no added antiseptic and was diluted before use. Liberation of *o*-nitrophenol from ONPG, in 0·2 M Na_2HPO_4–0·1 M citric acid buffer, was measured as described by Conchie *et al.*[3]. The effect of *p*H on the rate of hydrolysis was determined over the *p*H range 2·2–8·0 (Fig. 1). The *p*H optimum was 5·3, a higher value than that for other galactosidases (4·5 for plant glycosidases[4]; 3·6 for mammalian glycosidases[3]). The optimum *p*H was the same for each of two substrate concentrations (2·5 mM and 6·0 mM).

The effect of various substrate concentrations on the reaction velocity was investigated at *p*H 5·3 (Fig. 2). The limiting velocity was never attained, and there was no indication of inhibition by excess of substrate. Fig. 3 shows the variation in activity with enzyme dilution (the amount of substrate split in unit time increased linearly with the amount of enzyme, up to 30 per cent hydrolysis of the substrate), and Fig. 4 shows the variation in activity with time of action. The rate was unchanged for an incubation period of up to 2 h, after which there was some

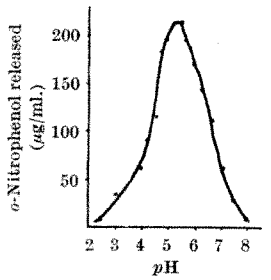

Fig. 1. Effect of *p*H on the rate of hydrolysis of *o*-nitrophenyl-β-D-galactoside (6·0 mM) in phosphate-citrate buffer; juice dilution 1/7,000, 1 h; 37° C

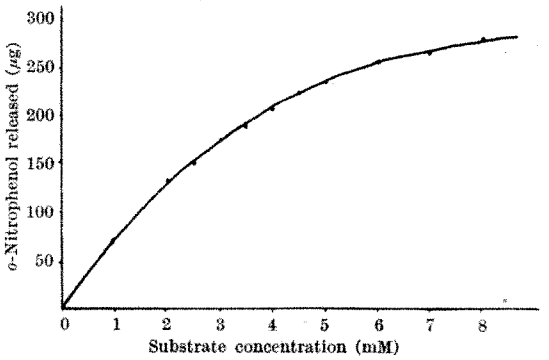

Fig. 2. Effect of varying the substrate concentration on the rate of hydrolysis of ONPG in phosphate-citrate buffer *p*H 5·3; juice dilution 1/6,000, 1 h; 37° C

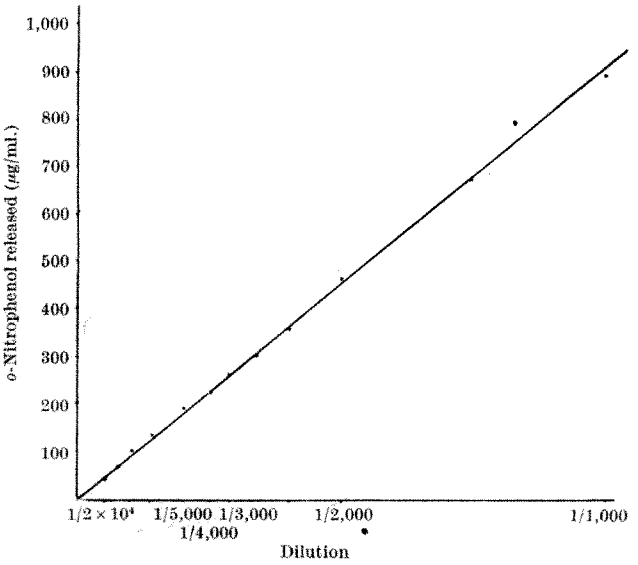

Fig. 3. Variation of β-galactosidase activity with amount of enzyme; 2·5 mM ONPG, *p*H 5·3, 1 h; 37° C

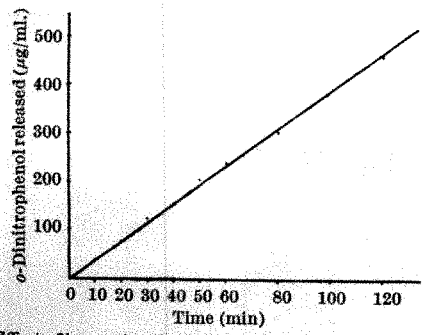

Fig. 4. Effect of increasing the period of incubation on the hydrolysis of 6 mM ONPG, *p*H 5·3, 37° C

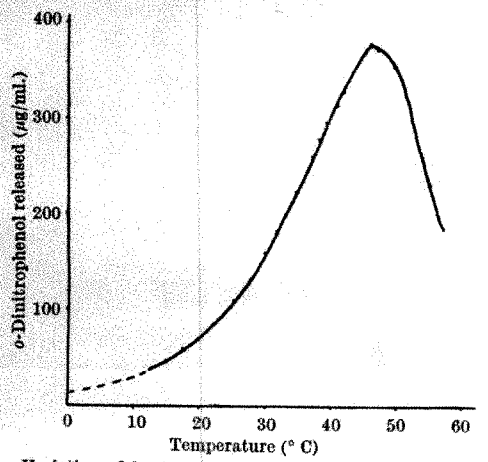

Fig. 5. Variation of β-galactosidase activity with temperature; 6 mM ONPG, *p*H 5·3, 10 min; 37° C, *p*H 5·3; juice dilution 1/1,000

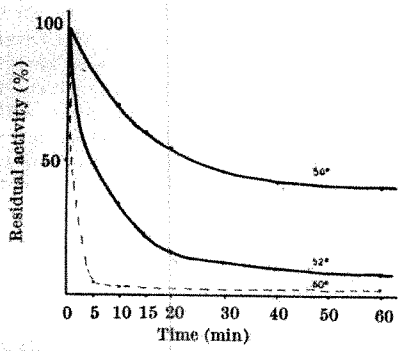

Fig. 6. Residual activity of β-galactosidase after varying period of pre-incubation at 50° C, 52° C and 60° C; *p*H 5·3

inactivation. With a 1/500 juice dilution and 6·0 mM substrate concentration, 90 per cent of ONPG was hydrolysed in 7 h, at *p*H 5·3 and 37° C.

Fig. 5 illustrates the variation in activity with temperature. Inhibition occurred at 50° C. Partial heat inactivation is plotted in Fig. 6, the enzyme being pre-incubated for various times in the absence of substrate at 50° C, 52° C and 60° C, at *p*H 5·3.

The rat epididymis is among the richest known sources of β-galactosidase[3]. It is difficult to compare results expressed as μg *o*-nitrophenol released per g moist tissue (47,000) and per ml. digestive juice (1,500,000), but the enormously high activity of β-D-galactosidase in the digestive juice of *Helix pomatia* makes this a most convenient source of the enzyme.

Tryptophan Modification in Polypeptide Chains

It is known that tryptophan in proteins is completely destroyed during acid hydrolysis or performic oxidation of disulphide bridges[1]. Our purpose is to remove some difficulties that occur during sequential investigations of tryptophan-containing polypeptides and proteins.

In previous work[2] it was shown that ozone treatment in formic acid at room temperature converted tryptophan, methionine, cystine and tyrosine, respectively, to N'-formyl-kynurenine, methionine sulphone, cysteic acid and aspartic acid. In the same conditions all the other amino-acids were stable. In the present work we have investigated the selectivity of ozone oxidation towards the aforementioned amino-acids. When ozone is allowed to bubble slowly through an equimolecular solution of tryptophan, methionine, cystine and tyrosine in formic acid at 8° C, the observed order of reactivity is:

tryptophan > methionine > cystine > tyrosine

In an attempt to minimize the extent of the oxidation of tyrosine we have examined the utilization of some aromatic compounds. We have found that in the presence of resorcinol the oxidation of cystine and of tyrosine begins with a delay proportional to the quantity of resorcinol added (Fig. 1). In a typical experiment we have interrupted the ozone oxidation of a 10^{-2} M solution of tryptophan, methionine, resorcinol, cystine and tyrosine after complete disappearance of tryptophan followed spectrophotometrically at 283 mμ. The reaction mixture was analysed according to Spackman, Stein and Moore[3] after removal of formic acid and deformylation of N'-formyl-kynurenine[2]. The results are shown in Table 1.

Table 1. Products of Selective Ozonization of a Mixture of Oxidizable Amino-acids in Formic Acid at 8° C with Resorcinol added

Compound	Recovery after ozonization (%)	Products from ozonization	Yield (%)
Tryptophan	0	Kynurenine*	96
Methionine	0	Methionine sulphoxide	97
Cystine	93	Cysteic acid	5
Tyrosine	100	—	—

* Kynurenine emerges as a separate peak on the effluent curve before lysine.

It is clear that the resorcinol allows a quantitative conversion of tryptophan and methionine to kynurenine and methionine sulphoxide while tyrosine and cystine are quantitatively recovered.

In another experiment, after ozone oxidation until tryptophan had completely disappeared, we have added performic acid at 0° C as described by Hirs[4] and analysed the mixture again according to Spackman, Stein and Moore[3]. In Table 2 are shown results concerning recovery of kynurenine and tyrosine after performic oxidation, with conversion of cystine to cysteic acid and methionine sulphoxide to methionine sulphone.

Table 2. Products from Selective Ozonization of Oxidizable Amino-acids in Formic Acid at 8° C with Resorcinol added and further Performic Oxidation at 0° C

Compound	Recovery after oxidation (%)	Products from oxidation	Yield (%)
Tryptophan	0	Kynurenine	94
Methionine	0	Methionine sulphone	95
Cystine	0	Cysteic acid	92
Tyrosine	97	—	—

In peptides of tryptophan the conversion

$$\text{tryptophan} \xrightarrow{O_3} \text{kynurenine}$$

takes place without break-down of peptide bonds[5]. We suggest that such a conversion in a polypeptide chain could be used: (1) for the analytical determination of tryptophan in proteins by acid hydrolysis (since kynurenine is stable in such conditions); (2) for the performic oxidation of —S—S— bridges in polypeptide chains containing tryptophan; and (3) for the synthetic preparation of unknown kynurenine peptides from corresponding peptides of tryptophan.

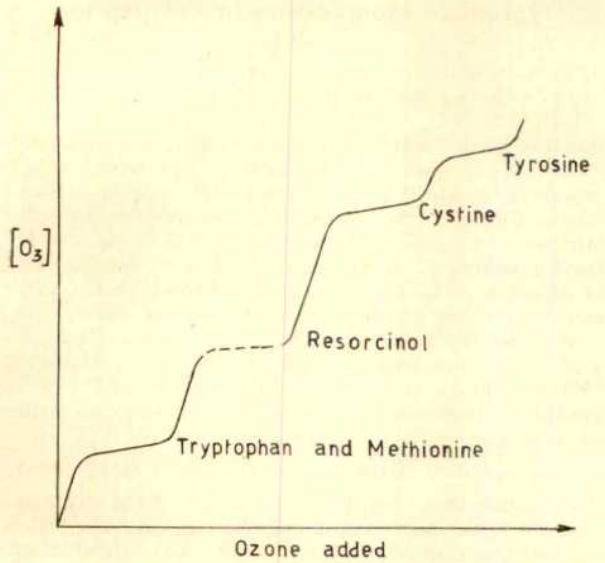

Fig. 1. Hypothetical increase of ozone concentration as a function of oxidizable amino-acids and resorcinol

The selective oxidation of the aforementioned amino-acids could be conveniently used to investigate the biological activity of modified polypeptides and proteins.

An Inhibitory Substance present in Milk

During investigations into the efficiency of ultra-high-temperature sterilizing plants, Franklin *et al.*[1] observed that the test organism, a strain of *Bacillus stearothermophilus*, was inhibited by the heated milk. Inhibition became apparent when comparisons were made between the recoveries obtained from direct plate counts and from dilution counts in which the ultra-high temperature sterilized milk was used as diluent; a similar but weaker effect on *B. subtilis* spores had been previously noted by Franklin *et al.*[2].

a *b*

Fig. 1. (*a*) Zones of inhibition from *R*, raw milk, and in a clockwise direction, milk heated to 80° for 20 min, to 80° for 60 min, to 90° for 20 min and to 90° for 60 min. (*b*) Zones of inhibition obtained with factors prepared from milk. *R*+, obtained from raw milk, and in a clockwise direction, from milk heated to 80° for 20 min, to 80° for 60 min, to 90° for 20 min and to 90° for 60 min

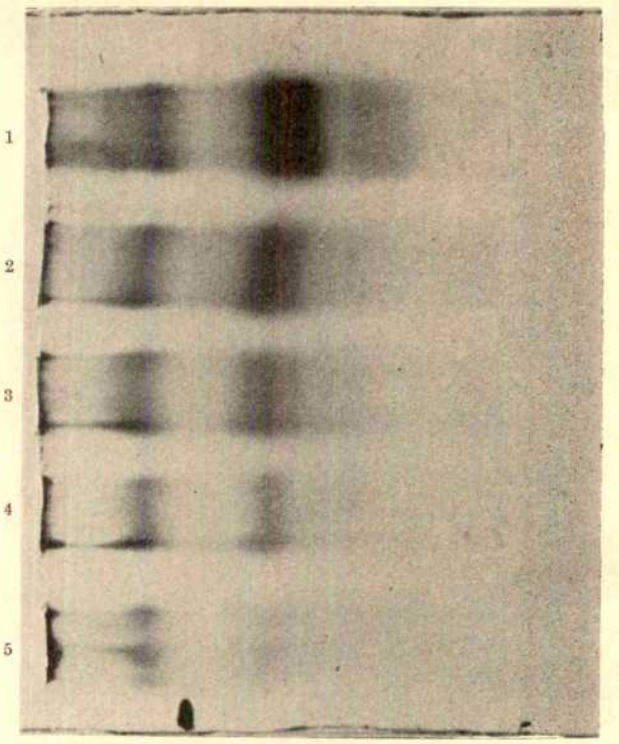

Fig. 2. Electrophoresis patterns of inhibitory material prepared from milk samples as described in text. (1) From raw milk; (2) from milk heated to 80° for 20 min; (3) from milk heated to 80° for 60 min; (4) from milk heated to 90° for 20 min; (5) from milk heated to 90° for 60 min. The anode is on the right

In a preliminary communication Jayne-Williams[3] reported that the inhibitory factor(s) occurred also in raw, pasteurized and dried milk and were active against 23 out of 60 strains of thermophilic spore-formers tested. The material was shown to be associated with the 30 per cent $(NH_4)_2SO_4$ precipitate obtained from milk serum at *p*H 6·5, to be stable to heat and low *p*H and to maintain activity in the presence of sulphydryl compounds. The stability of the factor(s) to heat is demonstrated in Fig. 1(*a*). The extent of inhibition against *B. stearothermophilus* was the same for material obtained from raw skim milk and from milk heated at 80° for 20 and 60 min and at 90° for the same times. Autoclaving at 121° for 15 min, however, destroyed the activity.

It has been shown recently that the factor(s) can be obtained in good yield by the following technique. Skim milk is acidified with concentrated H_2SO_4 to 0·2 N; the precipitate formed is removed by centrifuging and ethyl alcohol is added to the supernatant to a final concentration of 20 per cent (v/v). The precipitate which forms on standing overnight at 4° is removed by centrifuging, re-dissolved in water and the *p*H adjusted to 6·5–7·0 with N NaOH. The activity of the material obtained in this way from raw milk and the same milk heated as outlined above is shown in Fig. 1(*b*). The material was concentrated five-fold compared with the original milk.

The factor(s) is not dialysable, separates with the milk protein on filtration on 'Sephadex *G*–25' and loses activity rapidly on treatment with trypsin or chymotrypsin. Activity is also lost in the presence of $FeSO_4$ (*c.* 0·02 M) and to a lesser extent in the presence of $MgSO_4$.

Analysis of the amino-acids present after acid hydrolysis of material derived from skim milk heated at 90° for 60 min

revealed no exceptional amounts of either acidic or basic amino-acids.

Electrophoretic patterns of the material are shown in Fig. 2. Separation was performed in 7·5 per cent polyacrylamide gels with 0·005 M *tris*-citrate buffer (*p*H 7·0) for 5·5 h at 300 V. The protein was afterwards stained with amido black. The effect of heating is to reduce the quantity of faster-moving major components but to leave a slower-moving component unaltered. There is some indication that activity is associated with this slower-moving fraction but, as only part of the initial activity was recovered from this zone, it may be that other components, as yet not determined, contribute either singly or synergistically to the total activity.

PHYSIOLOGY

Derivation of the Partial Differential Equations utilized in a Model describing the Na Concentration Profile in the Renal Medulla

THE purpose of this communication is to derive the partial differential equations and to clarify the mathematical details described in connexion with a model used to obtain the sodium concentration profile in the renal medulla[1]. An elementary operating unit of the model is shown in Fig. 1. A generalized segment of a vascular or tubular channel is shown in the top half of Fig. 2. Consider the case where fluid moves in a direction from left to right, corresponding to motion in the descending limbs of the vas rectum or the Henle loop. The net change of sodium concentration ΔC(g/cm³) in the differential volume element of length ΔX shown is given by equation (1).

$$\Delta C_m A_m \Delta X = \Delta t U_m A_m [C_m|_x - C_m|_{x+\Delta x}] + \delta_m \Delta X \Delta t (J - C_m) \quad (1)$$

A_m is the cross-sectional area of the tubule in cm², J is the interstitial concentration of sodium, and δ_m is a membrane constant of dimension cm²/sec. U_m is the magnitude of the rate of flow of fluid in the channel in cm/sec. Δt is a differential element of time (sec). The subscript m may be used to refer to a particular channel. In the original work, C was the concentration in the descending limb of the vas rectum, C' that in the ascending limb of the same element, C_h the concentration in the descending limb of the Henle loop, and C'_h the concentration in the ascending limb of the loop of Henle. It is assumed that δ is the membrane constant throughout the vas rectum, δ_h the constant in the thin segment of the Henle loop and δ'_h the appropriate constant in the thick segment of the Henle loop. Passing to the limit as Δt and ΔX both approach zero, the defining partial differential equation (2) is obtained.

$$\frac{1}{U_m}\frac{\partial C_m}{\partial t} = -\frac{\partial C_m}{\partial X} + \frac{\delta_m}{U_m A_m}(J - C_m) \quad (2)$$

For fluid moving in the ascending limbs, equation (1) becomes:

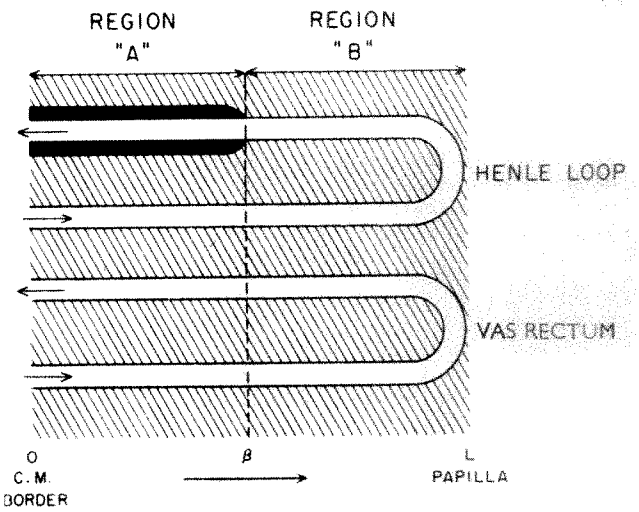

Fig. 1. Elementary operating unit

$$\Delta C_m A_m \Delta X = \Delta t U_m A_m [C_m|_{x+\Delta x} - C_m|_x] + \delta_m \Delta X \Delta t (J - C_m) \quad (3)$$

producing partial differential equation (4) in its limit:

$$\frac{1}{U_m}\frac{\partial C_m}{\partial t} = \frac{\partial C_m}{\partial X} + \frac{\delta_m}{U_m A_m}(J - C_m) \quad (4)$$

The thick segment of the ascending limb of the Henle loop, which is the only portion in which active transport of sodium is assumed to occur, produces the difference equation (5), and partial differential equation (6).

$$\Delta C'_h A_h \Delta X = \Delta t U_h A_h [C'_h|_{x+\Delta x} - C'_h|_x] - \delta'_h \Delta X \Delta t C'_h \quad (5)$$

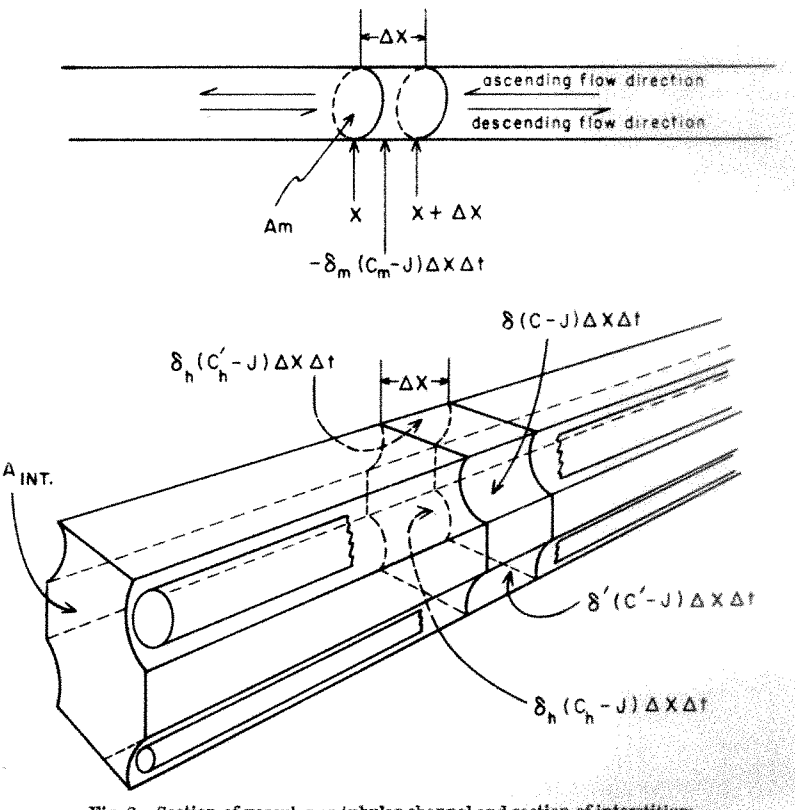

Fig. 2. Section of vascular or tubular channel and section of interstitium

$$\frac{1}{U_h}\frac{\partial C'_h}{\partial t} = \frac{\partial C'_h}{\partial X} - \frac{\delta'_h}{U_h A_h} C'_h \qquad (6)$$

The equation for the interstitium may be derived as follows: Consider a differential element of length ΔX as shown in the lower half of Fig. 2. In this case there is no fluid motion across the faces parallel to the channel directions, but only diffusion across the channel boundaries, into the interstitial region as shown in the figure. The net change of sodium concentration J in the element, neglecting longitudinal diffusion, is:

$$\Delta J A_{\mathrm{INT}} \Delta X = \Delta X \Delta t[\delta(C-J) + \delta(C'-J) + \delta_h(C_h-J) + \delta_h(C'_h-J)] \qquad (7)$$

for the region in which the ascending limb of the Henle loop is thin, and (8) where it is thick-walled.

$$\Delta J A_{\mathrm{INT}} \Delta X = \Delta X \Delta t[\delta(C-J) + \delta(C'-J) + \delta_h(C_h-J) + \delta'_h(C'_h)] \qquad (8)$$

The corresponding partial differential equations become:

$$\frac{\partial J}{\partial t} = \frac{1}{A_{\mathrm{INT}}}[\delta(C-J) + \delta(C'-J) + \delta_h(C_h-J) + \delta_h(C'_h-J)] \qquad (9)$$

$$\frac{\partial J}{\partial t} = \frac{1}{A_{\mathrm{INT}}}[\delta(C-J) + \delta(C'-J) + \delta_h(C_h-J) + \delta'_h(C'_h)] \qquad (10)$$

These equations, along with the boundary conditions that the solutions must match where physically realizable, that is, at turning points of tubes, etc., and that the concentrations of sodium at the input to the Henle loop and vas rectum are equal, can readily be evaluated to obtain the time-dependent solution of sodium concentration in the medulla, and are at present being solved by us.

The time-independent solution, reported on previously[1], is obtained from the foregoing partial differential equations by passing to the limit as time approaches infinity for a given set of input boundary conditions. This effectively makes all time differentiation terms zero, producing the time-independent equations utilized previously, with the following additional manipulation. Equation (9) is solved for J (in the time-independent case). The equation is differentiated with respect to X as shown:

$$\frac{\partial J}{\partial X} = \frac{1}{2(\delta+\delta_h)}\left[\delta\frac{\partial C}{\partial X} + \delta\frac{\partial C'}{\partial X} + \delta_h\frac{\partial C_h}{\partial X} + \delta_h\frac{\partial C'_h}{\partial X}\right] \qquad (11)$$

The values for the partial derivatives are obtained from the time-independent equations (2) and (4) utilizing appropriate values for the subscript m to denote which channel (vas rectum or Henle loop, ascending or descending) is utilized, giving equation (12).

$$\frac{\partial J}{\partial X} = \frac{1}{2(\delta+\delta_h)}\left[\frac{\delta^2}{AU}(J-C) - \frac{\delta^2}{AU}(J-C') + \frac{\delta^2_h}{A_h U_h}(J-C_h) - \frac{\delta^2_h}{A_h U_h}(J-C'_h)\right] \qquad (12)$$

In addition, the condition of equilibrium may be written as equation (13):

$$UC_0 + U_h C_{h0} = UC'_0 + U_{hh}C'_0 \qquad (13)$$

The subscript zero refers to concentrations at the cortico-medullary boundary. C_0 and C_{h0} were set equal.

A similar result is obtained from equation (10) for the thick segment. These equations were the actual ones utilized in the initial work. The 'catch-all' notation (which included the direction of the flow in the channels) utilized in the initial article may have introduced difficulty and it is hoped that the preceding derivation will help to clarify the results previously obtained.

Hepatic Pyrogen and Cortisone-antipyresis in Canine Endotoxin Fever

The pathogenesis of endotoxin fever has been much elucidated since the observation of the appearance in the serum of a fever-producing substance (endogenous pyrogen) after endotoxin[1]. The transient profound leucopenia which follows the intravenous injection of endotoxin has been cited in support of the idea that leucocytes are a source of endogenous tissue pyrogen. These observations on rabbits were further extended by Petersdorf and Bennett[2,3], who made their observations on dogs. However, these authors pointed out that under certain conditions the leucopenic response to endotoxin could not be correlated with the appearance of endogenous serum pyrogen and that the dissociation of the febrile response and levels of endogenous serum pyrogen was observed. This was noticed especially when endotoxin was given on successive days. Development of endogenous pyrogen markedly decreased on the second day, despite the full febrile and the leucopenic response.

Here, attention should be directed to the species differences in the febrile and the leucocytic response to endotoxin in dogs and rabbits[4]. In dogs, contrary to rabbits, the leucocytic response to endotoxin remains almost unaltered in the endotoxin tolerant state induced by daily administration of increasing doses of endotoxin, though the febrile response becomes markedly reduced. In the case of dogs there is no intimate relation between the initial leucopenic response and the fever. Moreover, after adrenalectomy the febrile response becomes markedly intensified and its latency is shortened when maintained with DCA, and the animals become extremely susceptible to endotoxin and succumb easily to collapse. Thus in dogs, contrary to rabbits, the febrile response seems to have a close correlation with the endotoxin intoxication and might be regarded as one of the signs of the endotoxin intoxication. The extreme susceptibility to endotoxin after adrenalectomy in dogs is attributed to the intensification of the metabolic response of liver to endotoxin after taking up endotoxin in its reticuloendothelial cells[5,6]. The liver glycogen becomes depleted almost completely within 1 h after endotoxin, and the liberation of an endogenous 'shock-inducing factor' from the liver follows, which can be proved also by passive transfer technique. Thus supposition will be made that the endogenous pyrogen in dogs might be liberated also from the liver as the result of the hepatic metabolic responses to endotoxin. This was tested as follows.

One hour after inoculation of commercial typhoid-paratyphoid vaccine (0·4 ml./kg, intravenously), blood was drawn for passive transfer test and the liver was removed under 'Nembutal' anæsthesia. The liver was cut into slices about 1 mm thick and soaked in physiological saline solution of about equal weight containing antibiotics (penicillin *G* 4,000 u., streptomycin 0·05 g in 100 ml.) and kept overnight at 4° C. The supernatant, after removing cellular debris by centrifugation, was given intravenously to the extent of 10 ml./kg to dogs which had been made tolerant to endotoxin beforehand. The recipients were also tested by cross-match blood test in order to avoid the homologous

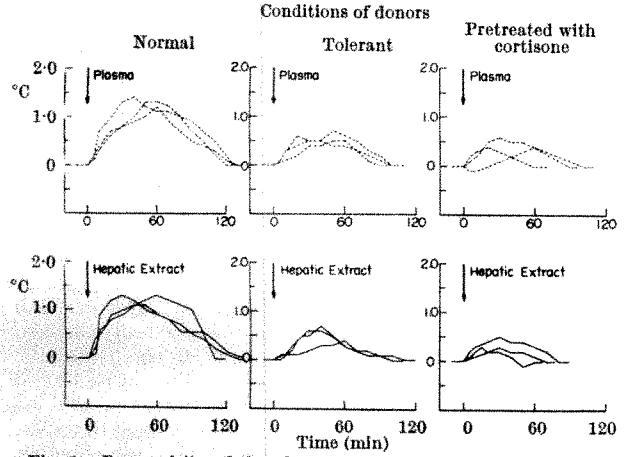

Fig. 1. Pyrogenicity of the plasma and the hepatic extract of dogs inoculated with endotoxin. Tested on normal recipient dogs, the condition of the inoculated donors varied as noted

blood syndrome[7]. As shown in Fig. 1, after infusion of the hepatic extract the rectal temperature immediately began to rise and after reaching a peak within 60 min declined slowly to the initial level.

Leucocyte counts made 15, 30, 60 and 120 min after the infusion showed no significant changes. This clearly indicated that the febrile response induced was not due to the endotoxin itself or some other macromolecular substances liberated in the extract. Saline extract of liver slices of non-inoculated dogs did not show any thermogenicity. Thus it is certain that the liver forms an easily extractable pyrogenic factor after taking up endotoxin in its reticuloendothelial cells.

This pyrogenic factor was found to be heat-unstable and lost its thermogenicity when heated at 56° C for 30 min. As shown in the same figure the passive transfer of the plasma (10 ml./kg) made the day before on the same recipients induced quite similar febrile responses. Thus the transferable endogenous pyrogen after endotoxin in dogs seemed to be due to the liberation of the hepatic pyrogen *in vivo*.

When the febrile response to vaccine was markedly reduced after making dogs tolerant to endotoxin by administering increasing doses of endotoxin (10–200 μg/kg *Salmonella typhosa*, Difco) in one week, the extractable pyrogenic factor in the liver and the plasma pyrogen after vaccine were both markedly reduced as shown in Fig. 1. The tolerant dogs, however, could show full febrile response on infusion of the effective hepatic extract. Thus the tolerance in fever response might result from the absence of the development of the hepatic pyrogen. The latter seemed to be due to the lessening of the hepatic metabolic response in tolerance[6,8].

Petersdorf and Bennett[3] have reported a puzzling result concerning the antipyretic effect of glucocorticoids. Three dogs given 50 mg of prednisone intravenously 1 h before, at the time of, and 1 h after the administration of 3 ml. of commercial typhoid vaccine developed transferable serum pyrogen, although the donor fever responses were suppressed. This was never the case when glucocorticoids of moderate doses were given more chronically. When cortisone (5 mg/kg, intramuscularly) was given for 3 days and 10 mg of prednisone was given intravenously 2 h prior to the administration of vaccine, no vomiting occurred in spite of the first-time inoculation, and the febrile response was markedly suppressed. As shown in Fig. 1, both the plasma and the saline extract of liver had only slight pyrogenicity in the recipient dogs. The antipyretic effect of glucocorticoids seemed to be due to the suppression of the hepatic metabolic responses including the liberation of the pyrogenic factor. This coincided well with the observations on adrenalectomized dogs previously mentioned.

In the absence of glucocorticoids the hepatic metabolic responses to endotoxin become intensified and not only the hepatic pyrogenic factor but also the 'shock-inducing factor' are liberated from the liver. The liberation of both factors together with the depletion of hepatic glycogen can be prevented by pretreatment with glucocorticoids[5,6]. Glucocorticoids, however, could not inhibit the fever induced by the effective hepatic pyrogenic extract, just as they fail to prevent the effect of the 'shock-inducing factor'[5,6]. It is certain that the antipyretic effect of cortisone on endotoxin fever was not due to the depression of the responsiveness of the central nervous system to the pyrogenic stimulus.

In passing, it may be mentioned that similar hepatic saline extract of rabbits did not show such a distinct and regular thermogenicity. However, the rabbit's extract, contrary to that of the dog, showed marked leucocytosis-inducing effect[9]. There exist also marked species differences in the hepatic response to endotoxin.

Uptake of Potassium at Low Temperatures in Kidney Cortex Slices of Hibernating Mammals

In hibernating hamsters and ground squirrels cationic concentration gradients between tissue cells and plasma are undiminished[1,2]. This fact probably accounts for the ability of the excitable tissues of these species to retain high resting potentials[3], to conduct action potentials[3–5] and to regulate fibre water content[6] at the exceptionally low body temperatures of hibernation. In most mammalian tissues at normal, high body temperature the maintenance of cationic gradients across cell membranes is an active process requiring the expenditure of metabolic energy by mechanisms which transport cations against electrochemical gradients in the face of passive leaks. The question arises whether gradients continue to exist during hibernation because these mechanisms still function or because membranes are less permeable to ions at low temperature.

Kidney cortex when prepared in thin slices is a convenient mammalian tissue for examining transport *in vitro*, because it can rapidly re-accumulate K and extrude Na in measurable net quantities[7,8] and has a high rate of oxidative metabolism, a large fraction of which is associated with cationic pumping[9]. The experiments reported here were designed to show whether kidney cortex taken from two species of mammals which hibernate was capable of establishing as well as maintaining a high tissue K and low tissue Na concentration *in vitro* at low temperature and whether such ability depends on concurrent metabolism.

The methods used have been described in detail elsewhere[9]. Hamsters (*Mesocricetus auratus*) or ground squirrels (*Citellus tridecemlineatus*) were killed by a blow on the head and the kidneys were removed through a mid-line incision. Slices of kidney cortex were made free-hand with a razor blade and were placed temporarily in a Petri dish containing medium at room temperature. When the slicing was completed, the slices were transferred

The index of variation after each mean value is the standard error. Means without *S.E.* are based on only two values. The normal medium contained 143 mM sodium ion. In the normal medium containing metabolic inhibitors the final concentration of dinitrophenol (DNP) was 0·02 mM and the final concentration of iodoacetate (IAA) was 0·1 mM. In the sodium-free medium NaCl was replaced with choline chloride. This medium was only completely 'sodium-free' at the outset of incubation because the small amount of sodium in the slice was eluted into it during the experiment.

to Warburg flasks containing 4 ml. of medium. After 1 h of incubation at 38° or 5° C, slices were removed from the flasks, blotted on hardened filter paper, placed in tared tissue beakers and were dried at 105° C overnight to obtain dry weight. Sodium and potassium contents were determined by internal standard flame photometry on samples of tissue which had been digested in concentrated nitric acid.

The incubation medium contained NaCl (143 mM) as its principal constituent and also $CaCl_2$ (3 mM), $MgSO_4$ (1·5 mM), potassium-phosphate buffer (3 mM, providing 5·5 mM K ion) and glucose (10 mM). Flasks incubated at 38° C were gassed with 100 per cent oxygen. For experiments in which a sodium-free medium was desired, choline chloride was substituted for NaCl.

The brief soaking of kidney cortex slices in such media prior to incubation results in a considerable reduction in concentration of potassium in the tissues from *in vivo* values[7–9]. In the experiments recorded here the objective was to measure net uptake or loss of potassium by comparing the final tissue concentration of potassium after incubation with this initial, depressed value. In slices of hamster kidney cortex, this 'initial' concentration of potassium after soaking in the normal, sodium-rich medium was 193 μequiv./g dry wt. (Table 1), compared with an *in vivo* value of 339 (ref. 2). Conversely, pre-soaking in a sodium-rich medium also led to a great increase in concentration (431 of sodium in the tissues compared to an *in vivo* value of 242 in hamster kidney), and the extent of net extrusion of sodium during incubation could be determined by reference to this initial high value. Slices of ground squirrel kidney cortex lost potassium and gained sodium in a similar way when soaked in sodium-rich medium. Hamster slices soaked in choline medium lost both potassium (to 211) and sodium (to 102). Slices of cortex from kidneys of ground squirrels, however, were prepared only in the ordinary sodium-rich medium and, hence, were not soaked in choline medium before incubation in this medium.

The principal finding of this investigation, shown in Table 1, is that in the kidney cortex slices of both hamsters and awake ground squirrels there was an uptake of potassium at 5° C equal to or greater than that occurring at 38° C. Incubation of slices with a combination of two metabolic inhibitors, dinitrophenol (0·02 mM) and iodoacetate (0·1 mM), blocked this re-accumulation of potassium at both temperatures. At 38° C these inhibitors caused a decrease in concentration of potassium in the tissues to about 100, but at 5° C the concentration of potassium in the tissues was unchanged from the initial value. These results are in marked contrast to those obtained in kidney cortex slices of such non-hibernating species as rabbits and guinea-pigs[7,8], in which incubation at a low temperature is as effective a block to uptake of potassium as inhibition of oxidative metabolism.

Previous investigations have shown that in slices of kidney cortex from rabbits uptake of potassium may also be prevented directly by replacing all sodium in the medium with choline, thus obviating transport of sodium, or by incubating the slices with the cardiac glycoside, ouabain, which is a specific inhibitor of cation transport[9]. Neither of these methods interferes directly with oxidative metabolism.

Incubation of kidney cortex slices of hamsters and awake ground squirrels in sodium-free medium blocked uptake at both 38° and 5° C. As with the metabolic inhibitors, incubation in sodium-free medium caused a fall in concentration of potassium in the tissues at 38° C, but no change occurred at 5° C. In kidney slices of awake ground squirrels ouabain (125 μM) had the same effect on concentration of potassium in the tissues as metabolic inhibition: it blocked net uptake at both temperatures, caused a loss of potassium at 38° but not at 5° C.

In two experiments ouabain in a concentration of 125 μM, which is sufficient to produce maximum inhibition of uptake of potassium in rabbit kidney cortex, had no effect whatever on concentration of potassium in the tissues of hamster kidney slices at either temperature. This apparent resistance is probably a specific example of the hamster's well-known general insensitivity to ouabain[10].

In slices of kidney cortex from ground squirrels which were hibernating at an ambient temperature of 5° C with a body temperature less than 7° C when killed, the 'initial' concentration of potassium in the tissues after the usual slicing procedure was 66 μequiv./g dry wt. higher than in 'initial' slices of kidney cortex from awake ground squirrels. Consequently, no net uptake occurred during subsequent incubation. At 5° C metabolic inhibitors and incubation in sodium-free medium caused no decline from this high initial value and ouabain caused only a slight decrease. At 38° C each of these agents depressed the concentration of potassium considerably, but even so the potassium values after 1 h of incubation with metabolic inhibitors were higher than in the comparable slices from kidneys of awake ground squirrels. The greater concentration of potassium after preliminary soaking reflects, presumably, the higher *in vivo* concentration of potassium of this tissue during hibernation[2], but whether the higher values of potassium after incubation with metabolic poison can be so explained is not certain. Conceivably, kidney cortex may acquire during hibernation a higher fraction of intrinsic or 'bound' potassium[11] which cannot be further diminished by leaching or poisons.

Because the extracellular space was not determined in these experiments, little emphasis has been placed on the tissue concentrations of sodium in these experiments. The values for concentration of sodium in the tissues given in Table 1, however, show that in general the movements of this ion are reciprocal to those of potassium. Thus, there is an extrusion of sodium at both 38° and 5° C which is reversed at 38° and only blocked at 5° C by dinitrophenol plus iodoacetate. In sodium-free, choline chloride medium the sodium content of the tissue is virtually abolished.

Unlike metabolic inhibitors, ouabain in these experiments did not cause a further increase in concentration of sodium in the tissues above the initial value produced by leaching. As in rabbit kidney slices[9], however, the concentration of sodium in slices after incubation with ouabain at 38° C was greater than that of slices incubated without ouabain by an amount (130 μequiv./g dry wt.) which is equal to the difference in concentration of potassium in the tissues (124) in these two conditions.

Thyroid Function of Friesian Cows during the Œstrous Cycle and in Conditions of Ovarian Abnormality

The physiological symptoms of heat in cows do not appear unless there is an optimal level of the thyroid hormone[1]. There is evidence that thyroid activity varies during the œstrous cycle, with maximal activity during œstrus[2–4]. Thyroidectomized cows failed to show physical signs of heat[1,5]. A low level of protein-bound iodine in the blood of infertile cows has also been demonstrated[6]. The levels of thyroid and thyrotrophic hormones in the blood of Friesian cows during œstrous cycle as compared to those affected with ovarian inactivity and cystic ovaries have been investigated as follows.

Fifty ml. of blood was obtained from the jugular veins of 58 Friesian cows, 3–7 years old. Ten were in œstrus, 10 in dioestrus, 23 affected with ovarian inactivity and 15 with cystic ovaries. The procedure for the determination of thyroid hormone was that adopted by D'Angello and Gordon[7], namely, 'the stasis tadpole method'. Tadpoles were divided into five groups of 20 each; one group was injected with saline; the other groups received five injections of 0·01 ml. of serum obtained from the four groups of cows on alternate days. Twenty-four hours after the last injection, the tadpoles were killed with chloroform and stored in 80 per cent alcohol. Their hind limbs were then measured and their length used as a criterion of thyroid hormone activity. Thyrotrophic hormone extracted from the sera of cows[8] was assayed by the use of one-day-old male chicks[9]. The chicks were injected daily with a subcutaneous injection of 0·5-ml. serum for 4 days. They were then killed by ether 24 h after the final injection. The thyrotrophic hormone level was indicated by its effect on the weight of the thyroid and expressed in terms of chick units (a chick unit represents 50 per cent increase above control).

Table 1. Levels of the thyroid and thyrotrophic hormones in the blood of Friesian cows during the œstrous cycle in comparison with those affected with ovarian inactivity and cystic ovaries

	Saline control	Œstrus	Dioestrus	Inactive ovaries	Cystic ovaries
Length of tadpole hind limbs (mm)	0·99 ± 0·33	2·42 ± 0·33	1·77 ± 0·19	1·83 ± 0·11	3·16 ± 0·17
Thyrotrophic hormone (chick unit)	—	0·34	1·59	0·26	0·00

± Standard error.

It appears from Table 1 that the level of thyroid hormone was significantly high during œstrous as compared to that of dioestrous cows. The level of thyroid hormone in cows with cystic ovaries was even higher than that observed at œstrus, but in cows affected with inactive ovaries it was similar to that of the dioestrous cow.

The thyrotrophic hormone level was highest during dioestrus and low at œstrus and in cows with inactive ovaries, while it was totally absent in cows with ovarian cysts.

In the case of œstrous cows and those with ovarian cysts the increase in the level of thyroid hormone was accompanied by a decrease in thyrotrophic hormone. On the other hand, during dioestrus decreased thyroid hormone level was accompanied by a sharp rise in thyrotrophic hormone level. In the case of animals with inactive ovaries, thyroid and thyrotrophic hormone levels were low, suggesting that such a condition accompanies pituitary hypofunction.

The increased thyroid activity at œstrus and in animals with ovarian cysts is most probably due to an increase of œstrogen in the blood[10].

Serum Calcium and Phosphorus in Rabbits during Fracture Healing, with Reference to Parathyroid Activity

The level of serum androgens, and thyroid activity, are both increased in the second and third weeks after bone fracture during cellular regeneration of the callus[1,2]. The early period of catabolism was found to be accompanied by increased adrenal function[3].

The present work was planned to investigate the levels of serum calcium and inorganic phosphorus during fracture healing in rabbits. The hormone content of the parathyroid glands of these animals was also determined.

Thirty-five Boscat male rabbits of an average weight of 1·5 kg were used. They were divided into 7 groups of 5 animals each. One group was left intact and served as a control. The other groups were subjected to experimental fracture of the left tibia by a closed method under ether anæsthesia[4]. The operations were so arranged that rabbits were obtained 1, 2, 4, 8, 15 or 21 days after fracture. The animals were killed and blood samples were obtained. Double determinations of serum Ca (ref. 5) and inorganic phosphorus[6] were made. Analysis of variance was carried out to evaluate the differences between the serum Ca and P levels in the experimental rabbit groups.

The thyroid and parathyroid glands of the rabbits of each group were kept in acetone and preserved in the deep freeze. Parathyroid hormone was extracted[7] and a saline suspension of the extract was prepared so that the hormone from each animal was contained in 1·0 ml. saline. It was assayed by the method depending on its antagonism to magnesium narcosis[8]. Groups of 10 mice were injected subcutaneously with 3 doses of 0·1 ml. of the parathyroid suspension at intervals of 3 h; 90 min after the final injection the animals were given 20 mg of magnesium sulphate contained in 0·1 ml. saline. After half an hour the dead, narcotized and unnarcotized animals were counted. The percentage of animals unnarcotized is

proportional to the parathyroid hormone content of the extract. A standard log–dose response curve was established under the same conditions, using parathyroid extract ('Paroidin'; Parke, Davis).

Table 1 shows that the serum Ca level fell significantly 2 days after fracture and rose significantly during the fourth and eighth days. It then returned to a level approximating to normal. Serum inorganic phosphorus was significantly increased 24 h after fracture, and then returned to normal level, with a temporary depression below the normal level about 15 days after fracture.

As shown in Table 2, it appears that the parathyroid hormone was only detectable in normal rabbits and 8 days after fracture.

Table 1. Levels of Calcium and Inorganic Phosphorus in Rabbit Serum during Fracture Healing

Days after fracture	Calcium (mg/100 ml.)	Phosphorus (mg/100 ml.)
Control (normal)	13·41 ± 0·45	6·81 ± 0·44
1 day	14·86 ± 0·23	8·42 ± 0·39
2 days	10·80 ± 0·97	6·44 ± 0·36
4 days	17·63 ± 1·95	7·32 ± 0·28
8 days	16·32 ± 0·34	6·76 ± 0·20
15 days	14·50 ± 0·61	5·35 ± 0·08
21 days	15·06 ± 0·49	6·84 ± 0·36
F value	7·09*	3·14†
d.f.	60, 6	61, 6

± Standard error.
* Significant differences between groups at 1 per cent level of probability.
† Significant differences between groups at 5 per cent level of probability.

Table 2. Hormone Content of Parathyroids of Rabbits during Fracture Healing (Antagonism to Magnesium Narcosis)

Days after fracture	No. of mice 20 g body-weight Dead	Narcotized	Unnarcotized	
Saline	5	4	1	
Controls (normal rabbits)	3	2	5	(56·53 U.S.P. units/rabbit)
1 day	5	3	2	
2 days	4	4	2	
4 days	2	6	2	
8 days	4	–	6	(92·13 U.S.P. units/rabbit)
15 days	5	3	2	
21 days	4	4	2	

Table 3. Slope, Standard Error and Fiducial Limits of the Standard Log–Dose Response Curve of Parathyroid Hormone

b =	0·47 ± 0·06
Fiducial limits at 5 per cent	0·11
Fiducial limits at 1 per cent	0·15
X (average log.-dose)	1·16
Y (average response)	0·47

The early rise in P level in the blood corresponds to the necrotic disintegration of the cells at the site of fracture. This is followed by a drop in serum Ca level which favours the resorption of bone spicules resulting from the trauma. By 4–8 days after fracture there is a pronounced rise in serum Ca level, bringing about a state of supersaturation of the body fluids, favourable for the deposition of bone salts at the sites of healing. At this time great waves of new callus tissue are sweeping towards the break from the osteogenic layer of the periosteum[9]. Serum Ca then returns to its normal level and new bony trabeculæ replace the cartilage until the trabeculæ from each fragment meet and join.

The rise in the level of P in the blood of rabbits 24 h after fracture, and the pronounced drop in serum Ca on the next day, might be expected to stimulate the secretion of parathyroid hormone[10]. This is possibly why the parathyroids of such animals had no detectable amounts of the hormone. At this time, stress is accompanied by increased adrenal function, and ACTH markedly lowers the Ca level in the blood of rabbits[11]. By the fourth day adrenal function has returned to normal and parathyroid hormone predominates, resulting in a sharp rise in Ca level in the blood. It brings about hypersaturation by its general effect on the skeleton[4]. This, by a feed-back mechanism, evidently acts on the parathyroid glands by the eighth day after fracture, interfering with the release of parathyroid hormone. The hormone content of the parathyroids of such rabbits was high. Hypercalcæmia is also believed to release a hypocalcæmic factor (calcitonin) from the parathyroids, and this, by its antagonism to parathyroid hormone, brings blood Ca back to the normal level[12]. Such a condition probably prevails during the period 15–21 days after fracture.

Volume Change accompanying Passive Stretch of Frog Muscle

The existence of a volume change accompanying passive stretch of frog muscle was first noted by Ernst and Tigyi[1]. They concluded that passive stretch of a pre-shortened frog muscle was accompanied by a volume decrease, but they did not record the magnitude of the decrease.

A method of measuring volume changes in frog muscle, previously described by Abbott and Baskin[2], has been modified. This modification involves a measurement of the pressure change, which is caused by the muscle contracting in a closed vessel. In fact, since the volume changes are small the results by a volume transducer method are exactly the same as those using a pressure transducer method. The muscle is mounted in a chamber (Fig. 1) and the chamber is sealed. The top of the muscle is attached to a wheel which is mounted concentrically through the chamber on to a smaller shaft to which is attached a piece of chain. The chain goes over the pulley

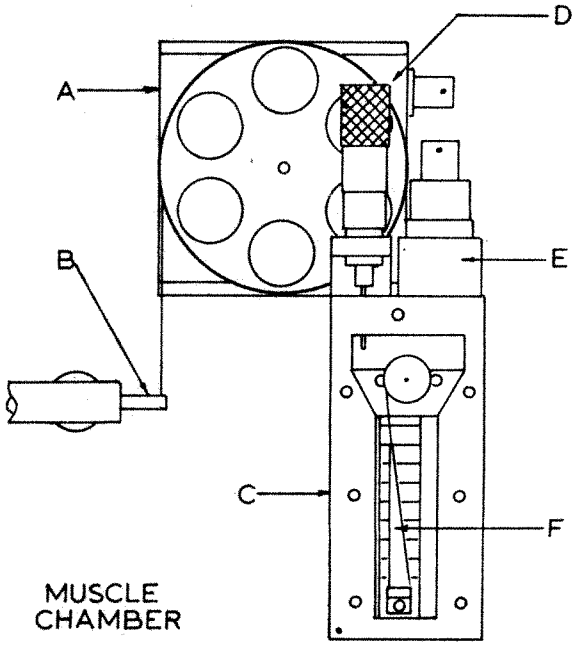

Fig. 1. Diagram of muscle chamber. *A*, muscle length reference transducer; *B*, Levin–Wyman ergometer; *C*, muscle chamber; *D*, micrometer volume adjustment; *E*, pressure transducer; *F*, sartorius muscle

and is attached to a Levin–Wyman ergometer. By this method the length of the muscle may be varied by the Levin–Wyman ergometer without the process of stretching the muscle in itself introducing any pressure change into the chamber. A calibration is made by use of a micrometer-controlled rod which is pushed into the chamber to a precisely determined amount. The pressure change accompanying this is recorded through a special amplifier circuit and displayed on an oscilloscope. The oscilloscope tracings are photographed.

Using the new chamber, the volume changes accompanying passive stretch of pre-shortened frog muscle have been measured. A muscle is placed in the chamber and attached at reference length to the wheel. It is then given three shocks to bring it down to a length determined by a setting on the Levin–Wyman ergometer. The chamber is next sealed and filled with Ringer's solution. The system is allowed to equilibrate for 20 min. A release is then allowed and the Levin–Wyman ergometer stretches the muscle to a specified length. The pressure changes accompanying this are noted and are reported in terms of volume change. The studies of Ernst and Tigyi have been confirmed. A volume decrease results when a pre-shortened muscle is passively stretched. Table 1 lists six experiments. In each the muscle has been stretched by a different amount. An average value for the volume change per millimetre of

Table 1. VOLUME CHANGE ACCOMPANYING PASSIVE STRETCH

Exp.	Passive stretch (mm)	ml./g. mm
1	4·5	$9·5 \times 10^{-6}$
	4·5	10·9
	4·5	10·5
	4·5	15·7

	7·0	5·4
	7·0	6·4
	7·0	3·0
	7·0	5·9
4	2·5	$9·0 \times 10^{-6}$
	2·5	7·5
	2·5	8·0
5	8·5	$9·5 \times 10^{-6}$
	8·5	4·0
6	5·0	$14·0 \times 10^{-6}$
	5·0	6·0

stretch is approximately 1×10^{-5} ml./g of muscle. The velocity of stretch, controlled by the Levin–Wyman ergometer, does not affect the magnitude of the volume change. Within the accuracy possible in this measurement it appears that the magnitude of the volume decrease is a function of the amount of stretch only, and not of the position of the muscle at the start of stretch. That is, the volume decrease varies linearly over the stretching distance used in this investigation.

This observation is of special interest in view of the recent demonstration of volume changes accompanying contraction and relaxation in isolated myofibrils by Baskin[3]. It is postulated that the volume changes observed in the isolated frog sartorius muscle have the same origin as the volume changes which are observed in isolated rabbit muscle myofibrils under the influence of ATP. The origin of these changes has been ascribed to molecular rearrangement, that is, folding or unfolding occurring in the actomyosin. These results indicate the existence of large configurational changes taking place in actomyosin during both shortening and stretch of pre-shortened muscle. These changes are not accompanied by large amounts of tension. Since these volume changes have been shown to occur in isolated glycerol extracted myofibrils under the influence of ATP, it appears impossible to ascribe their origin to biochemical changes occurring in creatine phosphate or other muscle constituents. It seems likely that these changes occur in the actomyosin molecules, either alone or in combination with ATP. They might have their origin in the exposure of previously infolded groups or in the ionization of previously unionized groups.

PHARMACOLOGY

Effect of Methylamphetamine on the Psychomotor Depression produced by Adrenaline in Mice

INTRAPERITONEAL injections of catecholamines produce a marked depression of the psychomotor activity of mice, accompanied by vegetative phenomena, such as tachycardia, exophthalmos and pilo-erection. These vegetative phenomena are, however, independent of the psychomotor depression, for they can be suppressed by phentolamine ('Regitin *R*'), an adrenergic blocking agent, without modifying the depressed behaviour. Furthermore, isopropylarterenol produced, in higher doses, a similar psychomotor depression, without vegetative symptoms[1].

Catecholamines, especially noradrenaline, are generally considered to be central neuro-humoral agents with ergotropic functions[2]. Notwithstanding this, their administration to animals or human beings may also produce, in certain circumstances, signs of a central nervous depression (analgesia, stupor, etc.[2]). The mechanisms of these phenomena are unknown. Some workers consider them to be a consequence of central inhibitions due directly to an excess of catecholamines; other authors suppose the existence of feed-back mechanisms, triggered by stimulation of baro- or chemo-ceptors. It is possible that the depression of psychomotor activity of mice after an intraperitoneal injection of catecholamines, described by us[1], pertains also to these phenomena. In this case, a feed-back mechanism seems more likely than a direct inhibition by an excessive local concentration, for it is not very probable that catecholamines can reach the central nervous system in important amounts after an intraperitoneal administration. The supposed feed-back mechanism does not seem to depend on vegetative phenomena, such as vasoconstriction (baroceptors), etc., because the administration of an adrenergic blocking agent did not suppress it[1]. It is a well-known fact that amphetamine and similar drugs produce a central sympathetic stimulation, characterized also by an elevated psychomotor activity. The adrenergic action of amphetamine-like substances is mainly of indirect character, that is, produced through liberation of endogenous catecholamines. Nevertheless, it seems that the amphetamine action has also a direct adrenergic component (substitution of catecholamines in their receptive sites[2]).

The work recorded here refers to the effects of a combined treatment of mice, with adrenaline and methylamphetamine, on their psychomotor activity. The experiments were performed in order to see if it is still possible to raise the psychomotor activity by methylamphetamine above the normal after an intraperitoneal injection of adrenaline and if a subsequent injection of this substance by the same route abolishes the psychomotor excitation caused by a previous administration of methylamphetamine.

The technique of our experiments was essentially the same as in our earlier investigations[1]. The mice received two intraperitoneal injections (adrenaline–methylamphetamine, adrenaline–distilled water, methylamphetamine–

distilled water, distilled water–distilled water), in both orders of sequence with an interval of 15 min. The mice were placed in an actophotometer 15 min after the final injection, measuring their locomotion during 10 min. Every group consisted of seven animals.

Table 1

First injection:	Distilled water	Second injection: Methylamphetamine 1·0	Methylamphetamine 2·0
Distilled water	67 ± 7	100 ± 3	118 ± 5
Adrenaline 0·25	38 ± 4	72 ± 7	—
Adrenaline 0·50	23 ± 2	31 ± 4	31 ± 3
Adrenaline 1·00	17 ± 5	30 ± 3	29 ± 4
Adrenaline 2·00	7 ± 2	13 ± 2	18 + 3

Table 1 shows the results obtained when the mice were injected first with adrenaline and 15 min later with methylamphetamine, using always the intraperitoneal route. The doses are expressed in mg/kg, the values correspond to the actophotometer reading ± the standard deviation of the mean.

It can be seen that ascending doses of adrenaline depress progressively the psychomotor activity in these conditions. Methylamphetamine produces a hyperactivity only when injected into mice not treated previously with adrenaline. After an injection of adrenaline, methylamphetamine only lessens the degree of psychomotor depression, without abolishing it completely, except for the slight depression caused by 0·25 mg/kg of adrenaline, that did not appear in methylamphetamine-treated mice. If the sequence of injections is reversed, the results are somewhat different (Table 2).

Table 2

First injection:	Adrenaline 0·50	Second injection: Adrenaline 1·0	Adrenaline 2·0
Methylamphetamine 1·0	33 ± 5	44 ± 13	45 ± 17
Methylamphetamine 2·0	36 ± 3	41 ± 3	49 ± 8

The results in Table 2 show that methylamphetamine reduces the psychomotor depression caused by adrenaline more efficaciously if injected first. For example, 2·0 mg/kg of adrenaline alone depresses the psychomotor activity to a value of 7 ± 2; this value is raised after a following injection of 2·0 mg/kg of methylamphetamine to 18 ± 3 (Table 1), but it will be nearly normalized by a preceding injection of this substance (value of 49 ± 8). It is also interesting to note that in the last case the locomotion remains somewhat depressed but the animals show signs of excitation of other kinds (incessant rotating movements, cleansing and other small movements).

We believe that our results support the supposition that intraperitoneal injection of adrenaline depresses the psychomotor activity by some feed-back mechanism involving central adrenergic ergotropic functions, blocking herewith also the indirect stimulating effect of methylamphetamine, but leaving unblocked its direct stimulating action, so that a reduction of the psychomotor-depressing effect of adrenaline can be achieved.

Distribution of Cobalt-60 in the Rat as influenced by Chelating Agents

The recent development of quantitative co-ordination chemistry is paralleled by remarkable advances in the therapeutic use of chelating agents, for example, in the removal of toxic or radioactive metals from the body.

In the particular case of radiocobalt, however, our knowledge about the efficacy of chelators is rather scanty: ethylenediamine-tetraacetic acid (EDTA)[1–5], diamino-*cyclo*hexanetetraacetic acid[6], diethylenetriaminepentaacetic acid (DTPA)[2], cysteine (Cy)[4,5] and cysteamine (CyA)[4,5] have been tested and found to be effective, DTPA being slightly superior to the other compounds.

In order to find chelators with still higher efficacy, one must take into account the fact that Co(II) is a transition metal. With regard to co-ordination properties, the transition metal ions are known to behave quite individually and to react not only with oxygen as ligand atom, but also with nitrogen and sulphur. Therefore, screening tests with a greater number of corresponding chelators were necessary.

Albino rats of the Heiligenberg strain (6–10 weeks old, 170–210 g) were intravenously injected with approximately 5 μc. of carrier-free $^{60}CoCl_2$. To achieve maximum effectiveness, the different compounds were administered immediately after the injection of ^{60}Co. The dosage was 200 μmoles per animal, with the exception of the relatively toxic 2-mercapto-ethyliminodiacetic acid (MEIDA) (25 μmoles). The animals were killed 48 h later, and the radioactivity of the organs assayed by means of a KI(Tl)-scintillation crystal.

In good agreement with earlier investigations, ^{60}Co was eliminated rather quickly from the body, and the total retention after 48 h amounts to 8–11 per cent. The highest concentrations are observed in liver and kidneys. As can be seen from Table 1, our data confirm the findings of Foreman[2], that is, the superiority of DTPA over EDTA. This accords with the ratios of the relevant stability constants $K^{Co}_{CoL}/K^{Ca}_{CaL}$: $10^{8\cdot4}$ for DTPA[7] and $10^{5\cdot5}$ for EDTA[8]. DTPA does not occupy, however, the same unique position as it does with other metal ions[9], and its efficacy is equalled by triethylenetetraminehexaacetic acid (TTHA), 2 : 2′-*bis*[di(carboxymethyl)-amino]diethyl ether (BADE), 1 : 2-*bis*[di(carboxymethyl)-aminoethoxy]ethane (BAE), MEIDA, Cy and CyA and clearly surpassed by the sulphur-containing 2 : 2′-*bis*-[di(carboxymethyl)amino]diethyl sulphide (BADS), 1 : 2-*bis*[di(carboxymethyl)aminoethylthio]ethane (BATE) and D-β,β′-dimethylcysteine (DMCy). Although the participation of the sulphur atoms in chelating Co(II) is beyond doubt, it is not yet clear (since the K^{Co}_{CoL}-values are not available) whether the high efficacy of the sulphur

Table 1. ^{60}Co-CONTENT (MEANS OF 5–6 RATS AND STANDARD ERRORS) IN DIFFERENT ORGANS 48 H AFTER INJECTION

The chelating agents (with the exception of DMCy, Cy and CyA, given as Ca-Na-chelates) were administered intraperitoneally, immediately following the injection of the radionuclide

DMCy*	0·151 ± 0·005	0·576 ± 0·026	0·592 ± 0·016	0·138 ± 0·008
MEIDA†	0·268 ± 0·022	2·228 ± 0·219	1·070 ± 0·096	0·441 ± 0·042

* The dose of 20 μmoles DMCy was given orally.
† The MEIDA contains ~10 per cent of cystaminetetraacetic acid as impurity.

compounds is due only to their low K^{Ca}_{CaL}-values or also to high K^{Co}_{CoL}-values.

The chelators show different patterns of effectiveness, that is, the differences in effectiveness are more pronounced in relation to the kidney than in other organs: EDTA, DTPA, TTHA, CyA are not able to reduce the retention of ^{60}Co by the kidney, whereas the other compounds were found to be markedly effective. The reasons for this discrepancy are not yet fully understood. Tentatively, different metabolic behaviour of particular chelates as well as the formation of ternary complexes in the kidneys (which are known to possess a high concentration of SH-groups[10]) can be assumed.

From the practical point of view the therapeutic use of BADS and BATE in cases of internal contamination with ^{60}Co is obvious. However, the highest significance must be attributed to D-dimethylcysteine (commonly known as penicillamine). Its high efficacy compares favourably with BADS and BATE. Our experimental data show that it can be administered orally without loss of effectiveness. Finally, its low toxicity must be stressed. More detailed studies on the effectiveness of these and other chelators, as influenced by several factors and, in particular, the time of their administration, are now under way and will be published elsewhere.

The generous supply of the polyamino-acids by J. R. Geigy AG., Basle, and of D-dimethylcysteine by Heyl and Co., Berlin, is gratefully acknowledged.

A New Class of Antimicrobial Agents

The mesoionic 1,3,4-thiadiazoles, I, were first reported by Busch[1], who assigned a bicyclic structure to the compounds.

(I)

(II)

Schoenberg[2] later re-examined the structure of Busch and offered a resonance hybrid structure, now accepted as being typical of a large group of heterocycles described as being mesoionic[3]. We became interested in the mesoionic 1,3,4-thiadiazoles as a natural extension of our interest in the pharmacology and pharmaceutical chemistry of the sydnones II[4–7]. It occurred to us that since the two ring systems are isoelectronic (that is, being mesoionic they both possess an aromatic, positively charged, 5-membered ring, and a balancing negative charge on an exocyclic atom) the possibility might exist that the two ring systems could also be bioisosteric. That is, the ring itself may behave as a pharmacologically active functional group and that this already expressde similarity between the ring systems may impart similar pharmacological activity. A more conservative speculation would be that perhaps the mesoionic 1,3,4-thiadiazole ring system would have some prominent pharmacological activity.

Accordingly, a number of these compounds were synthesized in our laboratory. The synthesis of the *C*-ethyl, *N*-phenyl derivative will be used as a typical procedure. Phenylhydrazine (32 g, 0·3 mole) was dissolved in 350 ml. of absolute ethanol and carbon disulphide (24 g, 0·3 mole) was added with stirring. A precipitate rapidly formed. This was not isolated but was treated directly with an ethanolic solution of potassium hydroxide (17 g in 120 ml., 0·3 moles). The precipitate dissolved and, after stirring, a precipitate of potassium phenyldithiocarbazinate formed in 85 per cent yield, m.p. 144°–46°. This acid salt (22 g, 0·1 mole) was suspended in 500 ml. of toluene and the slurry warmed to 60°. To this was added propionyl chloride (9·3 g, 0·1 mole) at a slow rate, maintaining the temperature at 60°. After the addition, the reaction mixture was cooled and the 4-phenyl-5-ethyl mesoionic 1,3,4-thiadiazole precipitate removed and recrystallized from ethanol to give a 5 per cent yield, m.p. 191°–192° (found: N, 53·84; S, 28·96). The nomenclature recommended by Katritzky for mesoionic compounds[8] becomes anhydro-4-phenyl-5-ethyl-2-thio-1-thia-3,4-diazolinium thiol.

In the course of a broad screening of these compounds for potential medicinal activity we assayed them for antibacterial activity by the standard disk method against *Staphylococcus aureus*, *Diplococcus pneumoniae* and *Escherichia coli*. Disks saturated with these compounds were incubated with brain heart infusion agar plates of the organisms and observed at 24- and 48-h intervals for zones of inhibition of growth. Penicillin was used as an antibacterial reference. Four of the 4-phenyl derivatives, namely, the 5-methyl, 5-ethyl, 5-isopropyl and the 5-propyl, were found to produce significant zones of growth inhibition of *S. aureus* and *D. pneumoniae*. The extent of inhibition was the same as that produced by the penicillin reference. The effect on the *E. coli* was minimal.

Preliminary pharmacological tests indicated a low order of acute intraperitoneal toxicity in mice. The acute median lethal dose was found to be greater than 500 mg/kg for the four compounds cited here.

These investigations indicate that these compounds might be safe antibacterial agents against at least some Gram-positive organisms.

Reversal of Hormonal Effects as a Result of Chronic Morphinization

Morphine accelerates the rate at which the rat diaphragm takes up glucose from synthetic media, to an extent comparable with the effect of insulin. With tissue from a chronically morphinized animal this acute effect of the drug is reversed, and the rate of glucose-uptake is retarded[1]. These effects of morphine are antagonized by hydrocortisone[2]. Hydrocortisone alone, in the concentration used for the experiments ($7{\cdot}7 \times 10^{-4}$ M) with morphine, has no significant effect on the rate of glucose-uptake by either normal or chronically morphinized tissue. We have confirmed this by additional experiments, and have concluded that the previously observed effects of the hormone in the presence of added morphine may be attributed entirely to a suppression by the hormone of the effects of the drug.

We now find, however, that hydrocortisone in lower concentrations has a marked and apparently direct effect on the glucose-transport mechanism. The effect on tissue from the chronically morphinized animal is the reverse of that on normal tissue. Following the experimental procedure previously described[2], we find that hydrocortisone, in concentrations of $3{\cdot}85 \times 10^{-4}$ M and below, strongly retards the uptake of glucose by diaphragm from normal rats, but accelerates its uptake by diaphragm from rats which had received daily injections of morphine sulphate (30 mg/kg body wt.) for 4–6 weeks. As previously emphasized[2], there is no significant difference between the normal and chronically morphinized rat diaphragm in the rates of glucose-uptake in the absence of added hormone or drug. Results are presented in Table 1.

Differences between normal and chronically morphinized rats in tissue response to adrenaline have also been observed in a study of the effects of hydrocortisone and adrenaline[3] analogous to that with hydrocortisone and morphine. There is a possible analogy here between the reversal of hormonal effects by morphine and the reversal of the effect of vitamin B_1 on yeast fermentation as a result of growth in the presence of cocaine[4,5], for, in both cases, reversal of the effect of the active substance is induced by chronic exposure to a drug which to some extent it resembles in chemical structure. The morphine molecule embodies both a steroid-like and an adrenaline-like structure and it is to be expected that the drug would interfere with the normal action of both types of hormone.

While we cannot as yet offer a full explanation for our observations, it would seem that, in the hormonal control of metabolic processes, a hormone or other active substance such as a hormone-simulating drug may either activate or inhibit a process according to its concentration relative to that of other active substances, and depending on the state of the tissue on which it acts, this latter factor being related to the established hormonal balance of the organism. There is ample evidence that morphine disrupts the normal hormonal balance so far as adrenal hormones are concerned[6,7].

Table 1. *In vitro* Effects of Hydrocortisone on Glucose-uptake by Diaphragm of Normal and of Chronically Morphinized Rats

	Glucose-uptake, mg/100 g wet tissue/h (Mean ± S.E.)			
	Control	+Hydrocortisone ($7{\cdot}7 \times 10^{-4}$ M)	Difference	*t*-test
Normal rats (17)	205 ± 31	171 ± 34	−34 ± 81	N.S.
Chronically morphinized rats (12)	139 ± 28	134 ± 46	−5 ± 44	N.S.
		($3{\cdot}85 \times 10^{-4}$ M)		
Normal rats (6)	193 ± 41	52 ± 27	−141 ± 27	($P < 0{\cdot}01$)
Chronically morphinized rats (7)	228 ± 29	325 ± 35	+97 ± 35	($P < 0{\cdot}05$)
		($1{\cdot}92 \times 10^{-4}$ M)		
Normal rats (8)	253 ± 27	163 ± 26	−90 ± 30	($P < 0{\cdot}02$)
Chronically morphinized rats (8)	196 ± 25	276 ± 20	+80 ± 13	($P < 0{\cdot}001$)

Our observations lead us to suggest that morphine, directly as well as indirectly, induces a change in the tissues which are targets for hormonal action, somewhat in the nature of an adaptation to the changed hormonal balance, with the additional complication that morphine itself participates in that balance by virtue of its hormone-simulating properties. We suspect that, in this way, morphine induces a biological dependence in tissues which are sensitive to the adrenal hormones and that this is the basis of morphine addiction.

HÆMATOLOGY

Inhibition of ADP-induced Platelet Aggregation by Substituted Amino-acids

Aggregation of platelets in the presence of adenosine diphosphate (ADP) appears to be important in hæmostasis and in the genesis of platelet thrombosis. There is evidence that this reaction is common to platelet clumping induced by a variety of stimuli, including collagen, adrenaline, long-chain fatty acids, and perhaps weak solutions of thrombin. Although this phenomenon is under investigation in many laboratories, the mechanism by which ADP causes platelet aggregation is largely unknown. Certain inhibitors of platelet clumping have been described (for example, inhibition of thrombin-induced platelet aggregation by heparin[1] or of ADP by adenosine[2]), and investigation of the inhibitory reaction has afforded some insight into the underlying process.

We have examined platelet clumping induced by ADP, using the turbidimetric technique of Born[3]. This reaction is strongly inhibited by certain substituted α-amino-acids, such as arginine methyl ester. Arginyl esters in which the α-amino group is also blocked, such as BAME, BAEE and TAME, are equally effective. The degree of inhibition varies with the concentration of the inhibitor. The inhibition becomes manifest immediately on addition of the substituted amino-acid and is not enhanced by incubation before addition of ADP, unlike inhibition produced by adenosine. Indeed, if the addition of the inhibitor is delayed until the maximum effect of ADP has been achieved, the platelet aggregates promptly disperse. Fig. 1 illustrates this phenomenon with benzoyl-arginine methyl ester (BAME); similar data have been obtained with other inhibitory agents in this family.

If the reciprocal of the velocity of platelet aggregation in platelet-rich citrate plasma is plotted against the reciprocal of the concentration of added ADP by the technique of Lineweaver and Burk[4], a straight line is obtained (Fig. 2, control) which intersects at the ordinate with a similar curve derived in the same manner by adding ADP to platelet-rich plasma in the presence of arginine methyl ester. Analogous curves may be derived with other concentrations of inhibitor and with other members of the family of inhibitors, and the lines characteristically con-

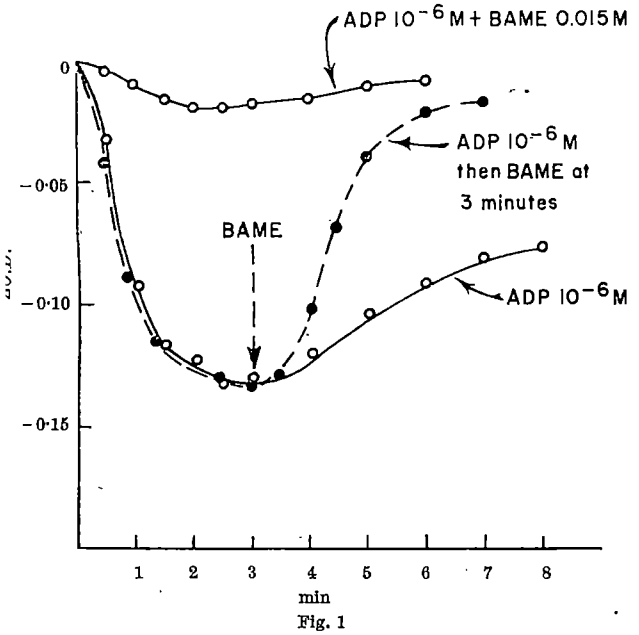

Fig. 1

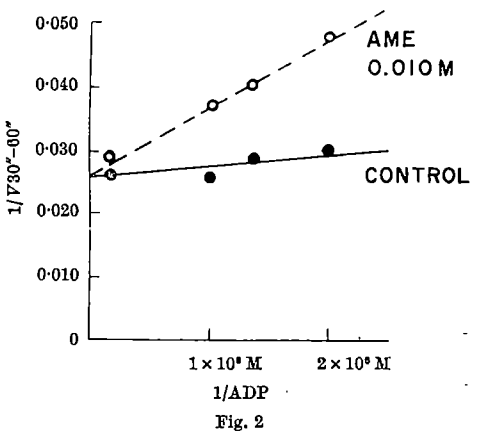

Fig. 2

verge on a single point on the ordinate. As conventionally interpreted, this type of plot indicates competitive inhibition. The components of the reaction blocked by AME are not known, but these results suggest that ADP is one of the reactants.

The potency of various amino-acids and their relatives in blocking ADP-induced platelet clumping is shown in Table 1. All substances were tested in equimolar concentration. Derivatives of arginine inhibit effectively whether the carboxyl group is substituted by an ester or an amide and whether the α-amino group is free or blocked. Arginine does not inhibit ADP-induced aggregation, however, nor does guanidine, which resembles the non-carboxyl end of the arginine molecule.

Table 1. INHIBITORS OF ADP-INDUCED PLATELET AGGREGATION
(tested in 0·015 M)

Upper 1/3		
	Arginine methyl ester (AME)	Arginyl amide (AA)
	Benzoyl arginine methyl ester (BAME)	Tosyl arginyl amide (TAA)
	Benzoyl arginine ethyl ester (BAEE)	Cysteine methyl ester
	Tosyl arginine methyl ester (TAME)	Histidine methyl ester
Middle 1/3		
	Tyrosine methyl ester	Lysine methyl ester
	Phenylalanine methyl ester	Aspartic acid β-methyl ester
	Guanidino-butyric acid methyl ester	Cysteine
Lower 1/3		
	Leucine methyl ester	Isoleucine methyl ester
	Glycine ethyl ester	Serine methyl ester
	Proline methyl ester	Reduced glutathione
	Epsilon amino caproic acid methyl ester	2-Mercaptoethanol
No inhibition		
	Arginine	Methionine
	Alanine	Alanine methyl ester
	Glutamine	Glutamic acid ethyl ester
	Epsilon amino caproic acid	

Guanidino-butyric acid methyl ester, which resembles AME but lacks the α-amino group, is moderately effective as an inhibitor. Epsilon amino caproic acid methyl ester, which bears the same relation to lysine methyl ester, is only slightly less potent, but non-esterified epsilon amino caproic acid has no effect. It would appear that the presence of a substituted carboxyl group is necessary for these compounds to function as inhibitors of ADP-induced aggregation. Of the free amino-acids tested, only cysteine exhibited any inhibitory capacity, and this disappeared if its free sulphydryl group was blocked, as in methionine. Reduced glutathione has a modest ability to inhibit the effect of ADP, as does 2-mercapto-ethanol. Simultaneous addition of cysteine and AME produces greater inhibition of ADP's effect than does either alone, suggesting diverse sites of action. Methionine does not enhance AME's potency as an inhibitor.

These results are consistent with the hypothesis that an enzymatic reaction is involved in aggregation of platelets by ADP, and that this reaction is competitively inhibited by these synthetic substrates. It would appear that sulphydryl groups are involved. The case for an enzymatic reaction is supported by the high degree of specificity of the aggregation phenomenon, induced by ADP and by a few of its closest relatives but not by a large group of related nucleotides tested by Gaarder[5]. Since guanidine does not block ADP-induced platelet clumping, while BAME is a potent inhibitor, the inhibitory effect does not seem to be a non-specific one based on ionic strength. The substituted carboxyl group appears to be required, perhaps by blocking an active enzyme site.

As many workers have shown, platelet aggregation induced by thrombin can be blocked by BAME and its α-amino substituted analogues[6,7]. However, if an enzyme is, in fact, involved in platelet aggregation produced by ADP, the enzyme is probably not thrombin. Heparin inhibits platelet clumping produced by thrombin and blocks the thrombin-fibrinogen reaction but does not inhibit ADP's effect on platelets. Arginine methyl ester, on the other hand, blocks platelet aggregation produced by either ADP or thrombin. Unlike its α-amino-substituted relatives, such as BAME, however, AME is a weak inhibitor of the thrombin-fibrinogen reaction. This observation provides additional support for the thesis[8,9] that platelet clumping produced by dilute thrombin is mediated through ADP.

Although BAME and the other synthetic substrates studied are known to be hydrolysed by certain proteolytic enzymes and thus to compete with the natural protein substrate (as, for example, with trypsin or plasmin), the aggregation of platelets induced by ADP is not inhibited by such naturally-occurring proteolytic enzyme inhibitors as ovomucoid, lima bean trypsin inhibitor, and 'Trasylol'. In addition, we were unable to demonstrate rapid hydrolysis of BAME[10] in platelet-rich plasma in the presence of ADP, although inhibition of the effect of ADP on platelets was almost immediate. Therefore, the inhibitory reaction appears to be of a nature different from that involving proteolytic enzymes.

Platelet adhesiveness *in vitro*[11] is impaired by mixing native blood with BAME and other substances capable of inhibiting ADP's effect. Platelet adhesiveness is deficient in von Willebrand's disease, and there is much evidence that this abnormality is the result of a missing plasma factor[12,13]. It occurred to us that this plasma factor might be the enzyme postulated here. However, the ability of a given concentration of AME to inhibit platelet aggregation in von Willebrand's disease proved to be the same as in normal subjects. Since the sensitivity of ADP-induced aggregation to AME is not enhanced in this disease, it appears that the enzyme we postulate is not the deficient 'von Willebrand's factor'.

Arginine does not inhibit ADP's effect and, if one adds both arginine and arginine methyl ester to platelet-rich plasma, the inhibition of ADP is less than with AME alone. The explanation for this observation is not clear, but may reside in the differing affinities of arginine and AME for the postulated enzyme.

The proof that platelet aggregation induced by ADP is an enzymatic reaction must await isolation of the pertinent enzyme and identification of its natural substrate. Meanwhile, the demonstration that this reaction can be blocked by a family of compounds typified by arginine methyl ester provides stimulus for further experiments.

Certain of the compounds tested were furnished through the kindness of Dr. Sol Sherry. This work was supported by grants from the U.S. Public Health Service and the American Heart Association. We thank Dr. G. Mechanic for his advice.

Abnormal Hæmoglobin in Sheep

In man there exists a large number of abnormal genetically determined hæmoglobins. To our knowledge no abnormal hæmoglobins are yet reported found in domestic animals. When investigating the hæmoglobin phenotypes of experimental sheep with the technique of starch-gel electrophoresis an animal having atypical hæmoglobin was found.

This abnormal type is shown in Fig. 1, which is a photograph of a gel stained with amido-black and where samples representing the two normal sheep hæmoglobin phenotypes AB and AA have been run for comparison. We have in this communication used the nomenclature of Evans *et al.*[1]. For better demonstration of the two bands in the type AB this sample was less concentrated than the other three shown in Fig. 1. The abnormal hæmoglobin type is shown on the right of Fig. 1. It was first found in a sample from a 7-months-old lamb and appeared as a band having a rate of migration on starch gel which was markedly slower than that of the B band. This special band was of approximately the same strength as the A band and has preliminarily been named N (for Norway). The lamb with this band had been heavily invaded by intestinal parasites during the last three months, primarily *Haemonchus contortus*. Accordingly the animal was anæmic, having a hæmoglobin value of only 7·1 g/100 ml. The lamb had lost 5·2 kg in weight in the last three months and had a considerably lower live weight than the average of the lambs in the control group. The parents of the lamb were of hæmoglobin phenotypes AA and AB, respectively. Testing of the lamb was repeated after a few days on a new blood sample and with the same result. However, when investigating another blood sample four weeks later, which is also shown in Fig. 1, the N band was very faint. Unfortunately the death of the lamb prevented any further investigations.

A year later another group of experimental lambs was hæmoglobin typed. One 7-months-old animal was found which also had the N band. This is shown in Fig. 2, which is a photograph of a gel stained with benzidine and where samples representing the three normal sheep hæmoglobin phenotypes were run for comparison. This animal was also anæmic, due to parasite invasion (mainly *Haemonchus contortus*). The lamb has been tested every week for 2 months. Its hæmoglobin value averaged 4·9 g/100 ml. This lamb has not gained any weight during the last four months, whereas the control group showed an average increase of 6·9 kg. The strength of the N band varied from approximately 2 per cent to 15 per cent of total hæmoglobin.

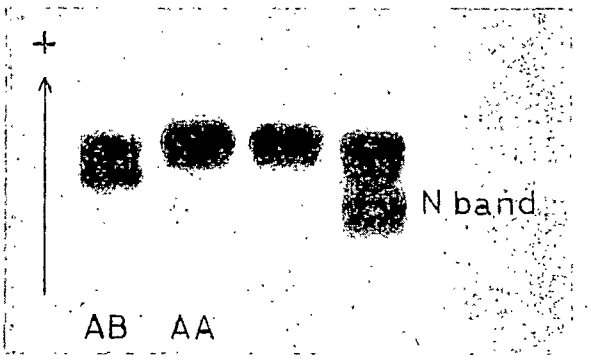

Fig. 1. Photograph of a stained gel showing two examples of the abnormal hæmoglobin type in sheep

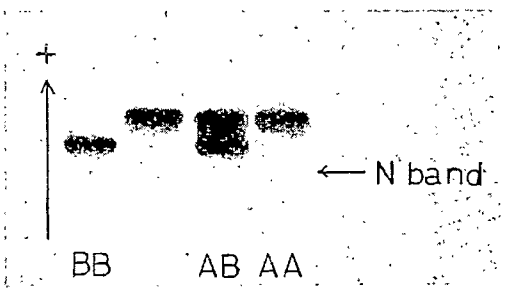

Fig. 2. Comparison between a third example of the abnormal type and the three normal sheep hæmoglobin phenotypes

Recently we have also found the abnormal hæmoglobin type in adult sheep used in special feeding experiments. They did not, however, have any abnormally high number of intestinal parasites.

A definite explanation for the occurrence of this abnormal hæmoglobin type cannot be given at this stage. It is perhaps not genetically determined in the same sense as the many abnormal human hæmoglobins. A condition showing deviations in relative amounts of the two hæmoglobin components has been found in strongly anæmic sheep of phenotype AB by Huisman *et al.*[2] and Efremov[3]. Of special interest, in our opinion, would be the possibility of producing the abnormal hæmoglobin type N in sheep experimentally.

Oxygen Equilibria of Red Cell Hæmolysates of Adult Individuals, Heterozygous for Different Rare Abnormal Hæmoglobins

In the past few years, oxygen equilibria of various normal and abnormal adult human hæmoglobin types have been studied. No differences were observed between normal Hb-A ($\alpha_2\beta_2$) and the β-chain abnormalities Hb-S (ref. 1), Hb-C (ref. 2) and Hb-E (ref. 3). Investigations of the isolated Hb-A_2' ($\alpha_2\delta_2$) and its abnormal variant Hb-A_2 revealed a considerable increase in oxygen affinity when compared with normal Hb-A (ref. 4). Hb-Lepore, which is composed of normal α-chains and 'β' chains being related to the β-chain of Hb-A as well as to the δ-chain of Hb-A_2 (ref. 5), showed a high affinity for molecular oxygen similar to that of Hb-A_2 (ref. 1). The affinities of the α-chain lacking abnormal hæmoglobin types Hb-H (β_4) and Hb-Bart's (γ_4) for molecular oxygen were found to be extremely high, while no Bohr effect or hæm–hæm interactions were detectable[6,7].

This investigation was an additional step in our search for possible functional alterations of different abnormal human hæmoglobin types. The experimental situation made it necessary to limit our investigations to the determination of the oxygen affinity of red blood cell hæmolysates obtained from adult individuals, known to be heterozygous for various α- or β-chain abnormalities. The methods used for the oxygen equilibria determination and for the quantitation of abnormal components either by CM- or DEAE-cellulose chromatography have been described before[1,8,9]. Four β-chain abnormalities and three α-chain abnormalities were investigated. The electrophoretically fast-moving β-chain abnormalities, Hb-$J_{Georgia}$ (ref. 10) and Hb-Jenkins (ref. 11), each found in two Negro families, were present in the blood of heterozygous carriers in quantities exceeding 50 per cent (Table 1). The quantities of Hb-D_{Punjab} (ref. 12), discovered in several members of two families of Caucasian extraction, and of another Hb-D with unknown structural alteration of the β-chain, discovered in a Negro family (fam. M), were approximately one-third of the total hæmoglobin (Table 1). The three major α-chain abnormal hæmoglobins, Hb-Dα, found in two members of a Negro family, the electrophoretically fast-moving Hb-I (ref. 13) and Hb-Russ (ref. 14), both discovered in members of families of Caucasian extraction, were present in different quantities; the percentage of Hb-Dα amounted to approximately one-third, that of Hb-I to approximately one-fifth and that of Hb-Russ to approximately one-tenth of the total hæmoglobin present in the red cell hæmolysates of heterozygous carriers (Table 1).

Table 1. Oxygen Equilibria of Various Hæmolysates at 37° C and *p*H 7·0

Type of hæmolysates	Abnormal chain	% Abn. Hb.	% A_2	Log P_{50}*	Δ Log P_{50}	n
Normal			2·3–2·7	1·280		3·2
Hb-$J_{Georgia}$	β	55·5	2·3	1·280	0	3·2
Hb-Jenkins	β	51·7	2·3	1·275	−0·005	3·15
Hb-D (Fam. M)	β	37·8	2·4	1·270	−0·010	3·2
Hb-D_{Punjab}	β					
Fam. Jon.		35·7	2·4	1·245	−0·035	3·2
Fam. E		34·2	2·3	1·250	−0·030	3·2
Hb-D (Fam. J)	α	32·9	1·4†	1·270	−0·010	3·2
Hb-I (Fam. S)	α	19·4	1·6†	1·280	0	3·2
Hb-Russ	α	11·7	2·1†	1·265	−0·015	3·0

* The value given for normal hæmolysates is the mean of 13 determinations with a standard deviation of the mean of 0·010. All other values are mean values of duplicate determinations with the exception of those given for Hb-D_{Punjab} hæmolysates, which are the mean of four separate analyses.
† The percentages of the corresponding abnormal (in α-chain) Hb-A_2 components were 0·8 for Hb-Dα, 0·7 for Hb-I and 0·4 for Hb-Russ.

The results of the oxygen equilibrium investigations are also summarized in Table 1; the oxygen affinities are presented as the logarithms of the oxygen pressures required to half-saturate the different hæmolysates, while the slopes of the oxygen dissociation curves are described by the values found for the constant n in Hill's equation[15]. All different hæmolysates, except one, have oxygen affinities identical to that of a hæmolysate of normal adult red blood cells. The data obtained in several experiments with hæmolysates of red blood cells of an Hb_{Punjab} trait carrier indicate that the presence of this abnormal hæmoglobin increases the oxygen affinity, the difference being slightly greater than twice the standard deviation of the mean. A similar small difference was observed when blood samples of Hb-D_{Punjab} trait carriers were analysed. The values for the log P_{50} values at 37° C and *p*H 7·4 were 1·300 for the D trait carrier and 1·325 for the normal control. These results, which are in accordance with the observations made with isolated Hb-D_{Punjab} (ref. 1), suggest that the structural abnormality in this hæmoglobin type, namely, the replacement of a glutamic acid residue by glutamine in position 121 of the α-chain, does interfere with the affinity for molecular oxygen. It might be argued that the results from the experiments with the other six hæmoglobin solutions do not definitely prove that the structural changes in these abnormal hæmoglobin types do not interfere with their oxygen equilibria, since mixtures with varying percentages of normal hæmoglobin types were investigated. It seems, however, that such differences, if present, are too small to change the physiological characteristics of hæmolysates prepared from these red blood cells.

We thank Mr. R. Lee for his help in locating the carriers of the abnormal hæmoglobin types investigated. This work was supported by U.S. Public Health Services grant *H*–6982.

Ellipsometer Recordings of Changes in Optical Thickness of Adsorbed Films associated with Surface Activation of Blood Clotting

Recent publications[1–4] indicate that when blood comes into contact with glass, Factor XII is adsorbed and in turn adsorbs Factor XI. Much of the resulting 'activation product' can be recovered from the adsorbing surface[1,3], but other indirect evidence shows that measurable amounts are released[4–7].

To observe adsorption directly at a wettable solid interface before and during surface activation, a recording ellipsometer was used in our work. Details of technique were described elsewhere[8,9]. As reflecting adsorbents, the following were used: tantalum-sputtered glass object slides, anodized to form an optically sensitive thickness of oxide, and with an approximately 25 Å thicker oxide step at one end of the slide for calibration of the recorder span at the beginning of each experiment; and slices of silicon crystal which could be rendered wettable by exposure to hot nitric acid. Normal intact (non-activated)

Table 1. Activation of Barium Stearate-treated Normal Intact Plasma

0·1 ml. normal intact plasma + 0·1 ml. of:	Clotting time (min)
Normal intact plasma recalcified immediately *	8½, 9½
Intact BaSt-treated plasma recalcified immediately *	9½, 10½
Activated BaSt-treated plasma recalcified immediately *	6½, 7
Intact BaSt-treated plasma incubated separately †	11½
Intact BaSt-treated plasma incubated together †	8½, 9
Activated BaSt-treated plasma incubated separately †	6½, 6½
Activated BaSt-treated plasma incubated together †	4, 4½

* All tests at 37° C in 12 mm × 75 mm polystyrene tubes; 0·2 ml. plasma mixture + 0·2 ml. 0·025 M $CaCl_2$, tilted at 15-sec intervals.
† Normal intact plasma sample and additive incubated for 10 min at 37° C in styrene tubes separately, or together as indicated; then mixture recalcified.
BaSt, barium stearate.

plasma was obtained by centrifuging fresh ACD blood for 30 min at 4° C and 1,000*g*, and then the collected plasma at 4° C and 40,000*g* for 60 min, using 'Nalgene' tubes. The plasma was then aspirated from under the lipid film that had formed, and incubated in 'Styrene' test-tubes for 1 h. Intact, Factor XI-deficient plasma was prepared from this 'whole' intact plasma by adsorption with 50 mg neutral barium stearate (Witco Chem. Co., New York) per ml.[8] for 20 min, followed by centrifugation. Activation was achieved by adding 1 part of quartz powder (No. 520, 3–5μ, Engelhart, Newark, New Jersey) or 'Speedex' (Great Lakes Carbon Corp., Los Angeles, Calif.) to 3 parts of plasma by volume, gently mixing for 10 min[3] at about 25° C, and centrifuging at 20,000*g* for 15 min. The recalcified clotting time of normal plasma in 'Styrene' tubes was shortened about five-fold by this treatment, and the ability of similarly treated barium stearate adsorbed plasma to correct the clotting time of whole intact plasma was improved (Table 1).

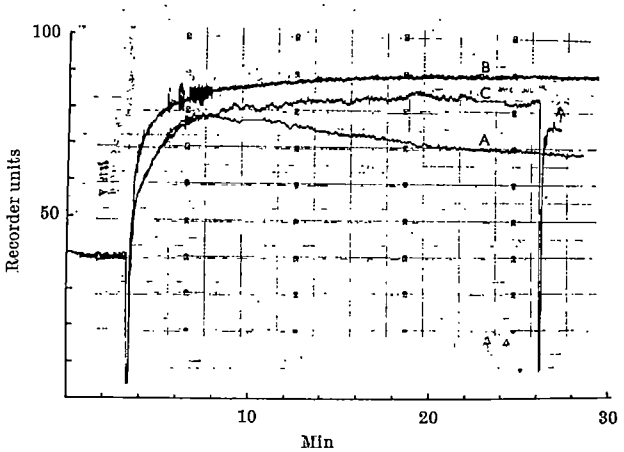

Fig. 1. Adsorption and spontaneous desorption of normal intact plasma (*A*), and adsorption of activated (*B*) and barium stearate-treated plasma (*C*). Superimposed transparent photocopies. 24 Å barium stearate film is equivalent to 80 recorder units

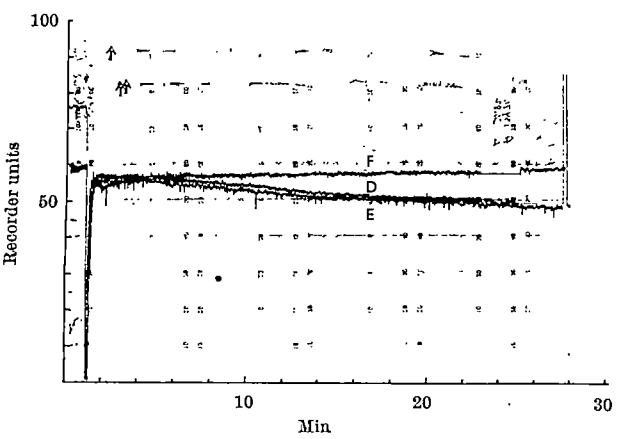

Fig. 2. Removal of barium stearate-treated plasma by normal intact (*D*) and Factor XII-deficient 'activated' plasma (*E*); no removal by normal activated plasma (*F*). Superimposed transparent photocopies

The recordings shown here (Figs. 1 and 2) were obtained with 5461 Å light polarized at 45° to the plane of incidence, and incident at 75°; for recording, the analyser was set about 6° from compensating position. Adsorption was initiated as follows: the tantalum/tantalum oxide slide was lowered into a strain-free glass cuvette containing 60 ml. of 1 part 'VBIS'[8] to 4 parts of normal saline, stirred continuously at 300 r.p.m.; when the recording indicated equilibrium was obtained, 1 ml. of plasma was added. At proper intervals, the instrument was switched from recorder to photometer and minimum settings of quarter wave plate and analyser were determined; these were then both returned to the original recording settings.

Since recordings obtained with the analyser set above its minimum position were more or less the mirror images of those obtained with the analyser set below its minimum position, none of the results reported here was due to significant changes in any optical properties other than those attributable to optical thickness of the reflecting film; moreover, the direction of recorded curves always corresponded to the changes in phase and amplitudes of reflected light components measured with quarter wave plate and analyser. The following results were obtained (Table 2 and Figs. 1 and 2):

(*a*) Adsorption of whole, intact plasma yielded at first a more or less hyperbolic curve, indicating steadily decreasing rate of adsorption; after about 4 min, it reversed to indicate slow partial desorption (Fig. 1*A*).

(*b*) Adsorption of quartz-treated or 'Speedex'-treated whole plasma, or of barium stearate-treated intact or quartz-treated plasma, is completed in about 10 min, and is not followed by desorption (Fig. 1 *B* and *C*).

(*c*) Whole intact plasma, and quartz-treated Factor XII-deficient plasma (obtained through the courtesy of Dr. L. Weisfuse, Garden City, New York), were able to remove constituents from adsorbed films of barium stearate-treated normal intact plasma (Fig. 2 *D* and *E*); quartz-treated normal plasma was not (Fig. 2*F*).

(*d*) No desorption could be induced either by normal intact plasma when it was brought into contact with a film left by activated (quartz-treated) barium stearate-treated plasma, or when barium stearate-treated serum instead of plasma was used as the substrate.

The following tentative conclusions are drawn from the corresponding findings: (1) when plasma which contains intact Factors XI and XII is adsorbed under our conditions, part of the adsorbate—possibly activation product—is soon released; (2) no adsorbate is removed spontaneously by plasma which does not contain intact Factors XI and XII both; (3) adsorbate formed from barium stearate-treated plasma can only be removed by plasma containing intact Factor XI; and (4) only if the adsorbate contains intact Factor XII.

These conclusions fit the presumption that Factor XII is adsorbed, and is removed by Factor XI only if both were initially intact.

The expression of quantitative data (Table 2) in Ångströms is based on the customary presumption that the optical properties of barium stearate layers are identical to those of protein[8,9]. This is not the case[10], and

Table 2. Change in Compensating Analyser Position, and its Barium Stearate Equivalent in Ångströms, after Adsorption and Desorption of Intact Plasma

Slide	Sample	Degree change (Å)	±	*S.D.*	Equiv. (Å) of compressed barium stearate	*N* *

HISTOLOGY

Compensatory Growth of Villi in Postmature Human Placentæ

HISTOLOGICAL changes have been investigated in the postmature human placenta. This is an obstetric abnormality known to be associated frequently with antenatal asphyxia and stillbirth. Fœtal loss occurs as a result of hypoxia, attributed to functional placental insufficiency[1–4]. It is generally stated that in postmaturity the placenta displays signs of ageing and degeneration: widespread vascular obliteration, thrombosis and infarction with excessive fibrinoid and calcified deposits. The appearance of 'young' placental villi in postmaturity, reported by certain investigators[5–7], does not seem to have received adequate attention.

A total of 253 placentæ were studied. These included placentæ from cases of postmaturity of various grades (pregnancy extending to 46 weeks or longer), as well as 25 placentæ delivered at 38–40 weeks (normal labour) used as control.

Specimens for histological investigation were obtained from central, medial and marginal placental zones and embedded in paraffin after fixation in 10 per cent formol. Sections were stained with hæmatoxylin–eosin or with van Gieson's stain. Histological characteristics were related to the clinical data concerning the course of pregnancy and the outcome of labour for mother and child.

Contrary to the present-day view that signs of ageing, and widespread degeneration, tend to prevail in the placenta with prolongation of pregnancy, our observations pertaining to different degrees of postmaturity have demonstrated the occurrence of areas of complementary compensatory villous growth (Fig. 1) against a background of mature or 'ageing' placental structure. These areas were generally located in peripheral portions of the placenta, being more scarce in the central part. The newly-formed groups of terminal villi displayed unequal grades of maturity in different placentæ, suggesting that they probably originated at different stages of pregnancy. In a number of these placentæ, the new villi showed 'harmonic' development of stroma and fœtal capillaries, the latter tending mostly to underlie the plasmodiotrophoblast of the villi, and forming the so-called 'syncytial-capillary' membranes. Compensatory villous growth contributed to the enlargement of the placental surface available for exchange.

At certain sites, however, terminal villi proved to be set more closely. Their surfaces then tended to approximate while the intervillous spaces became more and more narrow. In some of these cases approximation of villi resulted in their conglutination (Fig. 2). Disappearance of intervillous spaces was brought about in this way, the circulation of maternal blood was interrupted and the villous surfaces were excluded from gas exchange and other metabolic processes. Fibrinoid deposition was occasionally seen at these sites.

In some of the placentæ, development of embryonic connective tissue and capillaries was also subject to variation in these foci of compensatory growth. In a number of cases capillary development was poor, the fœtal capillaries being extremely narrow. The distribution of these foci was often restricted to the central part of the villous, but they were occasionally found throughout the stroma. In either case, however, most capillaries were separated from the trophoblast by thick collagen fibres (Fig. 3). In other placentæ, there was excessive development of capillaries in the terminal villi within the foci of compensatory growth. These villi were completely occupied by a multitude of wide capillaries, pressed together and only separated by narrow streaks of connective tissue (Fig. 4).

Irrespective of the prolongation of the period of gestation, some of the placentæ presented the usual appearance of mature placental structure, occasionally

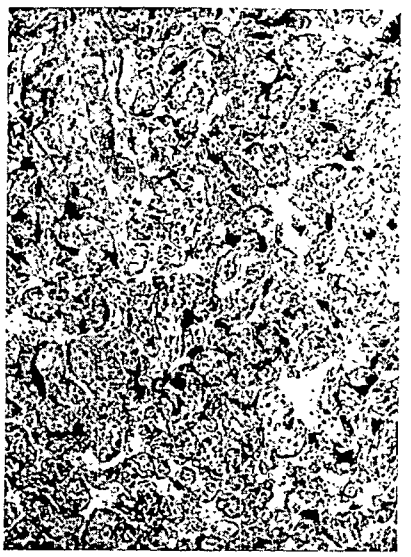

Fig. 1. Focus of compensatory villous growth in human placenta. Gestation, 300 days. (Hæmatoxylin–eosin, × *c.* 55)

Fig. 2. Conglutination of villi in foci of compensatory growth. Gestation, 300 days. (Hæmatoxylin–eosin, × *c.* 500)

Fig. 3. Young villi with deficient development of capillaries. Gestation, 388 days. (Hæmatoxylin–eosin, × *c.* 500)

Fig. 4. Young villi with excessive development of capillaries. Gestation, 319 days. (Hæmatoxylin–eosin, × *c.* 500)

showing signs of ageing, such as extensive accumulations of fibrinoid matter, white infarcts, obliteration of vascular trunks, etc.

All the available material could be classed under three large groups: (1) mature placentæ; (2) placentæ displaying compensatory growth of villi, (*a*) with normal fœtal capillaries or (*b*) with defective fœtal capillary development. Conglutination of villi may occur in (*a*) or (*b*); (3) 'old' placenta.

The distribution of these morphological groups among afterbirths from pregnancies of varying duration are given in Table 1. It is evident that with the prolongation of pregnancy beyond term, the percentage of mature placentæ decreases, while that of placentæ with compensatory growth of villi increases.

When the results of microscopic examination were related to the clinical course of pregnancy and its outcome for the child, a certain pattern could be revealed. In most of the women delivered, within 43–46 weeks, of living babies showing no signs of asphyxia, the placentæ displayed foci of compensatory villous growth without conglutination of the villi and with efficient capillary development. The abnormal development of capillaries in the foci of compensatory growth, associated with conglutination of villi, aggravated conditions detrimental to fœtal development by reducing the functional placental

Table 1

Group	Gestation (weeks)	No. cases	'Mature' No.	'Mature' %	Placenta Displaying compensatory growth of villi No.	Placenta Displaying compensatory growth of villi %	'Old' No.	'Old' %
I	38–40	25	20	80·0	5	20·0	—	—
II	40–42	35	14	40·0	21	40·0	—	—
III	42–44	106	31	29·2	72	68·0	3	2·8
IV	44–46 and over	87	23	26·4	61	70·1	3	3·4
	Total	253	88	—	159	—	6	—

surface area. This type of placental structure was revealed in three-quarters of the cases of stillbirth[8,9].

Thus, investigation of placentæ in postmaturity has shown that the outstanding morphological characteristic of the condition is the occurrence of foci of compensatory growth of terminal villi, rather than the processes of ageing and degeneration, which naturally tend to increase also with postmaturity. Compensatory growth of villi evidently sets in with any deficiency of oxygen and other vitally important substances for fœtal development. It can probably be regarded as a compensatory response of the placenta. In certain cases, compensatory growth of villi fails to bring about favourable results, due to abnormal development of the fœtal capillaries and the impairment of maternal circulation in the intervillous spaces, owing to conglutination of the villi. These changes affecting the placenta, particularly when associated with other unfavourable factors (uterine inertia, etc.), are among the major causes of oxygen lack and perinatal fœtal deaths.

IMMUNOLOGY

Role of Debris of Tumour Ascitic Fluid in Transplantation Immunity

Examination of the chemical nature of histocompatibility antigens is not easy, because of the rapid inactivation of cell-free extracts and the difficulty in obtaining these antigens in a soluble form.

Attempts have recently been made to discover another source of these antigens, more favourable than cells. It has been found that cell-free tumour ascitic fluid possesses some antigenic activity. Hašková and Hilgert[1] detected transplantation antigens in cell-free ascitic fluid of sarcoma I by means of the second-set reaction. Davies[2] isolated from the ascites form of tumour *BP* 8 an iso-antigenic lipoprotein complex absorbing hæmagglutinins from specific antisera. Manson *et al.*[3] extracted soluble transplantation antigens from leukæmic cells grown *in vitro*.

The experiments recorded here were planned to find out whether the antigenic activity of cell-free ascitic fluid was

bound to soluble components or to particles of cellular origin (debris). Three ascitic tumours were used: *Sa I* (*A* strain specific), *BP*-8 (*C3H* strain specific) (kindly provided by Dr. Davies), and *EL*-4 (leukosis-*C57BL*, *H*-2^b-strain specific).

Cell-free ascitic fluid was prepared from ascites collected by four times repeated centrifugation for 10 min at 10,000*g* (maximum). After each centrifugation the supernatant was carefully transferred with a syringe. Absence of tumour cells in the last sediment was controlled by the intraperitoneal injection into the indigenous strain of mice of the tumour. That sediment never gave rise to growth of a tumour.

The debris and the plasma were separated from the cell-free ascitic fluid by centrifugation for 60 min at 105,000*g* (average).

Both fractions were injected intraperitoneally for the examination of the sensitizing activity by means of the 'second-set' reaction[4]. The dosage of debris was expressed by the original volume of ascitic fluid, from which it was extracted. Large volumes of plasma were injected; but they failed to induce any transplantation immunity. The debris exhibited a different sensitizing activity depending on the nature of the tumour from which they were extracted. The debris from the tumours *EL*-4 and *BP*-8 were highly active, but the debris from the tumour *Sa I* were only weakly active (Table 1).

The results observed *in vitro* were consistent with these findings. The debris of tumour *Sa I* inhibited hæmagglutination[5] to a lesser extent than similar preparations of tumours *EL*-4 and *BP*-8. These results were not surprising since cell-free extracts or non-repopulating cells (cell suspension irradiated by 15,000 r. prior to an accumulation) prepared from sarcoma I had a lower activity than similar preparations obtained from tumour *EL*-4 or *BP*-8 or spleen cells.

In the strain combination *A-CBA*, a fully sensitizing extract required a starting material of some 10×10^8 cells of sarcoma I, but only 2×10^8 spleen cells.

The extract of sarcoma I is a weak antigen for two main reasons: if *Sa I* cells are lacking some antigenic factors, or if they possess a smaller amount of antigenic factors per cell.

It is known that the cells of *Sa I* are deficient in some antigenic factors. O'Gorman and Mikulska[6] detected very weak or no antigenic factors *E* and *K* by means of specific antiserum. Kandutsch and Stimpfling[7], however, found *K* antigen to be present, but their preparations contained no antigen *C* and *E*. Davies[8] noted that the cells of tumour *Sa I* had no specificity *E* and *K*.

It may be concluded from the foregoing findings that:

(1) The debris seemed to be responsible for antigenic activity of cell-free ascitic tumour fluid. It was suggested that no transplantation antigens existed in its soluble form in that fluid. But debris was not an easy or economical material to handle for the preparation of some antigenic extract. The amount of debris in the ascitic fluid was mostly variable.

Since the cellular origin of the debris has been proved by electronmicroscopy, it would seem more logical to start from tumour cells rather than from debris for the extraction of iso-antigens.

(2) The extracts from sarcoma I were weakly antigenic and, since the sub-lines of this tumour have proved to possess different antigenic properties (detected *in vitro*)[9], they are not so suitable as the extracts from tumours *EL*-4 and *BP*-8 or spleen or epidermal cells for the investigation of transplantation antigens.

We thank Dr. Ivan Hršel, of the Institute for Experimental Biology and Genetics, Prague, for the electronmicroscopy investigations of ultrastructure of debris.

Species Specificity of the Immunogenic Complexes of the Tapeworm Hexacanth Embryo

IN a previous article[1] evidence was reported supporting the hypothesis that at least two immune responses occur against larval tæniid tapeworms in the intermediate host; and that these responses can be elicited by a single parenteral injection of homologous activated embryos in previously unexposed animals. The initial response appears to occur before the penetration of the hexacanth embryo through the intestinal barrier, and the later response occurs at the site of election against the growing metacestode.

The question was raised as to whether the protection inducing immunogenic complexes of each species of hexacanth embryo are species specific, or some parts of the complex are shared to a greater or lesser extent by

species within the same genus as well as with some of those of different genera.

To assess the species specificity of the immunogenic complexes of cestodes within the same genus, three trials involving 170 worm-free (*Strongyloides* spp. excepted) sheep and 112 rabbits have been carried out, using the hexacanth embryo of *Taenia hydatigena*, *T. ovis* and *T. pisiformis* as the test antigen complexes.

The activated hexacanth embryo antigen complex for each species was prepared by immersing eggs expressed from gravid proglottids in Silverman's[2] hatching solutions. The viable but resting embryo antigen complex (passive) consisted of untreated eggs. The killed embryo complex was prepared by freezing viable eggs at −70° C for 24 h. After treatment, each antigen complex was suspended in lamb's serum (for *T. hydatigena* and *T. ovis*) or rabbit's serum (for *T. pisiformis*) and injected intramuscularly. The animals were approximately three months of age at vaccination. The time interval between vaccination and challenge with aliquot doses of up to 2,500 fresh eggs was about eight weeks. The interval between challenge and autopsy was also about eight weeks.

Table 1 gives the number of animals used to test the protective efficiency of each antigen complex and shows the number of embryos which became established (that is, the minimum number of challenge organisms which penetrated the intestinal barrier and reached the site of election), as well as the number which survived to reach maturity at the site of election in the immunized animals and in those comprising the control groups.

Table 2 shows the percentage of protective efficiency of each of the three species of embryo in different phases of metabolism in inducing an immune response to the establishment and subsequent survival of a homologous and a heterologous challenge.

The specificity of the response to the homologous oral challenge in immunized animals compared with that in the controls in each trial, together with the remoteness of the site of injection from the sites of entry and election of the challenge, give a reasonable basis for assuming an immunological origin for most of the resistance phenomena induced against the challenge of the immunized animals.

These data also show (Table 2) that the activated form of *T. ovis* induced a recognizable response at the 5 per cent level of significance against the invasion of *T. hydatigena*, and the activated embryos of *T. hydatigena* induced a similar response against the invasion of *T. ovis* through the intestinal barrier. The activated embryos of *T. ovis*, however, induced a higher overall protection against *T. hydatigena* than those of *T. hydatigena* elicited against *T. ovis*, because the activated embryos of *T. hydatigena* failed to induce any protection against the long-term survival of *T. ovis*, whereas those of *T. ovis* induced a protective response at the 1 per cent level of significance against the long-term survival of *T. hydatigena*.

Table 2. Percentage Protective Efficiency of the Antigen-complexes of the Hexacanth Embryo

Antigen / Parasite	Stage of embryo	Challenge infection with: *T. hydatigena* in sheep, Immunity at: Intestinal level	*T. hydatigena* in sheep, Immunity at: Site of election	*T. ovis* in sheep, Immunity at: Intestinal level	*T. ovis* in sheep, Immunity at: Site of election	*T. pisiformis* in rabbits, Immunity at: Intestinal level	*T. pisiformis* in rabbits, Immunity at: Site of election

	Dead	28·93	0·0	—	—	—	—

* 1 per cent level of significance.
† 5 per cent level of significance.
The percentage immunity in each phase is calculated from the following:

$$\text{Immunity at the intestinal level is } \left[1-\frac{Nt+Vt}{Nc+Vc}\right]\times 100$$

$$\text{Immunity at the site of election is } \left[\frac{\frac{Nt}{Nt+Vt}-\frac{Nc}{Nc+Vc}}{1-\frac{Nc}{Nc+Vc}}\right]\times 100 \text{ or } \left[\frac{NtVc-NcVt}{Vc(Nt+Vt)}\right]\times 100$$

Where Nt is the number of necrotic lesions per animal within each test group. Nc, the number of necrotic lesions per animal within each control group. Vt, the number of viable cysticerci per animal within each test group. Vc, the number of viable cysticerci per animal within each control group.

The resting form of the embryos of *T. hydatigena* induced a recognizable response at the 5 per cent level of significance against the invasion and subsequent survival of *T. ovis*. The embryos of *T. ovis* injected in the same form appeared to induce some immunity at the intestinal barrier against *T. hydatigena*, but this response did not reach the 5 per cent level of significance.

The activated embryos of both *T. hydatigena* and *T. ovis* induced a recognizable response at the 5 per cent level of significance against the establishment and long-term survival of *T. pisiformis* in rabbits, but those of *T. pisiformis* did not appear to induce an equivalent protective response against either *T. ovis* or *T. hydatigena* in sheep.

Since some protection against a homologous challenge can be induced at the intestinal level as well as at the site of election by the prior parenteral injection of activated as well as resting but not by killed embryos, it would appear likely that metabolic, possibly enzymatic, rather than purely somatic antigen complexes may be involved. However, this cannot be determined on the evidence presented, since it is possible that protection may be given by the somatic tissue which is destroyed by freezing, or by new somatic tissue developed in the resting and particularly in the activated form of the embryos after injection.

The results obtained in these trials indicate that the whole antigenic complex is species specific, but that parts of the protection-inducing complexes are common to the embryonic as well as to the cystic forms of *T. ovis* and

T. hydatigena. The evidence, however, for a similarly shared immunogen between the embryos and cysticerci of the two sheep metacestodes and those of the rabbit metacestode *T. pisiformis* is less certain.

ANATOMY

Effect of Light Deprivation on the Postnatal Development of the Optic Nerve

Gyllensten and Malmfors[1] examined *inter alia* the cross-sectional area and myelinated fibre distribution of the optic nerve in mice reared in the light or in the dark. In mice reared in complete darkness for 20 and 30 days, delay in myelination of the optic nerve fibres caused a reduction in the number of myelinated fibres of some 12 per cent. The number of larger fibres was affected to a greater extent than the number of smaller ones. At 20 days the cross-sectional area of the optic nerve was reduced by 3·4 per cent and at 30 days it was increased by 0·4 per cent; this was said to be insignificant. This latter finding prompts me to report some preliminary observations and a new experimental technique for light deprivation.

The classic experiments in this field are those of Held[2] (cited by Sattler[3]). "Bei neugeborenen Kaninchen, Katzen und Hunden öffnete er einseitig die Lidspalte und fand bei Untersuchung in polarisiertem Licht, 'einen deutlichen, wenn auch nicht sehr beträchtlichen Unterschied in der Markreife', während ein vollständig im Dunkeln gehaltener Hund, dessen eine Lidspalte vorzeitig geöffnet worden war, keinen Unterschied in der Markentwicklung zwischen beiden Sehnerven erkennen liess." In Held's experiments, since the closed eyelids of the new-born are translucent, the difference in stimulus between the two retinæ was one of degree only. It was thought that occlusion of all light from one eye from the time of birth would give a more clear-cut effect and would permit quantitative assessment of the effect of function on fibre size. Even in these experiments, however, the difference may be one of degree only, as the question of spontaneous activity[4] must be considered.

The occluding shield was made from tantalum foil (0·002–0·003 in.). Circular disks of 5 mm diameter were cut from the sheet and made ovoidal with a specially-shaped punch. Newborn mice were operated on within a few hours of birth. From a midline incision over the sagittal suture the skin was undercut over one eye and a shield was inserted. The shape of the shield kept it in position over the convexity of the eyeball and the incision was closed by holding the wound edges together with toothed forceps for a while. The mice were then returned to a foster mother of a hybrid strain who had littered a day or two earlier. The use of recently-littered or highly-strung pure-strain mice resulted in cannibalism. In experiments conducted so far the unoccluded eye opened on the 12th to 14th day but the lids of the occluded eye usually remained fused and the shield remained in position. The eyelids of control animals (operation but no shield) opened at the normal time. The animals were weaned 10 days later and anæsthetized at 75 days with intraperitoneal 'Nembutal'. The animals with occluded eyes were normal in weight and the eye beneath the shield was normal in size and structure. The calvarium was removed and the brain divided in the mid-coronal plane so that the optic nerves and chiasma were left *in situ* when the rest of the brain was removed. For light microscopy the nerves were prepared as follows: the nerve of the operated side was cut longer than the other for identification; the nerves and chiasma were then removed and processed *en bloc* so that the nerves received identical treatment; they were sandwiched between pieces of liver, the operated side being identified by a human hair placed alongside it, and placed in a cell; the cell was frozen in a CO_2–acetone mixture and transverse sections were cut at 7μ in a cryostat[6]. The sections were fixed and stained on a slide with potassium permanganate[5] and mounted in Farrant's medium.

The fresh-frozen section technique is particularly suitable for detecting a gross effect since it 'fixes' tissue fluid and preserves the relations of living tissues so that the shrinkage and distortion which accompany most routine methods of fixation and embedding[7] are absent. In the control animals the cross-sectional areas of the nerves of the two sides were similar. In the animals with occluded eyes the nerves of the operated side had a cross-sectional area some 10 per cent less than those of the unoperated side.

The question of which tissue component or components of the optic nerve was responsible for this gross effect could not be settled with certainty. Difficulties in quantification with this method may be related to the large number of small fibres and to the intimate membrane contacts which exist in this situation[8]. The visual impression gained was that both axon diameter and sheath thickness failed to reach normal values. Substantiation of this is being sought by electron microscopy; phase contrast microscopy is unsuitable for precise dimensional estimations of this kind[6]. Gyllensten and Malmfors[1] commented only on overall fibre diameter. Since their experiments affect the time of onset of myelination, which is an incremental process, it is likely that sheath thickness has been affected. Has axon diameter also been affected by light deprivation? Is the retardation of myelination secondary to retardation of axonal growth? One would expect, *a priori*, a primary effect on the axon, but the secondary effects of this cannot be predicted. While axons do not myelinate below a certain minimum diameter (which varies with site and species) the diameter of newly myelinated axons varies quite widely[9-11] and it may be that myelination is related more closely to neuronal type and maturity, as indicated by the pattern of Nissl substance[12], and to neuronal activity, which does not necessarily depend on connexions. Whatever the factors, it would be interesting to know whether the rate of incremental myelination (increase in sheath thickness) as well as its onset are affected by light deprivation. This is yet another situation in which analysis is incomplete without determination of both axon diameter and sheath thickness[13].

The pilot study was undertaken in the Department of Anatomy, Guy's Hospital Medical School. I thank Prof. R. Warwick for facilities and Mr. Graham Stevens for assistance.

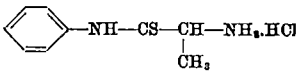
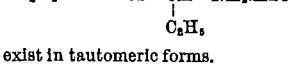
RADIOBIOLOGY

Aminothioamides as Protectors against the Effect of Gamma-rays in *Allium cepa*





Several aminothioamides of the general type R_1—NH—CS—CH(NH_2)—R_2 have been synthesized[1]. As is generally known with thioamides, these aminothioamides can exist in solution in two tautomeric forms:

$$R_1\text{—NH—CS—CH—}R_2 \rightleftharpoons R_1\text{—N=C—CH—}R_2$$
$$\qquad\qquad\quad |\qquad\qquad\qquad\quad |\quad\ |$$
$$\qquad\qquad NH_2\qquad\qquad\quad SH\ NH_2$$

Notably in their thiol form they exhibit a free sulphydryl group as well as a free amino-group separated by two carbon atoms. Such arrangement was shown to favour protection against ionizing radiation[2–4].

The protective potentialities of a number of amino-thioamides (Table 1) were tested against the action of gamma-rays from a cobalt-60 source. *Allium cepa* seeds, variety 'White May', were germinated and seedlings with primary roots reaching 3–5 mm were selected and pre-treated for 1 h with a non-toxic concentration of the chemical under investigation. Then together with the respective solution the seedlings were irradiated.

Table 1. Aminothioamides Tested

	Chemical name	Formula
(1)	Amino-thioacetamide hydrobromide	H_2N—CS—CH_2—NH_2.HBr
(2)	*N*-Ethyl-amino-thioacetamide hydrobromide	C_2H_5—NH—CS—CH_2—NH_2.HBr
(3)	Amino-thioacetanilide hydrochloride	
(4)	*N-cyclo*hexyl-aminothio-acetamide hydrobromide	
(5)*	Amino-thioacetpiperidide hydrobromide	
(6)	*N*-Ethyl-D,L-α-aminothiopro-pionamide hydrobromide	
(7)	D,L-α-aminothiopropion-anilide hydrochloride	
(8)	*N*-Ethyl-D,L-α-aminothiobutyr-amide hydrobromide	

* This compound, in solution, does not exist in tautomeric forms.

The protective activity was assessed from: (*a*) the rate of growth of *Allium* roots which received a dose of 350 r. delivered as 5 r./sec; (*b*) from reduction in chromosome aberration at the same dose-level; (*c*) from the survival of roots against a lethal dose. In this communication, results obtained from the rate of growth are given (Fig. 1). Seedlings which were pre-treated with the chemical and then irradiated were thoroughly washed, transferred to Petri dishes containing moistened filter papers and then kept at 26° ± 1° C in a thermostat into which daylight was allowed through a glass door. The rate of growth of the primary roots was measured every 24 h. Measurements were carried out until the ninth day after irradiation, the day in which the normal non-irradiated control generally ceased to grow. Such short experimental duration enabled us to repeat and reproduce our results several times. Protective factors were derived from the rate of growth of irradiated roots pre-treated with one of those chemicals to that of roots irradiated in tap water, that is, irradiated control. This ratio was taken at a time when the normal non-irradiated control showed a maximum rate of growth.

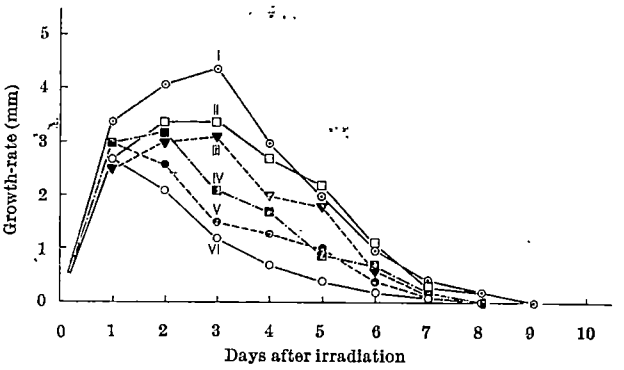


Fig. 1. Rate of growth of *Allium cepa* primary roots after different treatments. I, Normal, non-irradiated control; II, irradiated under anoxic conditions. Pretreated with and irradiated in cysteine (III), amino-thioacetamide hydrobromide (IV) and *N*-ethyl-aminoacetamide hydrobromide (V). VI, irradiated control

Among the eight compounds thus screened, two were found to offer some protection, the others being ineffective. Amino-thioacetamide hydrobromide was effective at 1×10^{-2} M concentration with the result that a protective factor of 1·7 was obtained, while *N*-ethyl-amino-thioacetamide hydrobromide at an optimum concentration of 5×10^{-3} M gave a factor of 1·25.

In comparison, roots pre-treated with a 5×10^{-2} M cysteine solution for 1 h and then irradiated in the same solution showed a protective factor 2·3, while roots irradiated in tap water deoxygenated by bubbling nitrogen for 45 min before irradiation (anoxic condition) showed a factor of 2·8.

Our results have thus shown that amino-thioamides, in which R = H or C_2H_5, were protective in *Allium*, though the degree of protection was lower than that shown by cysteine. The rest of the compounds having other substitutions were thoroughly ineffective.

It is of interest to note that thioacetamide was recently reported[5] as protecting *Allium cepa* cells against the action of alpha-rays and thermal neutrons, though the effect was limited in time.

I thank Prof. Z. Devidé for his advice, Prof. V. Hahn and Dr. K. Jakopčić for synthesis, supply of the chemicals and many other suggestions during this work, as well as the authorities of the Institute 'Rudjer Bošković', Zagreb, for facilities.

Trophic Level Effect on the Accumulation of Cæsium-137 in Cougars feeding on Mule Deer

In aquatic ecosystems, cæsium-137 levels in predators exceed those of herbivores under conditions of equal contamination of the environment[1–3]. Examples of the step-wise increase in contamination-levels of cæsium-137 in four species of fish representing three trophic levels, and an explanation of the reason for the increase, will be published soon[4]. To our knowledge, no example of trophic level increase has been demonstrated in terrestrial wildlife, although an approximate 2- to 3-fold increase in cæsium-137 in man over his integrated food has been reported by several workers[5–7], and similar results were obtained by feeding cæsium-137 to animals[8,9].

An examination of the accumulation of fall-out nuclides in the tissues of mule deer (*Odocoileus h. hemionus*) (Raf.) has been carried out at this laboratory since September 1961. In the course of this work, a series of three cougars (*Felis concolor hippolestes* Merriam) was taken within a period of six weeks (December 1, 1962–January 16, 1963). Deer had been taken earlier, and additional samples were collected as soon as possible after the cougars were killed.

All the animals discussed in this communication were taken in the field with firearms[10], and most of the deer were collected from the same areas as were the cougars. The animals were skinned, and tissue samples were placed in plastic bags until counting was done with an 8-in. × 4-in. sodium iodide (Tl) crystal and a 400-channel γ-ray spectrometer. Flesh samples consisted of the hind leg from the hip joint to the knee (haunch). The femur was not removed.

Since deer flesh is the major source of food for the cougar, and the principal site of deposition of cæsium-137 in the body of the deer and cougars is muscle tissue, comparisons of accumulation between the two animals can be made using the skinned haunch as the sample (Table 1).

Table 1. CÆSIUM-137 IN FLESH OF MULE DEER AND COUGARS

Sample date	Deer		Cougars		^{137}Cs/kg flesh cougar/deer	^{137}Cs/gm K cougar/deer
	pc. ^{137}Cs/kg flesh	pc. ^{137}Cs/gm K	pc. ^{137}Cs/kg flesh	pc. ^{137}Cs/gm K		
12/1/62–1/5/63	425	107	1,080*	230	2·54	2·15
			2,270	526	3·89	5·11
1/15–16/63	583	103	1,860	424	3·20	4·12
Average	504 ($\bar{X}d$)	105	1,736 ($\bar{X}c$)	393	3·21	3·79

* A small, gravid female; this animal had been eating porcupines as well as deer. The other cougars were large males, and the gut contained few porcupine quills.

The average cæsium-137 content for the deer was 504 pc./kg and the average for the cougars was 1,736 pc./kg. Thus, 1,736/504 gives an increase ratio (*IR*) between deer and lions of 3·4. Although slightly higher, the Cs/K ratio shows the same relationship.

The results demonstrate a clear-cut increase of three-fold or better between the cæsium-137 level in deer flesh and cougar flesh and are in good agreement with the 3·4 increase that should be expected, according to Anderson *et al.*[5]. Implications of a trophic level (Λ) increase can best be demonstrated diagrammatically:

Λ^1 Photosynthetic plants (many species) Contamination level = X $\xrightarrow{IR = 3\cdot(?)}$ Λ^2 Primary consumers (herbivore-deer) Contamination level = $3X$ 504 pc. ^{137}Cs/kg $\xrightarrow{IR = 3\cdot4}$ Λ^3 Secondary consumers (carnivore-cougar) Contamination level = $9X$ 1,736 pc. ^{137}Cs/kg

Since man may vary in his trophic level relationship from a pure herbivore to virtually the level of a carnivore, the radiation dose from internally deposited cæsium-137 will be closely related to his dietary habits.

It is probable that the high levels of cæsium-137 in Alaskan Eskimos[11] and Laplanders from Northern Sweden[12] are a direct result of a trophic level increase relative to their predominantly animal diet. The animals on which they feed, in turn, subsist on plants which grow in a maximum accumulation environment for cæsium-137 and strontium-90; that is, a region characterized by climatic conditions conducive to the growth of lichens and other mat plants, very rapid plant growth during a short summer, usually wet conditions during the growth period, and cold, shallow soils that restrict the root systems to within a few inches of the surface. This combination of factors leads to a high accumulation in plants, herbivores and, ultimately, man.

Accordingly, any human population which is predominantly carnivorous should have higher body burdens of cæsium-137 than neighbouring populations which are omnivorous or herbivorous. Exceptions to this would be expected if the carnivorous population obtained its food from the ocean, and the neighbouring population obtained its plant foods from terrestrial sources, or if the meat eaters occupied a dry area and the vegetarians occupied wetlands. Oceanic foods are low in cæsium-137 (ref. 13), and plants grown in terrestrial wet lands contain higher quantities of cæsium-137 than those from otherwise equivalent dry lands[14,15].

If the dosage to bone from cæsium-137 is equal to the dosage from strontium-90, as reported by Anderson and Gustafson[16], further investigations of the accumulation of cæsium-137 in the biosphere assume greater importance. Evaluations of hazards resulting from cæsium-137 ingestion should incorporate provision for the trophic level increase.

The effect of this trophic level increase in cæsium-137, applied to conditions to be expected following extensive testing or atomic war, would be an increase in the hazard for predators—either animal or human. Terrestrial and aquatic mammalian predators would be subject to the greatest risk of all the biota, but local 'hot spots' resulting from differential deposition or ecological conditions could lead to exposures hazardous to the lower trophic levels. Predaceous species should be studied in greater detail to determine relative accumulation efficiency in other ecological situations—particularly the arctic and sub-arctic zones.

Investigations of human populations having essentially carnivorous food habits should be made in as many areas of the world as possible, since these people appear to be at greatest risk from cæsium-137 incorporated via the food web.

This work was supported by the Division of Radiological Health, Bureau of State Services, U.S. Public Health Service (*RH*–30), and the Utah State Department of Fish and Game provided personnel and transportation.

Addendum. Since this communication was written, we have learned that McNeill and Trojan[17] have shown the same relationship of cæsium-137 and potassium for human beings as we have found in cougars.

BIOLOGY

Coding of the Colour Preference of the Gull Chick

GULL chicks (*Larus atricilla*) peck at their parent's red bill, an act which elicits regurgitation from the parent. In an investigation reported elsewhere[1], it was found that chicks peck preferentially in response to long and short wave-lengths of visible light (that is, they prefer red and blue to green and yellow). The following hypothesis attempts to account for this wave-length preference.

The bird's retina contains minute coloured oil droplets, a single droplet being contained in a single cone. Most avian species have three distinct colours[2]; the gull chick's eye appears to contain only red and yellow droplets[1]. The droplets are situated at the base of the outer segment of the cone, and thus filter incoming light before it strikes the visual pigment. The bleaching effect of the filtered light, and hence the response of the cone (C), for any given wave-length may be expressed as:

$$C = k_1 \log IOP \qquad (1)$$

where I is the intensity of the unfiltered light, O, the percentage transmission by the oil droplet, P, the percentage absorption of the visual pigment, and k_1, a constant of proportionality the value of which depends on the measurement of the cone response. The logarithmic transformation appears to be characteristic of visual receptors[3].

Assume that the red droplet-bearing cone is excitatory and the yellow one inhibitory. If inhibition is subtractive (as in lateral inhibition of the *Limulus* eye[3]), the pecking rate (R) at any given wave-length would be determined by:

$$R = k_2(C_r - C_y) = k_2 (\log IO_rP_r - \log IO_yP_y) \qquad (2)$$

which reduces to:

$$R = k_2 \log \frac{IO_rP_r}{IO_yP_y} \qquad (3)$$

where C_r and C_y are the responses of the red- and yellow-droplet-bearing cones, respectively, O_r and O_y are the transmissions of the droplets, P_r and P_y are the absorptions of the visual pigments, and k_2 is a proportionality constant.

Muntz[4] has suggested in another context that the interaction of visual receptors in wave-length coding is multiplicative (without logarithmic transformations), in this case:

$$R = k_3 \frac{IO_rP_r}{IO_yP_y} \qquad (4)$$

If the gull chick's eye contains but a single photopic pigment (as is probably true for the chicken[5] and the pigeon[6]), the P's cancel from equations (3) and (4), as must the I values, which are identical for a single wave-length. The pecking rate is thus proportional to the ratio of the transmissions of the oil droplets, or the logarithm of this ratio.

The chick's response rates were recorded automatically on a transilluminated pecking key for stimuli of selected wave-lengths between 450 and 650 mμ. The wave-length bands were obtained with interference filters, the energy transmissions of which were equated with a variable diaphragm using a thermopile and deflexion galvanometer. (The discrepancy between equal energy and the physiologically meaningful number of quanta at various wave-lengths thus introduces a small error.) Transmission spectra of the oil droplets were obtained using Strother's[1,2] method in his laboratory. The O_r/O_y ratios were computed for wave-lengths in the spectrum between 450 and 650 mμ, and are compared with the mean pecking rates in Fig. 1. Theoretical results from both forms of the hypothesis are in close agreement with the behavioural data.

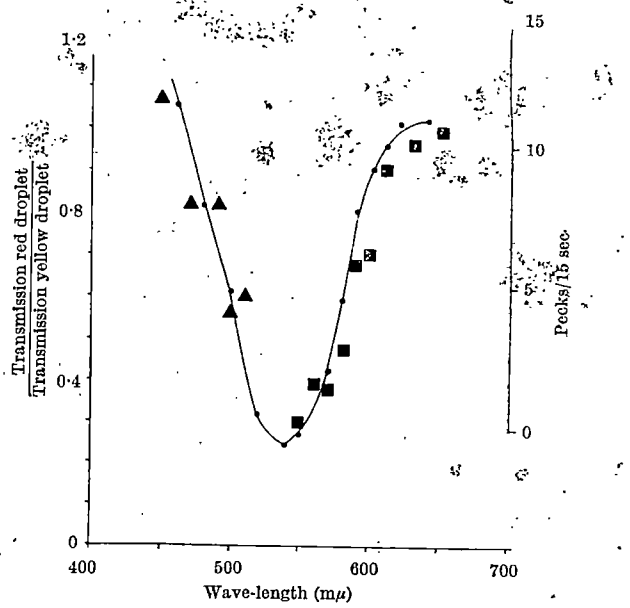

Fig. 1. The line and small dots represent calculated transmission ratios of the two oil droplet colours. The large triangles and the large squares represent mean pecking rates from groups of twelve and ten newly hatched *Larus atricilla* chicks, respectively

ENTOMOLOGY

Methyl Linolenate as an Essential Nutrient for the Cabbage Looper, *Trichoplusia ni* (Hübner)

A DIETARY requirement for polyunsaturated fatty acids has been demonstrated in several lepidopterous and orthopterous species. The most common expression of fatty acid deficiency was a slower larval growth-rate or faulty adult emergence with resulting wing deformity, or both[1–5]. In the lepidopterous species examined the requirement was fulfilled with either linoleic or linolenic acids[2,3,5]. In the genus *Ephestia*, the flour moths, linoleic or linolenic acids promoted larval growth and normal wing development[3]. Arachidonic acid improved the growth-rate of *Ephestia*, but had no positive effect on wing development[6]. Linoleic acid allowed normal wing development of the pink bollworm, *Pectinophora gossypiella* (Saund.), but, because lower levels were active, linolenic acid was considered more effective[5]. Normal wing development of the greater wax moth, *Galleria mellonella* (L.), was promoted with linoleic or linolenic acids, but not with arachidonic acid[2].

This communication reports on the fatty acid requirements of the cabbage looper, *Trichoplusia ni* (Hübner). A satisfactory meridic diet, a modification of that described for the bollworm, *Heliothis zea* (Boddie)[7], containing wheat germ (oil and solids) as the only plant

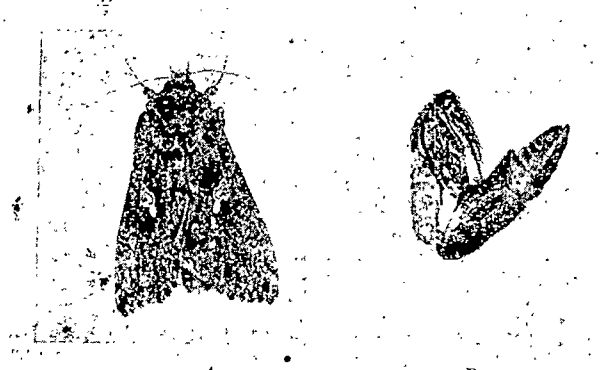
* Nutritional Biochemicals Corp. † Ref. 8

adjuvant and fatty acid source, has been developed for this insect. Table 1 shows the composition of the basal diet for *Trichoplusia*. Rearing procedures and fractionation investigations of the wheat germ have previously been reported[8]. The fractionation examinations revealed that wheat germ residue after chloroform–methanol 2 : 1 (v/v) extraction contained a factor required for normal larval growth, and the lipid fraction a material which promoted both larval growth and wing development. The latter was contained in the saponifiable fraction of wheat germ oil. Complete lack of this 'wing development factor' resulted in severe wing deformity and failure of the moths to emerge from the pupal case (Fig. 1). The condition shown in Fig. 1*B* was typical of the adults classified in the 'deformed wings' category in Table 2.

larvæ was very poor, being similar to that on the negative control diet (Table 2). This difficulty was obviated by the addition of methyl linoleate. A mixture of 200 mg of the linoleate plus 50 mg of methyl linolenate gave good growth (11·6 days to 50 per cent pupation), but of 38 adults produced, only four had normal wings. Thus the supplement of 100 mg of methyl linolenate was considered to be close to the threshold level.

The results from one assay of methyl oleate (> 99 per cent purity[10], 150 mg) tested as a mixture with 250 mg methyl linoleate indicated that methyl oleate did not promote normal wing development; of 31 adults produced all had deformed wings. Similar results were obtained when a mixture of 150 mg methyl arachidonate (> 90 per cent purity[10]) and 250 mg methyl linoleate was assayed.



Dietary supplements of 126 mg methyl eicosa-5,8,11,14,17-pentaenoate (> 90 per cent purity[10]) and 126 mg methyl docosa-4,7,10,13,16,19-hexaenoate (> 90 per cent purity[10]) stimulated larval growth but did not permit normal wing development (Table 2). The interpretation of these results is uncertain because of the possibility of oxidative degradation of the supplements during the assay period. In view of the stimulation of larval growth, however, extensive degradation probably did not occur.

§ Larvæ arranged in replicates of ten.

Several individual fatty acid methyl esters of a high degree of purity[9,10] obtained from the Hormel Institute, Austin, Minnesota, were tested for activity. A dietary supplement of 500 mg (and lower levels) methyl linoleate (> 99 per cent purity[10]) promoted larval growth and normal pupation, but did not promote normal wing development (Table 2)[8]. These results were contrary to the findings of the previous workers cited here, and prompted further tests on other fatty acids which are constituents of wheat germ oil. Table 2 shows that 500 mg methyl linolenate (methyl octadeca-9,12,15-trienoate, > 99 per cent purity[10]) allowed both good larval growth and normal wing development. Lower levels (250 and 100 mg) were equally effective except that for the 100 mg supplement the larval growth period was slightly prolonged (13·2 days to 50 per cent pupation). When still lower levels (50 and 25 mg) were tested, survival of the

A *B*

Fig. 1. *A*, Normal adult of *Trichoplusia ni*; *B*, adult partially emerged from pupal case showing extreme wing deformity

In many of the previous papers on insect fatty acid requirements, the purity of the unsaturated fatty acids used was not adequately documented. Some of the growth and wing development effects ascribed to linoleic acid may have been due to contaminating linolenic acid.

Our discovery that methyl linolenate is an essential nutrient for *Trichoplusia ni*, and that this requirement cannot be fulfilled by methyl linoleate, contrasts sharply with the reverse situation in the rat[11].

MICROBIOLOGY

Patterns of Interferon Appearance in Mice injected with Bacteria or Bacterial Endotoxin

Previous work[1] has shown that the intravenous injection of large numbers of live *Brucella abortus* into chickens results in the appearance in the serum of a viral inhibitor with the properties of interferon. Inhibitor reached maximum levels about 12 h after inoculation. It was also reported that large numbers of Newcastle disease virus (NDV) particles produced maximum levels of interferon in chickens about 12 h after intravenous inoculation. Injection of large doses of other gram-positive and -negative bacteria or bacterial endotoxins failed to produce demonstrable inhibitors in the circulation of chickens at 6–8 h.

Since these results were reported, further work with chickens has shown that a barely detectable, but consistent, inhibitor activity appears in the serum at about 2 h after inoculation of large numbers of *Serratia marcescens* and *Salmonella typhimurium*, and after *Escherichia coli* endotoxin. In the case of *E. coli* endotoxin, it was necessary to inject birds intravenously with at least 40 mg in order to demonstrate inhibitor in serum at 2 h. Inhibitor activity, which usually was barely detectable at 2 h, had disappeared by 4–6 h after injection. The small and transient amounts in the serum made it too difficult to investigate the properties of the inhibitor produced at 2 h.

Table 1. Viral Inhibitor in Plasma of Mice at Different Times following Intravenous Injection of Various Organisms and Bacterial Lipopolysaccharide

Material injected	Dose	Inhibitor titres* of plasma pools (hours post-injection)

* Reciprocal of the highest dilution of plasma giving 50 per cent inhibition of plaques of VSV in *L* cells.
† Nucleic acid not detected spectrophotometrically.

In extending these studies to other species, it was found that the intravenous injection of mice[2] with *B. abortus* or NDV resulted in significantly higher levels of circulating inhibitor than those found in chickens. This permitted us to examine the time pattern of appearance of viral inhibitor in mice as well as to compare the properties of the inhibitors produced in response to stimulation by different bacteria, NDV and endotoxin.

Swiss Webster female mice weighing about 25 g were injected in the tail vein with the different materials in a 0·1-ml. volume of saline diluent. Blood samples were obtained at different times from groups of about 10 mice by cardiac puncture with heparin-rinsed syringes. Pooled plasmas were assayed for viral inhibitor by the plaque-reduction method[3] using an interferon-sensitive line of *L* cells. Cultures of *L* cells in 60-mm Petri dishes were exposed for 20 h to 3 ml. of two-fold serial dilutions of plasma and then challenged with 40–60 plaque-forming units of vesicular stomatitis virus (VSV). The titres of viral inhibitors were calculated from the dilution of plasma which reduced the plaque count to 50 per cent of that of the controls. The dose of NDV was based on plaque-forming units; numbers of bacteria were given as viable units but it should be noted that approximately the same mass of bacteria, determined by optical density measurements, was employed in each case. Clumping or differences in size explain variations in viable counts.

Table 1 shows the inhibitor titres of mouse plasmas obtained at different times after the intravenous inoculation of several gram-negative bacterial species, *E. coli* 0111 : *B4* endotoxin (Difco), and Newcastle disease virus. The results show that there were two distinct patterns of appearance of inhibitor in the circulation. The injection of NDV or *B. abortus* resulted in maximum inhibitor activity at 12–14 h. In contrast, the injection of *S. marcescens*, *S. typhimurium*, or endotoxin was followed by the early appearance of inhibitor in the plasma; maximum levels, far greater than any obtained in chickens, were observed at 2 h and these rapidly declined. Preliminary experiments have shown that direct exposure of *L* cells to 100 μg of endotoxin in serum-containing medium for 20 h did not reduce the subsequent plating efficiency of VSV, indicating that residual endotoxin in the plasma probably played no part in our experiments.

The characteristics of early-appearing inhibitor produced by endotoxin and the late-appearing inhibitors resulting from inoculation of *B. abortus* and Newcastle disease virus in mice were studied. The results showed that all three inhibitors prevented plaque formation by vesicular stomatitis virus only in mouse cells, not in chick embryo cells, and did not neutralize virus directly but acted on the host cells. In addition, all three inhibitors were stable to *p*H 3 treatment overnight but showed loss of activity when incubated with crystalline trypsin (50 μg/ml.) or when heated at 56° C for 1 h. These observations lead to the conclusion that the properties of the early-appearing inhibitor produced by endotoxin and the late-appearing inhibitors stimulated by *B. abortus* and NDV are similar to those of virus-induced mouse serum interferon as reported by Merigan[4].

The results with mice indicate that, as in chickens[1], *B. abortus* stimulated the appearance of interferon which reached peak titres in about 12 h. In mice, *S. typhimurium* *S. marcescens* and endotoxin produced inhibitor which appeared much earlier than inhibitor stimulated by *B. abortus* or NDV. This early-appearing inhibitor also resembled in properties and time of appearance the 'serum sparing substance' of Gledhill[5]. It is possible that the early-appearing interferon may be preformed and released from the cells with which the stimulating agent reacts, while the late-appearing interferon may represent inhibitor synthesized in response to *B. abortus* or NDV. Other explanations, including differences in the type of cell affected or differences in the rapidity of cell damage produced by the different agents, must be considered. However, it is known that all the agents used, including endotoxin[6,7], are rapidly sequestered in cells of the reticulo-endothelial system and it is possible that the inhibitors produced by the different agents are released in response to damage or stimulation of these cells.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 16

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Lieut. Comm. J. B. Dixon, R.N.: "Hydrographic Surveying in the Antarctic".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. R. C. Brian: "Electronics and the Mode of Action of Certain Herbicides".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. P. M. S. Blackett, F.R.S.: "Britain and India's Development Plans" (Rickman Godlee Lecture).*

Monday, November 16—Thursday, November 19

INSTITUTION OF MINING AND METALLURGY, in co-operation with the Institution of Mining Engineers and the Institute of Quarrying (at Caxton Hall, Westminster, London, S.W.1)—Symposium on "Opencast Mining, Quarrying and Alluvial Mining".

Tuesday, November 17

BRITISH INTERPLANETARY SOCIETY, and the SOCIETY OF ENVIRONMENTAL ENGINEERS (at Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 9.30 a.m.—Symposium on "Space Environment Simulators".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN AND THE SOCIETY OF COSMETIC CHEMISTS OF GREAT BRITAIN (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 9.30 a.m.—Symposium on "Preservatives and Antioxidants".

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Meeting on "Soil Organic Matter".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. L. B. Keeble: "The Future of London".*

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. A. Bradley, Mr. C. D. Clarke, Mr. R. M. Davis and Dr. D. A. Jones: "Adjustable Frequency Invertors and Their Application to Variable-Speed Drives".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 12, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Population Control" initiated by Prof. A. S. Parkes, F.R.S., and Prof. Donald Reid.

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMATIC CONTROL GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "One-Line Determination of Process Dynamics".

RESEARCH DEFENCE SOCIETY (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. Alexander Haddow, F.R.S.: "The Contribution of Animal Experiment to Our Knowledge of the Causation and Therapy of Malignant Disease" (Thirty-third Stephen Paget Memorial Lecture); followed by the Annual General Meeting.

PLASTICS INSTITUTE, LONDON SECTION—REINFORCED PLASTICS SUB-GROUP (at the Coachmakers Arms, 88 Marylebone Lane, London, W.1), at 6.30 p.m.—Mr. G. T. Byast: "Plastics Equipment Fault Finding".

Tuesday, November 17—Wednesday, November 18

INSTITUTION OF GAS ENGINEERS (at Church House, Westminster, London, S.W.1), at 9.15 a.m. daily—30th Autumn Research Meeting.

Wednesday, November 18

BRITISH INSTITUTE OF RADIOLOGY, ISOTOPE STUDY SECTION (joint meeting with the Hospital Physicists' Association, in the Reid Knox Hall, 32 Welbeck Street, London, W.1), at 9.45 a.m.—Meeting on "Radio-isotope Scanning".

ROYAL INSTITUTION OF NAVAL ARCHITECTS (in the Memorial Building, 76 Mark Lane, London, E.C.3), at 10.30 a.m.—Discussion on "Ship Maintenance and Associated Design Problems".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Dr. F. T. Perkins: "The Science and Practice of Immunology" (Dr. Aldred Memorial Lecture).

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. J. Latham: "Change Transfer Associated with Temperature Gradients in Ice Crystals Grown in a Diffusion Chamber"; Mr. J. B. Matthews and Mr. B. J. Mason: "Electrification Produced by the Rupture of Large Water Drops in an Active Field".

INSTITUTE OF FUEL (at the Royal Institute of British Architects, 66 Portland Place, London, W.1), at 5.30 p.m.—Mr. K. Dixon, Mr. E. Skipsey and Dr. J. T. Watts: "The Distribution and Composition of Inorganic Matter in British Coals: Part 1—Initial Study of Seams from the East Midlands Division of the National Coal Board".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (joint meeting with the Science and General Division, at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "What is Measurement?" opened by Mr. L. Finkelstein, Mr. G. G. Gouriet, Dr. P. Vigoureux and Mr. A. C. Lynch.

WORSHIPFUL SOCIETY OF APOTHECARIES OF LONDON, FACULTY OF THE HISTORY OF MEDICINE AND PHARMACY (at Black Friars Lane, Queen Victoria Street, London, E.C.4), at 5.30 p.m.—Mr. R. R. Trail: "Sydenham's Influence on English Medicine" (Sydenham Lecture).

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, RADAR AND NAVIGATION AIDS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. R. L. Burr and Mr. J. Flounders: "An Air Surveillance Radar System".

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Effect of Low Temperatures on the Operation of Diesel Vehicles".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the South-West Essex Technical College Chemical Society, at the South-West Essex Technical College, Forest Road, Walthamstow, London, E.17), at 7 p.m.—Dr. F. W. Gibbs: "Science in Soho—Scenes from the 18th Century".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION, KENT SUB-SECTION (at the North-West Kent College of Technology, Liskin Road, Dartford, Kent) at 7 p.m.—Dr. S. R. Craxford: "The Removal of Sulphur from Flue Gases".

BRITISH INSTITUTE OF RADIOLOGY (at the National Hospital for Nervous Diseases, Queen Square, London, W.C.1), at 7.30 p.m.—Conversazione. Dr. Macdonald Critchley, C.B.E.: "The National Hospital—The Cradle of Neurology"; Dr. Richard Hunter and Dr. James Bull: "The Pineal Gland—a Radiological Landmark and its Place in the History of Psychiatry".

ROYAL AERONAUTICAL SOCIETY, GRADUATES' AND STUDENTS' SECTION (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Mr. G. Sage: "Structural Problems of Manned Space Flight".

Thursday, November 19

SOCIETY OF INSTRUMENT TECHNOLOGY (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 2.30 p.m.—Symposium on "Performance Evaluation of Industrial Instruments".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. B. F. Skinner (Harvard University): "The Technology of Teaching —Its Nature and Some Problems Encountered in its Use" (Review Lecture).

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. Philip H. Gregory, F.R.S., Prof. D. Müller and Mr. D. H. Bridger: "Mirror Yeasts".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting, followed by Prof. G. Higman: "Bundles of Null-Spaces".

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. J. B. Chappell: "Mitochondria —Permeability and Function".*

UNIVERSITY OF LONDON (at Charing Cross Hospital Medical School, London, W.C.2), at 5.30 p.m.—Lord Todd, F.R.S.: "Organic Chemistry and the Progress of Medicine" (Huxley Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dame Honor Fell, F.R.S.: "Organ Culture in Medical Research". (Eighth of fourteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 6 p.m.—Discussion Meeting on "Free Radicals".

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 6 p.m.—Informal Discussion on "Design in Relation to Service and Maintenance".

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Fuel as an Engine Lubricant and/or Coolant".

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. D. H. Mathews, Mr. D. M. Colwill and Mr. R. Yuce: "Adhesion Tests for Bituminous Road Materials".

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Mr. J. L. E. Baldwin: "A British Video Tape Recorder".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION, LEA VALLEY SUB-SECTION (at the College of Further Education, Hatfield Road, St. Albans), at 7.30 p.m.—Dr. R. A. Jeffreys: "Colour Photography".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at the Liverpool School of Tropical Medicine, Pembroke Place, Liverpool), at 7.30 p.m.—Laboratory Meeting.

Thursday, November 19—Friday, November 20

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2)—Conference on "Commutation in Rotating Machines".

Friday, November 20

BRITISH INSTITUTE OF RADIOLOGY (at 32 Welbeck Street, London, W.1), at 9.30 a.m.—Meeting on "Mammalian Radiobiology at the Cellular Level".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Prof. H. G. Miller: "Current Research in Multiple Sclerosis".*

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Mr. S. Serebreny: "Meteorology and Supersonic Transport".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. W. H. McCrea, F.R.S.: "Origin of the Solar System".

Saturday, November 21

SOCIETY FOR DEVELOPMENTAL BIOLOGY (at the National Institute for Medical Research, Mill Hill, London, N.W.7), at 10 a.m.—Dr. J. B. Solomon: "The Onset of Immunological Reactions in the Chicken"; Mr. D. James: "The Effects of Antigenic Differences on Placental Size in Mice"; Dr. J. A. Tata: "Amphibian Metamorphosis"; Dr. N. A. Mitchison: "Double Competence in the Response to Antigen".

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. Stanley B. Hamilton: "Ancient Methods of Building".*

Monday, November 23

Institute of Actuaries (at Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Mr. J. R. Ford and Mr. C. M. Stewart: "Population Trends in Great Britain".

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. F. Hoskins: "Loop Gain and Return Difference of Transistor Amplifiers".

Royal Institution of Naval Architects (at the North East Coast Institution of Engineers and Shipbuilders, Bolbec Hall, Newcastle upon Tyne), at 6 p.m.—Mr. W. D. Horsley: "The High Speed Generator—Eighty Years of Progress" (Sir Charles Parsons Memorial Lecture).

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (in the Renold Building of the College of Science and Technology, Manchester), at 6.45 p.m.—Discussion on "The Mechanics of High-Speed Weaving".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Assistant in the Geographical Research Division for work primarily in the field of economic geography—Dr. J. E. Martin, London School of Economics and Political Science, Houghton Street, London, W.C.2 (November 20).

Assistant Lecturer (honours graduate in pharmacy, preferably with a special interest in the physico-chemical aspects of pharmaceutical chemistry) in Pharmaceutical Chemistry—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (November 21).

Lecturer or Assistant Lecturer in the Department of Philosophy—The Registrar, The University, Leeds, 2 (November 23).

Senior Lecturer or Lecturer in Medical Statistics in the Departments of Mathematics and Public Health—The Secretary of the University Court, The University, Glasgow (November 27).

Lecturer or Assistant Lecturer (with interests in sensory processes and perception, or in the study of human learning) in Psychology—The Secretary and Registrar, Room 9, The University, Southampton (November 28).

Assistant Experimental Officer (with experience in biological or analytical laboratory work) in the Department of Biochemistry, to join a team investigating metabolic aberrations in cattle—The Secretary, Institute for Research on Animal Diseases, A.R.C., Compton, Near Newbury, Berkshire (November 30).

Junior Lecturer/Lecturer in Social Anthropology at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, November 30).

Lecturer in Physiology and a Senior Lecturer in Physiology—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (November 30).

Lecturer in the Department of Physics—The Secretary, University College, Gower Street, London, W.C.1 (November 30).

Lecturer (with a good honours degree in physiology and/or a veterinary qualification) in the Department of Veterinary Physiology in the Faculty of Veterinary Medicine—The Secretary, The University, Old College, South Bridge, Edinburgh, 8 (November 30).

Lecturers and Assistant Lecturers (honours graduates) in Chemistry, Botany and Zoology in the Faculty of Science, University College of Science Education, Cape Coast, Ghana—The Assistant Registrar, University College of Science Education, 15 Gordon Square, London, W.C.1 (November 30).

Research Assistant in the Department of Veterinary Physiology, to take part in an investigation, supported by the Agricultural Research Council, into the electrophysiology of the nervous control of gastrointestinal activity in sheep—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh, 8 (November 30).

Lecturer or Assistant Lecturer in Pure Mathematics—The Registrar, University of Kent at Canterbury, Westgate House, Canterbury, Kent (December 5).

Joseph Hunter Chair of Pathology—The Registrar, The University, Sheffield, 10 (December 12).

Lecturer in Mathematical Statistics at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 18).

Official Fellow and Lecturer in Philosophy—The Warden, Wadham College, Oxford (January 1).

Agricultural Superintendent (with a degree in agriculture) in Dominica, to be responsible to the Minister of Trade and Production for the administration of the Agricultural Department, for the agricultural development programme, including general supervision, and to act in an advisory capacity—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/52/01.

Head of the Chemistry Department—Grade VI; Head of the Mathematics Department—Grade IV; and Head of the Biology and Geology Department—Grade IV—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

Health Physicist (with an honours degree or equivalent in physics) to work on all aspects of safety and radiation protection and measurement—Recruitment Officer, U.K.A.E.A. Experimental Reactor Establishment, Dounreay, Thurso, Caithness, Scotland, quoting Ref. E.475/34.

Lecturer in Mathematics; a Lecturer in Computing; and a Lecturer in Statistics—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Lecturer or Assistant Lecturer in Numerical Analysis—The Registrar (Room 22, O.R.B.), The University, Reading.

Physicist or Physical Chemist (with at least three years research experience in the field of semiconductor material behaviour, photochemistry, or polymer structure characterization)—The Director, Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian, Scotland.

Senior Technician I for work in virology—Dr. H. B. E. Cadness-Graves, Public Health Laboratory, Peace Memorial Hospital, Watford, Hertfordshire.

Technician (preferably with experience with radioisotopes) for biochemical research on cerebral enzymes and proteins concerned in phosphorus metabolism—The Secretary, Institute of Psychiatry, The Maudsley Hospital, Denmark Hill, London, S.E.5.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

The British Drug Houses, Ltd. Industrial Applications of Panacide: Algicide, Bactericide, Fungicide. Pp. 10. Enzyme Substrates. Pp. 6. (Poole: British Drug Houses, Ltd., 1964.) [610

The Ramblers' Association. The Right to Roam: The Rambler and the Countryside. Pp. 32. (London: The Ramblers' Association, 1964.) 2s. [610

Imperial College of Science and Technology (University of London). Shorter Postgraduate Courses, Autumn Term, Session 1964–65. Pp. 16. (London: Imperial College of Science and Technology, 1964.) [610

Current Medical Research: a Reprint of Articles in the Report of the Medical Research Council for the year 1962–1963. Pp. iii+51+3 plates. (London: H.M. Stationery Office, 1964.) 4s. 6d. net. [610

Agricultural Research Council. Experimental Farm Buildings—Report No. 1: Cow Cubicles. By Dr. H. R. Livingston. Pp. 16. (London: Agricultural Research Council, 1964. Obtainable from H.M. Stationery Office, 1964.) 2s. 6d. [610

Electrical Research Association. Technical Report No. 5014: High Field Effects for Linear Chains of Dipoles or Limited Conducting Paths. By Dr. Vera Daniel and P. R. Vein. Pp. 13+3 figures. (Leatherhead: Electrical Research Association, 1963.) 12s. 6d. [610

Bulletin of the British Museum (Natural History). Botany. Vol. 3, No. 4: A Revision of the Genus *Petrorhagia*. By P. W. Ball and V. H. Heywood. Pp. 119–172+plates 13–15. 22s. Vol. 12, No. 1: Polyzoa from West Africa. Notes on the Genera *Hippoporina* Neviani, *Hippoporella* Canu, *Cleidochasma* Harmer and *Hippoporidra* Canu and Bassler (Cheilostomata, Ascophora). By P. L. Cook. Pp. 1–35+plates 1–3. 15s. (London: British Museum (Natural History), 1964.) [610

The University of Sussex. Prospectus 1964/65. Pp. 120. (Stanmer, Brighton: The University of Sussex, 1964.) [610

Institute of Seaweed Research. Annual Report for 1963. Pp. 23. (Inveresk, Midlothian: Institute of Seaweed Research, 1964.) [610

Other Countries

United States Department of the Interior: Geological Survey. Water-Supply Paper 1499–I: Water Resources of the Wichita Area, Kansas. By L. B. Petri, C. W. Lane and L. W. Furness. Pp. v+69+plate 1. Water-Supply Paper 1535–I: Sources of Mineral Constituents in Water from Granitic Rocks, Sierra Nevada, California and Nevada. By J. H. Feth, C. E. Robertson and W. L. Polzer. Pp. iv+70+plate 1. Water-Supply Paper 1535–J: Chemical Composition of Snow in the Northern Sierra Nevada and Other Areas. By J. H. Feth, S. M. Rogers and C. E. Robertson. Pp. iii+39+plate 1. Water-Supply Paper 1608–E: Hydrogeologic Reconnaissance of Poro Point and Vicinity, Luzon Island, Philippines. By G. F. Worts, Jr. Pp. iii+14+plate 1. (Washington, D.C.: Government Printing Office, 1964.) [510

United States Department of the Interior: Geological Survey. Water-Supply Paper 1653: Ground-Water Resources of the Lower Rio Grande Valley Area, Texas. By Roger C. Baker and O. C. Dale. Pp. v+56+plates 1–5. Water-Supply Paper 1654: Ground Water for Irrigation in the Snake River Basin in Idaho. By M. J. Mundorff, E. G. Crosthwaite and C. Kilburn. Pp. vii+224+plates 1–6. Water-Supply Paper 1656: Geology and Ground-Water Features of the Edison-Maricopa Area, Kern County, California. By P. R. Wood and R. H. Dale. Pp. vi+108+plates 1–12. Water-Supply Paper 1664: Geology and Ground Water of San Antonio Creek Valley, Santa Barbara County, California. By K. S. Muir. Pp. v+53+plates 1–4. Water-Supply Paper 1669–R: Geology and Ground-Water Conditions of the Redwood Falls Area, Redwood County, Minnesota. By George R. Schiner and Robert Schneider. Pp. iv+46+plates 1–11. (Washington, D.C.: Government Printing Office, 1964.) [510

United States Department of the Interior: Geological Survey. Water-Supply Paper 1696–B: Determination of Radium in Water. By F. B. Barker and J. O. Johnson. Pp. iii+29. Water-Supply Paper 1700: Geochemistry of Natural Waters of the Blue Grass Region, Kentucky. By G. E. Hendrickson and R. A. Krieger. Pp. vii+135+plates 1–9. Water-Supply Paper 1721: Compilation of Records of Surface Waters of the United States, October 1950 to September 1960. Part 1–A: North Atlantic Slope Basins, Maine to Connecticut. Prepared under the direction of E. L. Hendricks. Pp. x+317+plate 1. Water-Supply Paper 1726: Compilation of Records of Surface Waters of the United States, October 1950 to September 1960. Part 3–B: Cumberland and Tennessee River Basins. Prepared under the direction of E. L. Hendricks. Pp. viii+269+plate 1. Water-Supply Paper 1729: Compilation of Records of Surface Waters of the United States, October 1950 to September 1960. Part 6–A: Missouri River Basin Above Sioux City, Iowa. Prepared under the direction of E. L. Hendricks. Pp. xii+507+plate 1. Water-Supply Paper 1730: Compilation of Records of Surface Waters of the United States, October 1950 to September 1960. Part 6–B: Missouri River Basin Below Sioux City, Iowa. Prepared under the direction of E. L. Hendricks. Pp. xiii+514+plate 1. Water-Supply Paper 1733: Compilation of Records of Surface Waters of the United States, October 1950 to September 1960. Part 9: Colorado River Basin. Prepared under the direction of E. L. Hendricks. Pp. xv+586+plate 1. (Washington, D.C.: Government Printing Office, 1964.) [510

LETTERS TO THE EDITOR

Page

ASTROPHYSICS

Detection of an Interstellar Flux of Gamma-Rays.—Dr. Albert E. Metzger, Dr. Ernest C. Anderson, Prof. Marvin A. Van Dilla and Prof. James R. Arnold 766
On Intergalactic Gas as a Possible Absorber of Extra-galactic Radio Noise.—Dr. D. W. Sciama . . 767

PHYSICS

Standard Date Periods with Declination Limits.—Dr. H. Heywood 768
Propagation of Stress Waves in Liquids.—Dr. D. H. Trevena 768
Fast Flux Reversal in Laminated Nickel-Iron Thin Films.—Dr. Floyd B. Humphrey and Dr. H. Clow . 769
Single Sweep Oscillograph Traces of Sonoluminescence.—R. D. Finch 770
Variation in the Ratio of Strontium-89 to Strontium-90 in Precipitation Samples with Sampling Height.—A. Aarkrog 771
Equivalence of the Schroedinger and Heisenberg Pictures.—Dr. H. S. Perlman; Prof. P. A. M. Dirac, F.R.S. 771

GEOLOGY

Kink-bands and Related Geological Structures.—Brian Marshall; Dr. T. B. Anderson . . . 772
Live and Dead Foraminifera between the Sarns, Cardigan Bay.—Dr. John Haynes 774
M_2 Component at Hyderabad.—Dr. S. Balakrishna and B. R. Lakshmi 774

CRYSTALLOGRAPHY

New Representatives of the $NbAs_2$ and $ZrAs_2$ Structures.—Dr. F. Hulliger 775

CHEMISTRY

Water Structure around Silver Iodide Sol Particles.—A. S. Fawcett, Dr. G. D. Parfitt and A. L. Smith . 775
Reversible Photochemical Bleaching in Frozen Aqueous Systems at 77° K.—P. N. Moorthy and Prof. J. J. Weiss 776
Molecular Structure of π-allyl-palladium Acetate.—Dr. M. R. Churchill and Prof. R. Mason . . . 777
Phosphate-mediated Dehydrogenation of Alcohol in the Photochemistry of Ferrocyanide in Aqueous Solution.—Mrs. Miriam Shirom and Prof. Gabriel Stein 778

BIOCHEMISTRY

Heat-yellowing of Wool and Silk.—Z. Janowski and Prof. J. B. Speakman, C.B.E. 779
Scopoletin, Scopolin and Chlorogenic Acid in Tumours of Interspecific *Nicotiana* Hybrids.—Prof. T. C. Tso, L. G. Burk, L. J. Dieterman and Prof. S. H. Wender 779
Utilization of Saccharose and Maltose by Yeasts.—J. Santa María 781
Action of Phospholipase *C* on Influenza Virus.—Dr. Hiromichi Mizutani and Hiroko Mizutani . . 781
Fatty Acids of Beef Heart Sphingomyelin.—Dr. A. C. Schram, Prof. R. H. Wilson, A. P. Boer and V. E. Doty 783
Determination of Dipeptidase Activities.—Lars Josefsson 783

PHYSIOLOGY

Formation of Isorhodopsin in the Frog's Eye during Continuous Illumination.—Tom Reuter . . 784
Effect of *d*-Gamma-tocopherol on the Incidence of Teratogeny in Vitamin E-deficient Rats.—Prof. Dorothy Wei King 785
Site of Cardiac Glycoside Inhibition of Cation Transport.—Prof. Bruce F. Bower 786

PHARMACOLOGY

'Viractin': a Prophylactic Agent against Upper Respiratory Infections.—Prof. Byron E. Leach, Pearl E. Hackman and Dr. Lawrence W. Byers . 788
Solubility Relations of Fluorine Compounds and Inert Gas Narcosis.—R. A. Dawe, K. W. Miller and Dr. E. B. Smith 789

Page

Effects of Insecticide Synergists on Duration of Sleep induced in Mice by Barbiturates.—Dr. B. C. Fine and J. O. Molloy 789
TPNH Oxidation by the Prepuberal Rat Testis.—Dr. N. A. Schor and A. Perez 790
Alkaloid Content of Tobacco Seeds.—Dr. Y. Abdoh and H. Pirelahi 791

HÆMATOLOGY

Xg^a Investigations of the Family of a Child with a Ring *X* Chromosome.—Dr. L. E. Nijenhuis and Jeltje Gemser-Runia 792
Separation of White Blood Cells.—Dr. Arne Bøyum . 793

IMMUNOLOGY

Cell-bound and Cell-binding Antibody in the Peripheral Blood of Immunized Rabbits.—Dr. Ernst Sorkin . 794
7 *S* Globulin, Immunologically Identical to 19 *S* Gamma-1 (beta-2)-*M*-globulin, a New Protein of Horse Serum.—Dr. Georges Sandor, Stéphane Korach and Paul Mattern 795

RADIOBIOLOGY

Tritium Labelling of Antibodies.—C.-G. Rosén, L. Ehrenberg and G. Ahnström 796

BIOLOGY

Duration of Embryonic Hypersensitivity and its Relation to the Level of Differentiation of the Chick.—Prof. Pierson J. Van Alten . . . 797
Effect of Time of Year on the Roughage Intake of Housed Sheep.—Dr. John G. Gordon . . . 798
Destruction of Homologous Cells in Tissue Culture by Nuclei of Immune Lymphocytes.—Dr. George J. Svet-Moldavsky and Inessa Ju. Chernyakhovskaya . 799
Purification of Algal Cultures with Caffeine.—S. W. Bowne, jun. 801
Oxygen Diffusion from the Roots of Some British Bog Plants.—W. Armstrong 801

MICROBIOLOGY

Fatty Acid Composition of Lipids extracted from Three Spherical Bacteria.—Dr. Joseph P. Brown and Dr. Benjamin J. Cosenza 802
Use of a Fluorescent Brightener for tracing the Passage of *Salmonella* in Eggs.—Dr. A. M. Paton and Prof. J. C. Ayres 803
Carbon Dioxide-dependent Morphogenesis in *Arthrobotrys conoides*.—S. Bartnicki-Garcia, Jacob Eren and Prof. David Pramer 804

CYTOLOGY

Absence of Late Replication of a Human *X*-Ring Chromosome.—Dr. Rudolf A. Pfeiffer and Dr. Thomas Büchner 804
Percentage Incorporation of Leucine labelled with Carbon-14 into Isolated Mitotic Apparatus during Early Development of Sea Urchin Eggs.—T. Bibring and G. H. Cousineau 805

VIROLOGY

Growth of Bovine Parainfluenza-3 Virus in Chick Tissues growing on Polythene.—Dr. S. C. Arya . 807

SOIL SCIENCE

Studies of Sensitivity and Electro-kinetic Potential in Leda Clay.—Edward Penner 808

GENETICS

The *Histokinette* stays on the job

Diagnostic reports to hand hours earlier than they would be with manual processing and in far greater numbers—the release of a valuable technician for other duties . . . these are the outstanding advantages of the Histokinette Automatic Tissue Processing machine. Once the Histokinette has been put into operation, it will *without supervision* go through the entire cycle of fixation, dehydration, impregnation in wax, or alternatively can be set up for the washing or staining of tissues. It can handle large numbers of specimens at the same time and while staff is off duty—speed up almost any technique by ensuring quicker and more thorough penetration by reagents.

A 24-hour clock is fitted as standard. Change over to 1 hour or 7 day cycles (*the latter of great value in double embedding and bone decalcification techniques*) is simple and rapid.

Histokinette special features include :—

- Up to 24 hours delayed start
- Double processing capacity
- One or more motor members and baskets
- Unbreakable tissue basket and containers

The Hendrey Histokinette is in general use at home and overseas

BS PRECISION INSTRUMENTS

Polarimeter Model A

This instrument gives the highest degree of accuracy with divided circle on glass reading to 0.01 degree.

Circle centre on ball bearings · Easily removable trough · Divided drum replacing verniers · Stationary observation telescope · Circle reader enlarging image of scale · Slow motion adjustment always in action · Suitable, with additions, for measurement of rotatory dispersion.

This polarimeter has been supplied in large numbers both in this country and abroad and has always been acclaimed as being of advanced design and workmanship. Please ask for particulars "N".

BRITISH OVERSEAS RESEARCH AND DEVELOPMENT

THE latest pamphlet in the factual survey of *British Aid* which the Overseas Development Institute has published deals with technical assistance and is one of the most important the Institute has produced*. It is, moreover, fortunate in its timing, for it makes a fitting complement to the examination of the work of the Department of Technical Co-operation given in the tenth report from the Estimates Committee for the Session 1963–64†. It is no disparagement of the memorandum submitted on behalf of the Secretary for Technical Co-operation, in evidence before the Estimates Committee, to suggest that, factually, the Overseas Development Institute provides the more comprehensive account. At the critical level, the Institute's examination of the facts, however, is far more searching than that of the Estimates Committee and its comments and suggestions are more constructive and fundamental.

To the scientist, an important feature of both documents is the attention directed to overseas research. For the first time, we are given some idea of the extent of the effort that is being made, but there is a big difference between the two documents. This is illustrated by the simple fact that the Estimates Committee accepts without question the recommendation of the Trend Report for the dissolution of the Overseas Research Council. The Overseas Development Institute fully appreciates the ineffectiveness of the Research Council, but it sees a good deal further. The Overseas Research Council was deliberately made ineffective: the implication is that this was done to prepare the way for the recommendations from the Trend Committee, and if the Overseas Development Institute's pamphlet had done no more than bring the whole discreditable sequence into daylight it would have done sufficient public service.

It should be noted, of course, that the Estimates Committee was concerned primarily with the organization of the Department of Technical Co-operation and with the way in which financial control was exercised over its activities, and although some attention was directed to research, no specific recommendations were made in this field. It was stated in evidence that when the Department was established some 500 people were transferred from corresponding departments at the Colonial Office, including those for research and for communications and the whole of the Overseas Service Division. The Overseas Geological Survey with a staff of 193, the Directorate of Overseas Surveys with 419 and the Anti-Locust Research Centre with 48 were also transferred. The Department has some 30 advisers on technical subjects, most of whom come from the Colonial Office, and the duties of these advisers are described generally in the memorandum submitted for the Secretary for Technical Co-operation. Otherwise, while explaining the organization, the memorandum gives no information on the scale of overseas research.

In the evidence to the Committee the Department's expenditure on research is estimated at £1,961,000 apart from that on the Anti-Locust Research Centre, which brings the total to £2·2 million, of which about 40 per cent is spent in the United Kingdom and the remainder in the developing countries overseas, particularly in east and central Africa and in the Caribbean area. Of the £1 million spent in Britain, some £110,000 was spent on the Tropical Products Institute, £42,000 on the tropical section of the Road Research Laboratory, about another £40,000 each on the Tropical Stored Products Centre and the tropical division of the Building Research Station. About £45,000 is spent on two small units working on pesticides and other aspects of infestation, and some small projects at universities are also financed by the Department.

It was emphasized in evidence before the Committee that the purpose of these home-based research units is five-fold. First, they seek to continue the basic research which maintains a store of scientific capital. Next, they investigate specific problems, either in their own laboratories or by sending experts overseas as requested by overseas stations or Governments. Thirdly, they collect, collate, analyse and circulate the most recent information in their fields, thus keeping in touch the scientists working in isolation overseas. Fourthly, they assist in training overseas research workers, either in the institutes here or by sending training teams overseas, and fifthly, they serve as a home base for British scientists who can be seconded to overseas Governments, for short- or long-term investigations.

Besides stressing the importance of this continual traffic and contact between home-based scientists and overseas workers, particularly in formulating projects for investigation, and in avoiding duplication of effort, Mr. W. A. C. Mathieson, for the Department, emphasized the value of the work of the Anti-Locust Research Centre and its high international standing. He also pointed out that the work of the natural resources and research divisions of the Department was very closely linked, since the major part of the research effort was devoted to the application of the biological sciences to natural resources. He did not think that the recommendations of the Trend Report would significantly affect the research activities of the Department, and no questions were raised by the Estimates Committee concerning either the Overseas Geological Survey or the Directorate of Overseas (Geodetic and Topographic) Surveys.

The treatment of research in the study of the Overseas Development Institute is much fuller. First, in reviewing the development of British technical assistance up to 1961, it has a concise summary of the way in which colonial research developed and ramified, first under the Colonial Research Committee and later, when funds for research became available under the Colonial Development and Welfare Acts, under the Colonial Research Council: over the period 1946–62, about 7·5 per cent of expenditure under these Acts was on research schemes. Next, a chapter on the structure, finance and functions of the Department of Technical Co-operation considerably amplifies the information submitted in evidence to the Estimates Committee, and it also includes reference to the work of five Committees set up at various times to report on technical aid in specific fields: they include the Lord Bridges's Committee on Training in Public Administration;

* The Overseas Development Institute. *British Aid*—4: *Technical Assistance*. Pp. 196. (London: The Overseas Development Institute, 1964.) 7*s*. 6*d*.

† Tenth Report from the Estimates Committee together with part of the Minutes of the Evidence taken before Sub-Committee F and appendixes, Session 1963–64. Department of Technical Co-operation. Pp. xxix+243. (London: H.M. Stationery Office, 1964.) 16*s*. 6*d*.

Rawden Committee dealing with agriculture, animal health, forestry and fisheries; and the Brundrett Committee on overseas mining and geology.

The value of the survey should be sufficiently apparent from this, but before dealing with the chapter on research, it should be added that there are other chapters on the supply of personnel, on training, on regional programmes and Commonwealth Educational Co-operation, on multilateral technical assistance, and on co-ordination of technical and financial assistance. In one, on request procedures and priorities, it is noted that in research particularly most of the work supported from the Department's funds was started before independence with Colonial Development and Welfare Funds. It is probably easy to exaggerate the extent to which the pattern of assistance is determined by independent decisions in developing countries, especially in the field of research.

As regards the Department's sub-head for research, the survey explains that this is for "expenditure on the promotion of research for the benefit of developing countries" and that when it was first established its level was fixed for three years, from 1963–64, and it is intended each year to fix the provision for a further year ahead. This will enable the Department to give firmer assurances of support and facilitate forward planning. Professional advice on priorities is obtained from the Department's advisers and advisory committees, the research advisers being heads of the home-based research institutions supported by the Department, apart from the adviser on medical research and the agricultural research adviser. In this connexion the survey comments on the heavy concentration of research in agriculture and medicine and the relative neglect of economics, education and the social services. It is in the same connexion that the survey notes the demise of the Overseas Research Council. By implication the ineffectiveness of that Council in seeking to ensure the continuation of research units in former colonial territories after independence is attributed to the failure to supply the Research Council with funds of its own. Nevertheless, there is nothing in the account of the Department of Technical Co-operation's activities to suggest that the Overseas Research Council has become redundant or that, either within the Department or as an independent body, it could not strengthen the research effort overseas.

It might be observed in this same connexion that during the British Commonwealth Scientific Committee's third meeting in New Zealand (November 15–December 6), although the Agricultural Research Council and the Nature Conservancy are being represented as well as the Department of Technical Co-operation, there is no specific representation for overseas research such as the Colonial Research Council and the Overseas Research Council formerly supplied. The organizing agency for the Committee in Britain is the Department of Scientific and Industrial Research, which is also being represented at the meeting. Presumably it is too soon for the representation from Britain to reflect the changes in Government organization of civil science and overseas development, proposed for the new Cabinet, but such representation should receive the careful attention of the new Minister for Overseas Development and the Minister for Education and Science.

It is rather in the analysis of research expenditure that this survey by the Overseas Development Institute indicates the opportunities which confront an Overseas Research Council, and it is not easy to visualize an alternative method by which these opportunities can be seized and the concomitant responsibilities discharged. Of the £1·2 million in the 1963–64 budget for research in the developing countries, agriculture (including veterinary research and forestry) took £627,000 (£189,000 for East Africa, £144,000 for Central Africa and £133,000 for the Caribbean), and medical research £260,000 (East Africa, £91,000; West Africa, £67,000; Caribbean, £100,000). Most of this expenditure is in the form of grants towards the recurrent and capital costs of research institutions in the developing countries, normally on a 50–50 basis, but sometimes higher. The 800 or so research workers at these institutions include local as well as British nationals, and British support is still necessary in the countries that have recently become independent.

The mere list of some of the larger overseas institutions being supported in this way indicates the range of opportunity and the complexity of the task of securing adequate support for research. Of the ten East African institutions on the list some are known to be in difficulties, while those familiar with the reports of the Colonial Research Council will note that now only one is listed from West Africa, though there are three from the West Indies and one from Malacca. A further pertinent comment on this list is Dr. E. B. Worthington's remark in *Minerva* (Spring 1964) that while these and other institutions were vigorous before the break-up of the scientific edifice built by the colonial powers, many are but empty shells now. In refilling them the great need is for the marriage of the indigenous with the exotic. Here the rapid development of local universities gives most promise. Dr. Worthington was referring particularly to Dr. S. Dedijer's article on science in underdeveloped countries and to a subsequent article by Dr. M. Moravisik on "Technical Assistance and Fundamental Research in Underdeveloped Countries", and he also stressed the desirability of keeping the number of organizations in these countries to a minimum. Writing from Nairobi, Dr. D. Odhiambo in the same issue referred to the considerable lack of indigenous research workers in East Africa and to the absence of postgraduate schools capable of covering a broad spectrum of pure research. Technical assistance could help to meet both needs if foreign research workers were made available, if only for one to two years, to help create the appropriate atmosphere for research in the academic institutions, provided funds were made available for establishing postgraduate schools. It was in the hope of creating a scientific community in East Africa, as urged by Dr. Dedijer, that on independence the scientists in various East African regional research organizations had been organized into the East African Academy—from which Dr. Odhiambo wrote. Financial support is also given to government agricultural research stations in Sabah, Sarawak, Malawi and Swaziland, and the Department of Technical Co-operation is making a substantial grant to the reconstituted Agricultural Research Council of Central Africa over the three years from July 1, 1964. The Department also finances British participation in the work of the Natural Resources Research Council and the Medical Research Council in East Africa, and a new scheme is at present being considered for a few research fellowships to be offered by Britain each year for tenure at universities and other institutions in developing countries.

These fellowships are intended to attract those who have already had postgraduate research experience, and also to strengthen research at universities and other institutions, rather than to further the execution

of specific research projects. Both forms of support are essential, and under the organization that has existed since the Colonial Research Council was functioning it is the specific project that has tended to receive support. As the Overseas Development Institute comments pertinently: "The consideration that (overseas research institutions) are places where indigenous research workers could be trained and the foundations for a modern scientific community laid does not seem to play any significant part in British thinking". This, however, is probably the most urgent aspect of overseas research in the newly independent countries, and that in which British aid could have the most decisive effect. Fresh thinking and generous action at this point are as imperative from the point of view of the economic development and stability of these countries as they are from the point of view of research or of educational aid.

The home-based establishments which are wholly financed by the Department of Technical Co-operation include the Anti-Locust Research Centre, the Tropical Products Institute, the Tropical Section of the Road Research Laboratory, the Tropical Division of the Building Research Station, the Tropical Stored Products Centres of the Agricultural Research Council and the Tropical Pesticides Research Unit and Headquarters and Information Unit. Expenditure of £15,000 on the Central Pool of Scientists, which is administered by the Commonwealth Agricultural Bureau and the Department of Technical Co-operation, brings the total to £905,000 in 1963–64. Some £150,000 is spent by the Department on overseas research at universities and other independent institutions, of which £70,000 is spent equally on agricultural and medical research, £43,000 on trypanosomiasis and £29,000 on pesticides. This, however, represents only a part of the benefit which developing countries derive from research in British universities and institutes, and some of the work financed by the Department is extension of work on home products, while other work arises from contacts between universities and developing countries. The Tropical Products Institute, which has a staff of 160, estimates that about 40 per cent of its work is undertaken in response to requests and about 60 per cent on its own initiative.

Besides this, the Department of Technical Co-operation in 1963 spent about £115,000 on consultancies and about £1·1 million on geodetic, topographical and geological surveys—only about one-third of the surveys being carried out under regional programmes in 1963. The method of financing mapping surveys undertaken by the Directorate of Overseas (Geodetic and Topographic) Surveys, which employs a staff in Britain of some 500, has recently been changed to make regional programme funds cover virtually the whole cost of surveys in future. Its present budget is running at slightly more than £1 million a year and the developing country is usually expected to provide 15 per cent of the cost of aerial photography and the field survey work.

Overseas Geological Surveys has a staff of about 100, of whom normally 10 are overseas at any one time, and besides its major role of helping to build up local Geological Survey Departments in the colonies it offers specialist services, and its Geophysical Division conducts surveys in various countries. Expenditure in 1963–64 is estimated at £263,000, but it will be recalled that the Brundrett Report (see *Nature*, 203, 331; 1964) recommended that Overseas Geological Surveys should be amalgamated with the Geological Survey of Great Britain and the functions of the latter expanded to cover overseas work in geological and mineral assessment, the cost of the [illegible] being met by the Department of Technical Co-ope[illegible] Even the outlined budget is only of the order of £1 million, which, as already pointed out in these columns, seems a long way below what is desirable and compares poorly with expenditure in the same field by the United States or by France.

This recommendation has already been accepted by the Government, but the budget as well as the organization of the expanded Department could appropriately be reconsidered by the new Ministry of Overseas Development and the Ministry of Education and Science and probably also by the Ministry of Technology and the Ministry of Land and Natural Resources. The Overseas Development Institute in its present survey does not indeed discuss these particular recommendations, and it is silent on the further recommendation that the Extraction of Metals Group of the National Chemical Laboratory should be merged as soon as possible with the Mineral Processing Division of the Warren Spring Laboratory, which has also been accepted by the Government. This recommendation, however, which outwardly appears reasonable, has caused some concern among the scientific staff affected; apart from the actual merger there would appear to be room for further discussion about the new department, which clearly should be sufficiently strong to deal effectively with overseas work in this field.

The Brundrett Report could scarcely have stated better the case for expansion in overseas geology and mining, and while further consideration may well be required on the recommendation of the Trend Committee that the Geological Survey should itself be placed under the proposed Natural Resources Research Council, there appears to be no firm ground for concern as to the future of research generally in these fields. In particular, the Brundrett Committee's recommendation that a highly qualified Advisory Committee should be constituted to advise the Department of Technical Co-operation on problems of technical assistance in these fields may well be reconsidered. Even the Trend Committee, in recommending the dissolution of the Overseas Research Council, proposed that the Research Council should be replaced by a series of such advisory committees.

Even more concrete, however, are some of the conclusions and suggestions of the Overseas Development Institute in this field. First, it points out that 84 per cent of the Department of Technical Co-operation's bilateral expenditure in 1963 was in respect of parts of the Commonwealth which were still colonies at the beginning of 1960: Sarawak, for example, received more technical assistance than India, and virtually all the allocations to research mapping and geological surveys went to such countries, nor is it easy to see that Britain could have done less. Indeed, it is suggested that it would be a far-sighted act of statesmanship, leading to much happier relations, if the British Government assumed the complete cost of the compensation payments to British officials instead of the present 50 per cent.

Next, it is pointed out that on questions of technical assistance, the channels of communication are partly blocked, and are likely to remain so until Britain does more to influence and encourage requests and to identify the sort of help that developing countries need. The first step would be to arrange for permanent British representation overseas through technical advisers who have long acquaintance with the area concerned. Next, these divisions should be supported by a network of good aid

in all the major countries where Britain has large aid programmes. More frequent fact-finding and liaison visits by professional advisers or by full technical assistance missions are also desirable, and institutions in Britain should be encouraged to forge links with similar institutions in developing countries, and work out programmes of mutual co-operation. Arrangements to supply British staff to strengthen the Government departments in developing countries, responsible for requesting aid and planning its use, should be reviewed, and Britain should take more positive steps to let developing countries know what services she can make available.

The survey is particularly critical of the organization of Britain's resources for technical assistance. Too much research is on a hand-to-mouth basis with no certainty of continued employment. We need to build up institutions and a corps of people who will spend much of their working lives on overseas development. Only with such a nucleus of professionals and a framework of permanent institutions is it possible to draw fruitfully from time to time on the experience and expertise of research workers based in Britain. The establishment of a special institution for training and research in overseas development is being considered. This proposal, or the principle behind it, requires extension. A major recommendation of the survey is for the establishment of a career service, to provide a 'pool' of experts employed on a long-term basis.

With regard to training, integration of the supply of British university staff, and arrangements to give junior staff from developing countries administrative, teaching and research opportunities in Britain, are urged. As regards research, the main need is for more free resources to be available each year, thus permitting a more positive approach in applying British brains and ingenuity to tackle some of the technical problems of developing countries. In this field we cannot wait for requests. Developing countries are often unable to identify appropriate problems and it is important to ensure that activities are directed towards solving practical problems and that solutions, once found, are widely disseminated and applied.

Commenting on the present derisory allocations for economics, education and social sciences in the research budget of the Department of Technical Co-operation, the survey points out that these fields are crucial to development. It comments that research into birth control, which holds the key to the future of many developing countries, has as yet received no support. Even in agricultural and medical research there are scores of problems to which solutions could be found if resources were allocated. The geographical distribution of support for research is also uneven, and while the policy of housing units inside larger home organizations is sensible, in the absence of an effective Overseas Research Council it tends to aggravate the piecemeal development of research effort. Some such means is badly needed, to give a sense of direction to the whole research effort, to determine priorities and commission new research; the point should receive attention in any re-organization of the Department under the new Ministry.

Besides this, the survey stresses the need for more emphasis on the application of research findings and of other existing knowledge, and its reference to the importance of a close relation between research and capital aid seems to support the basic idea of the new Ministry of Overseas Development. The need for integrated administration and operation of capital and technical aid is regarded as a matter of high priority. Emphasis is placed on the urgent need for co-operation like that which already exists between the Directorate of Overseas Surveys and overseas survey departments, between the Anti-Locust Research Centre and the East African Locust Control Organization, and between British and overseas universities. Above, all, while generously acknowledging the magnitude of the British contribution to technical assistance, the survey shatters the idea of any complacency, either in research or in technical aid generally. There are now fewer British technical personnel overseas under official arrangements than there were seven years ago—and this is the vital factor.

The survey mentions the White Paper *Research Assistance for the Developing Countries* issued in July, 1964, just as the survey was being completed. That Paper* provides the first account of the research assistance given by the Department of Technical Co-operation and is the first attempt so far to fill in any measure the gap that was left when the report on *Colonial Research* was discontinued. It is clear that the general pattern is still the same; little is added in the very brief summaries of research to what is included in the survey of the Overseas Development Institute, though a figure of £150,000 a year is quoted for research grants to universities and research organizations in the United Kingdom for specific studies in various fields. Nevertheless, the White Paper is to be welcomed as a first step. With what is stressed by the Overseas Development Institute, and in the report of the Estimates Committee on the work of the Department of Technical Co-operation, it should at least help to keep the question of research to the forefront in the present re-assessment and re-organization of overseas development and of civil science. Taken together, the three documents could stimulate the constructive thinking that is sadly overdue in the whole field and without which neither re-organization nor more generous financial support will be fully effective.

* Department of Technical Co-operation. *Research Assistance for the Developing Countries.* (Cmnd. 2433.) Pp. 28. (London: H.M. Stationery Office, 1964.) 2*s.* net.

INDUSTRIAL ORGANIZATION AND SOCIOLOGY

Economics and Sociology of Industry

A Realistic Analysis of Development. By Prof. P. Sargant Florence. Pp. xiii + 258. (London: C. A. Watts and Co., Ltd., 1964.) 27*s.* 6*d.* net.

THE two main themes of Prof. Sargant Florence's work since his *Economics of Fatigue and Unrest* was published forty years ago both run through *Economics and Sociology of Industry*. First, there is his emphasis on the importance of sociological and social-psychological factors in industrial and economic problems and processes, and, secondly, there is his emphasis on the limitations of abstract, purely deductive model-building starting from assumptions of profit-maximization and over-simplified market forms, and his insistence on empirical and, where possible, quantitative, testing and measurement. This very wide-ranging book, composed of lectures delivered at Ruskin College, Johns Hopkins University, and the Royal University of Malta, amount to a review of Florence's leading interests and ideas in the fields of industrial organization and industrial sociology, extended, in the closing chapters, to the now absorbing problems of the development of the poorer countries.

Prof. Florence starts by setting out nine leading 'trends' or 'trains of events' in industrial development, such as the growing importance of industrial and service activities as against agriculture; the application of science; the growing importance of organizers, managers and administrators as against working operatives; urbanization; enlargement of scale in industry; the managerial revolution; and higher standards of living. This concept of a 'trend' that is something less than a 'law' seems somewhat vague but useful for the broad canvas on which Florence is engaged.

Prof. Florence then goes on to examine the mobility of labour geographically and occupationally, which always has been, and is to-day as much as ever, a key question in regional and national development policies, as to which analytical economists' assumptions have, since Ricardo, often been in terms of an unrealistic rapidity of movement in response to wage differentials. Prof. Florence's call for much more empirical investigation of the factors making for mobility and immobility can only be supported. The mobility of labour leads on to the economics of industrial location and urban development, and to problems of the selection of industries which can advantageously be stimulated in one way or another, towards the development of depressed or rural areas, and away from congested 'conurbations' (a Florentine term). Problems of the scale of industries come next, and of management and industrial relations and psychology, to which the trend to large scale gives rise. Here Prof. Florence is at his best. The last three chapters take us to the emergent countries, that is, those countries the economics of which have scarcely begun to follow out the 'trends' distinguished at the beginning of the book. The treatment here, though often lively and acute, becomes rather unsystematic, with disproportionate emphasis on one or two special enthusiasms, for example, the tourist trade. But Prof. Florence is never dull, and he manages to provide a just sufficient thread of argument to carry his readers through his wide-ranging variegated survey. Indeed, as regards some of the problems now recognized as central and critical, for example, population and birth control, Prof. Florence writes as a pioneer of long standing.

This would be a rousing, broadening book for students of economics to read alongside their narrower and more analytical text-books, setting before them in lively terms the realistic problems, for coping with which their analytical training is meant to prepare them.

T. W. Hutchison

REVIEW OF SOLID-STATE CHEMISTRY

Progress in Solid State Chemistry

Vol. 1. Edited by H. Reiss. Pp. vii+536. (London and New York: Pergamon Press, 1964.) 120*s*. net.

THE growth in the number of the various series "Advances in this . . .", "Progress in that . . .", is familiar to all practising chemists. The book under review is the first volume of yet another one, and consists of eleven chapters. These are entitled: "The Thermal Expansion of Ceramic Crystals" (H. P. Kirchner), "Lattice Energies and Related Topics" (M. F. C. Ladd and W. H. Lee), "Phases with the Nickel Arsenide and Closely-Related Structures" (A. Kjekshus and W. B. Pearson), "Lattice Imperfections and the Thermal Conductivity of Solids" (D. Greig), "The Relationship of Photoluminescence and Electroluminescence to Structure" (D. W. G. Ballentyne), "Ferrielectricity in Crystals" (C. F. Pulvari), "Alloy Semiconductors" (J. C. Woolley), "Physico-Chemical Aspects of Organic Semiconductors" (H. A. Pohl), "X-Ray Diffraction Studies of Crystal Perfection" (L. V. Azaroff), "Application of Nuclear Quadrupole Resonance" (G. A. Jeffrey and T. Sakurai), and "Use of Infra-red and Raman Spectroscopy in the [illegible] Organometallic Compounds" (Huggins and Ka[illegible]

The various 'Progress' and 'Advances' series now play an important part in the increasing volume of scientific literature, since they review the state of a limited area of subject matter at a given time. The value of a particular series, however, must depend to a considerable extent on whether it is up to date. Taking into account modern production techniques, it should be possible to reduce the time interval between submission of a manuscript to an editor and its appearance in a volume to less than one year. Volume 1 of *Progress in Solid State Chemistry* has evidently not met this requirement, because references to work published after 1961 are rare indeed. Clearly some of the authors deserve sympathy for the delay in appearance of their work. The book is unlikely to have a wide sale privately because of its high cost, and libraries which represent somewhat of a captive market for publishers of this kind of volume will have to judge whether the price of the book, coupled with the apparent two- or three-year delay in publishing some of its contents, makes purchase worth while.

Although the chapter on infra-red and Raman spectroscopy is excellent, one wonders why it is included at all in a book on solid-state chemistry, because the chapter is principally concerned with observations on liquids or solutions. To a lesser extent this criticism applies to the chapter on nuclear quadrupole resonance.

References in the book in general are not numbered, authors often being referred to by name within the cursive text with the year of their published work in parentheses. Since there are many hundreds of references this procedure has made the book longer than it need be. Even more important, in my opinion, because of the liberal scattering of names on most pages, the book has been made more difficult to read.

Production of the first volume of a series of books presents special problems. In view of this, perhaps the above comments are somewhat harsh, and a final judgement must await the publication of further volumes.

ASPECTS OF GEOLOGY

Les Volcans et leur Activité

Par Alfred Rittmann. Édition Française à Partir de la Deuxième Édition Originale Établie et Introduite par Haroun Tazieff. Pp. 461 (6 planches). (Paris: Masson et Cie., 1963.) 95 F.

The Study of Fossils

By Prof. J. F. Kirkaldy. (Hutchinson Biological Monographs.) Pp. 116. (London: Hutchinson Educations, Ltd., 1963.) 12*s*. 6*d*.

Minerals and Rocks

By Prof. J. F. Kirkaldy. Pp. 176+photographs. (London: Blandford Press, 1963.) 18*s*.

THE English translation of the second edition of Rittmann's important monograph, *Vulkane und ihre Tätigkeit* (*Nature*, 199, 1125; 1963), has now been followed by a translation into French made by J. Fridmann, and edited by H. Tazieff, of the University of Brussels. This version is noteworthy on account of the inclusion of 88 new text figures, additional to those originally used. Many of these are excellently reproduced photographs of volcanic phenomena, including a selection from the classic photographs taken by A. Lacroix in Martinique in 1902, and others that are recent and hitherto unpublished. Sixteen have been printed in colour, on four plates. A further addition, as an appendix, is an essay by Prof. Rittmann himself on the nomenclature and classification of volcanic rocks that have not been included in any previous edition. Libraries that do not already possess a

Rittmann's important work may find it worth while acquiring this attractively produced, though somewhat expensive, new edition.

Prof. Kirkaldy's *Study of Fossils* is a short discourse on palæontology intended specifically for biologists, though it may well serve others as a guide to the varied information which geologists derive from the examination of fossils. The first two chapters deal with the geological background, without which the significance of fossils cannot be appreciated. Two succeeding chapters discuss the nature and state of preservation of the organic remains, designated 'fossils', found in rocks, and the life succession which they illustrate. In the next three chapters the use of fossils as time markers, and as indicators of environmental conditions and palæoclimates, is dealt with. The final chapter discusses the evolutionary aspects of fossil remains. The book is adequately and clearly illustrated by a series of line diagrams.

Minerals and Rocks, in colour, is an elementary handbook on rocks and minerals, the chief merit of which is that 266 specimens are illustrated in colour. These were chosen, originally, to illustrate a book, *Stenar i färg* (Stones in Colour), by H. Lundegårdh, published in Stockholm in 1960, and were selected from Scandinavian museums. The colour photographs, made by Folke Johansson, have been used by Prof. Kirkaldy for his own book. On the whole, the colour reproductions are extremely good, and, no doubt, would serve to show a beginner the great variety in colour and texture that is encountered in rocks and minerals. They may serve to stimulate an interest in geology and mineralogy, but they cannot adequately take the place of actual specimens. The text that accompanies the plates has been entirely written by Prof. Kirkaldy. It attempts to compress within the compass of about 100 pages the essentials of the subject-matter of mineralogy, petrography and petrology. Unfortunately the book bears evidence of somewhat careless editing, the principal defect being that, in the index, the reference numbers given to specimens illustrated do not correspond with those given on the actual plates. METAZOAN PARASITISM

The Nature of Parasitism

The Relationship of Some Metazoan Parasites to Their Hosts. By W. P. Rogers. (Theoretical and Experimental Biology: an International Series of Monographs, Vol. 2.) Pp. ix + 287. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 7.50 dollars.

MANY biologists would consider the nature of parasitism too complex to be discussed adequately in such a small book as this, even when attention is focused on helminths and Protozoa are excluded from consideration. Prof. W. P. Rogers has selected nematodes for special treatment for various reasons and not least because his own researches have long been concerned with their physiology. From the evolutionary point of view, the group has been remarkably successful and, while some thousands of species have become parasites of animals or plants, many more have retained a free-living mode of life. Yet all roundworms have a comparatively simple morphological organization which suits various types of environment; reproductive processes are somewhat standardized, life-cycles not unduly complex and there is little apparent physiological specialization. In many respects, therefore, nematodes lend themselves to the study of a kind of parasitism in which adaptation has often shown little modification of structure and function.

The book consists of four parts and eleven chapters, each of which has its own list of references to the original literature and most of which carry a short summary, and physiological interest is sustained throughout. This has been a handicap for the author, because physiological knowledge of the group is fragmentary and incomplete. Although deficiencies in our knowledge are evident, however, hypothesis has been used to guide the reader through the intricacies of functional speculations. Prof. Rogers's avowed aim has been to try to stimulate research rather than to summarize existing knowledge. The first two chapters are devoted to speculations on the host–parasite relationship and the point is soon made that it is important to know what is meant by 'infectiousness', that is, the capacity of the organism to infect the host and to furnish its parasitic existence with a system of metabolic processes which are distinct from, but in harmony with, those of the host. The earliest stage of infection often involves the removal of a protective outer covering such as the shell of the egg, the wall of the cyst or the sheath of the larva, and sometimes a ciliated epithelium which serves as a dispersal mechanism in trematode miracidia. The environmental components which facilitate the establishment of the infective agent as a true parasite need not be highly specific but must ensure that protective properties are not lost until entry has been made into an environment which will support a closer and more intimate relationship between host and parasite and may entail moulting, migration and metamorphosis.

Free-living roundworms undergo a series of moults during their life-cycle and infection by parasitic forms is preceded by a moult, after which development is suspended until an appropriate host has been acquired. The infective stage is thus a resting stage which forms a 'bridge' by which the parasite passes from the environment of one part of the life-cycle to a new environment in another part of the cycle. In considering a physiological basis for the nematode life-cycle, Prof. Rogers suggests that the action of the environment is always indirect and that metamorphosis is evoked by internal secretions which are produced as a result of stimuli from the environment acting on the receptor organs of the parasite. In arthropods, moulting is controlled by internal secretions and it is possible that similar control occurs in roundworms. Infection with eggs or larvæ of certain nematodes is 'triggered' by certain physical factors and chemical agents in the intestinal contents of the host, mainly dissolved carbon dioxide or undissociated carbonic acid but also *Eh*, *p*H and temperature. The consequent stimuli evoke the secretion of hatching or exsheathing liquids and, possibly, affect more cryptic developmental mechanisms. This is a theme which Prof. Rogers, in collaboration with Dr. Sommerville[1], has developed in greater detail since the book was published, mechanisms of moulting and metamorphosis being regarded as closely analogous in parasitic nematodes, insects and amphibians.

The Nature of Parasitism contains the groundwork of many other important considerations. In Part 2 the discussion of problems of infectiousness is continued in chapters on life-cycles and infection, the physiology of free-living stages and the physiology of infection. The free-living stages of nematodes are considered in relation to food reserves, oxygen requirements, metabolism and its end-products, and infection covers entry by way of the intestines or through the surface of the body. In Part 3 the author is concerned with the lives of parasites in separate chapters dealing with the physiology of the parasitic stages, including intermediary metabolism, muscle–nerve physiology and osmoregulation, and with the oxygen requirements and nutrition of parasites. Part 4 has separate chapters dealing with the propagation of parasites, their specificity in various stages and their evolution. So far as knowledge goes it has been discussed succinctly and well documented in this small book, which deserves to succeed in its object of stimulating research and bringing it into line with other developments in modern biology. IN SITU DETECTION OF AN IONOSPHERIC ELECTRIC CURRENT

By Dr. K. BURROWS* and Dr. S. H. HALL

Department of Geophysics, Imperial College of Science and Technology, London, S.W.7

THE generally accepted basis for the explanation of the observed daily variations in the Earth's magnetic field is to be found in the dynamo theory, first postulated by Balfour Stewart in the 1882 edition of the *Encyclopædia Britannica*[1]. Schuster[2], Chapman[3] and other workers later elaborated the dynamo theory and, using magnetograms recorded at various observatories throughout the world, they were able to represent the complex and changing array of magnetic variations by a relatively simple system of horizontally stratified sheet currents, stationary relative to the Sun, but, relative to an observer on the Earth, continuously moving westward and varying in intensity with a predominantly 24-h period. The current system is identified by the symbol *Sq* to differentiate it from other proposed currents responsible for lunar (*L*) variations and storm-time (*D*) variations.

From an analysis of routine observatory magnetograms it is possible to estimate the integral, with respect to height of the postulated electric currents; a detailed analysis is, however, not possible from ground results alone. In particular it is difficult to assess such features as the height, vertical thickness and any possible stratification of the currents.

With the advent of high-altitude sounding rockets in 1946, direct *in situ* measurements of atmospheric properties became possible, and in 1947 Vestine *et al.*[4] first suggested that rocket-borne magnetometers could be used for investigating the distribution of these electric currents with height.

Assuming, for the moment, that the electric currents are located in the ionosphere, it follows that their horizontal dimensions must be large compared with their height and hence, to an observer on the ground, the *Sq* current system can be approximated to an infinite sheet current. The magnetic field associated with a current of this nature is $2\pi j$ œrsted, where j is the current density in absolute amps per centimetre, and it is independent of the height of the current sheet. Thus, if a rocket vehicle is used to carry a magnetometer, which is designed to measure F, the total scalar geomagnetic field, it should detect a change of $4\pi j . \cos I \sin \vartheta$ in passing through the current, where I is the inclination of the geomagnetic field below the horizontal, and ϑ is the angle between the direction of the current flow and the local magnetic north.

The much more intense current systems associated with auroræ have been detected[5] as also have the currents constituting the equatorial electrojet, a local intensified current which occurs, during the middle daylight period, in a narrow band (approximately 3° of latitude wide) along the magnetic equator[6,7]. In mid-latitudes, however, the expected 'discontinuity' due to the *Sq* current system is much less than at the magnetic equator, and this makes its detection correspondingly more difficult. Using the magnetograms from the Watheroo magnetic observatory in Western Australia (geomagnetic lat. −41·8°) it can be shown that the 'discontinuity' in F which might be observed by a rocket launched from Woomera (geomagnetic latitude −41·0°) is only of the order 10γ; furthermore, it is necessary to isolate this small effect from the 'background' field of the order 58,000γ, and as the sounding rocket ascends to its apogee, the ambient field it encounters will itself change by several thousand gammas[8].

Two *Skylark* rockets, *S.L.* 129 and 128, were fired from the Woomera rocket range (30° 56′ S., 136° 31′ E.) at 11.36 h c.s.t. on March 10, 1964, and at 11.37 h c.s.t. on March 12, 1964, respectively (c.s.t. = u.t. + 9½ h); each rocket carried a proton precession magnetometer as a secondary experiment. A description of the instruments and the data-processing techniques used is in course of publication[9].

In conjunction with the rocket flights a ground proton magnetometer[8] was operated, to record the diurnal variation in F, and a fluxgate instrument, kindly loaned by the Bureau of Mineral Resources, Melbourne, recorded

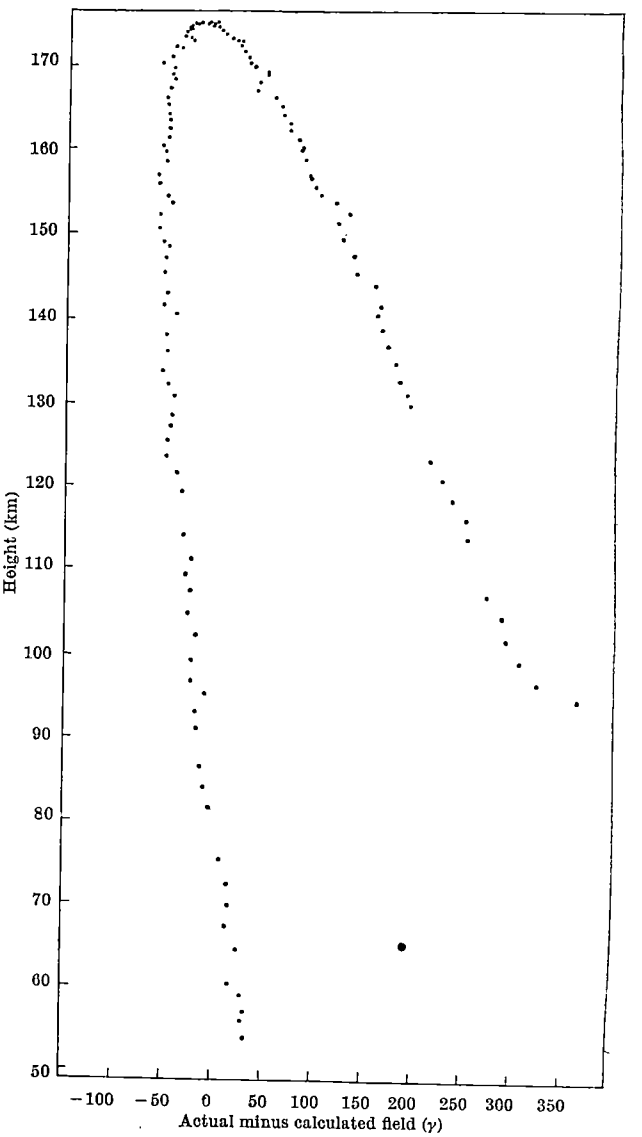

Fig. 1. Flight of *S.L.* 129

* Present address: Goddard Space Flight Center, Greenbelt, Maryland, U.S.A. (Fields and Particles Division).

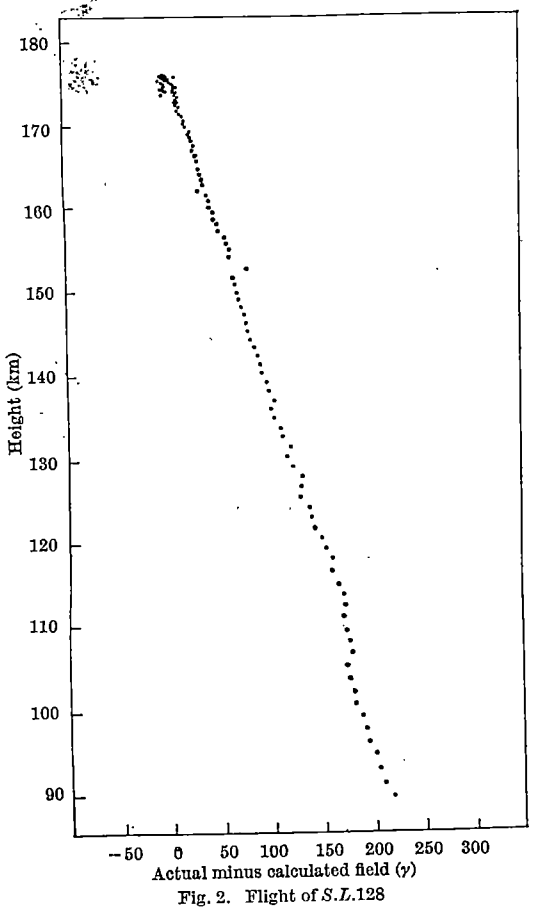

Fig. 2. Flight of *S.L.*128

H, the horizontal component. H was selected as being that component of the Sq variation field which is discontinuous in passing through the postulated current sheet.

Figs. 1 and 2 show the results of the flights on March 10 and 12, respectively, plotted in the form of differences between measured values of F and values computed by approximating the geomagnetic field to that of a geocentric dipole and neglecting the horizontal component of the rockets' trajectories. Only those readings obtained during the upward section of the second flight are presented; the data from the downward section have not yet been fully reduced, due to a shortage of computer time.

March 10 was an International Quiet Day[10] and the fluxgate record showed that, at the time of the flight, the value of H was close to the mean value for the day; it is not therefore surprising that no significant anomaly was recorded during the flight.

March 12, on the other hand, was a much more disturbed day. The fluxgate magnetometer recorded a significant departure from the undisturbed value at the time of the flight and the K_p index for the appropriate 3-h period was 4[10]. The reduced data from the rocket-borne magnetometer show an unmistakable change in slope at a height of about 104 km followed by a return to the original slope at about 112 km. The displacement of the upper section of the curve relative to the lower section is approximately 20γ. This indicates that, during this time, the rocket passed through an electric current sheet, flowing in a direction having a westerly component and of a nature similar to that which has been postulated to account for the daily magnetic variations recorded at ground-level. The absence of any similar 'discontinuity' during the rest of the flight up to apogee confirms that no other current system, of magnitude comparable with that already detected, was flowing in this height range.

The work is sponsored by the British National Committee on Space Research of the Royal Society; we thank Miss Helen Gibson, of the Weapons Research Establishment, South Australia, who did much of the routine data reduction.

OXFORD EXPEDITION TO ASCENSION ISLAND, 1964

By F. B. ATKINS, Dr. P. E. BAKER, Dr. J. D. BELL and Dr. D. G. W. SMITH

Department of Geology and Mineralogy, University Museum, Oxford

ASCENSION ISLAND (lat. 7° 57′ S., long. 14° 22′ W.) is situated in the South Atlantic Ocean and rises from the crest of the Mid-Atlantic Ridge. The island is roughly triangular in outline and some 36 square miles in area. High temperatures, low rainfall and persistent trade winds characterize the climate, and these factors are reflected in low erosion rates, the distribution of pyroclastic deposits (in particular the marked asymmetry of the scoriæ and cinder cones), and the generally sparse vegetation on the lower ground. In recent years, however, the vegetation cover, considerable at higher altitudes, has extended widely over previously barren ground.

The position of Ascension Island on the Mid-Atlantic Ridge renders it important in present theories concerning the structure and evolution of the Atlantic basin. The objects of the recent expedition (led by one of us, J. D. B.) were to produce a detailed geological map of the Island, a preliminary version of which is given in Fig. 1, to elucidate its volcanic history, and to make a comprehensive collection of material for further petrological, mineralogical and geochemical investigation now in progress at Oxford. Concurrently with the geological survey a geophysical programme comprising gravity, magnetic and palæomagnetic investigations was carried out by members of the Geophysics Department of the Imperial College of Science and Technology, London. A more detailed, combined report including these investigations will be published at a later date. Further work on the mineralogy and chemistry of the acid and intermediate ejected blocks (see following) is in progress at the Department of Mineralogy and Petrology, Cambridge, and strontium isotope investigations will be carried out at Oxford.

Previous geological accounts of Ascension Island include those of Darwin[1], who restricted his discussion to some of the more striking features, and Daly[2], whose systematic treatment of both the volcanology and petrology is the most comprehensive up to the present time.

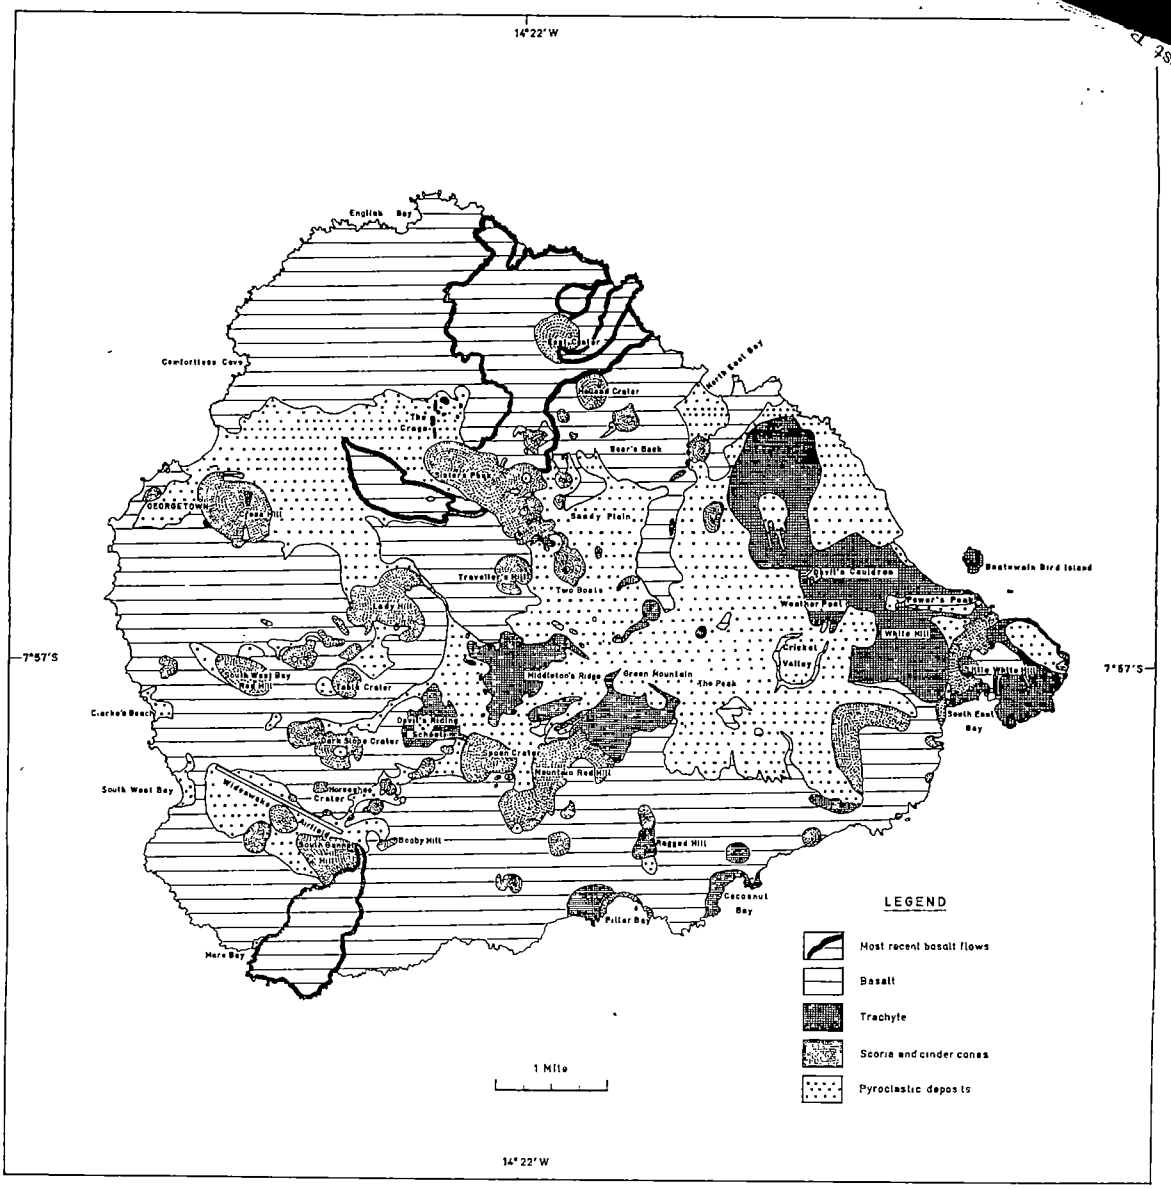

Fig. 1. Preliminary geological map of Ascension Island

Prof. D. S. Coombs, of the University of Otago, has also carried out certain mineralogical and chemical investigations of Ascension rocks (personal communication).

With the exception of thin local deposits of wind-blown sand and beach rock, Ascension Island is entirely volcanic in origin, being the uppermost part of a cone which rises from a depth of about 10,000 ft. below sea-level to the summit of Green Mountain at 2,817 ft. The main lava types are basalt and trachyte, with the principal trachyte masses occurring in the eastern part of the Island while basalt outcrops predominate in the west. Green Mountain itself is composed largely of trachyte, partly mantled by trachytic pumice and basaltic cinders, the latter forming most of the summit region.

Many of the trachyte hills are volcanic domes, for example, Weather Hill, the domes pass laterally into the thick flows. Daly described in some detail the structural features of the trachytes, such as carious weathering and silicified interfaces, and also directed attention to the occurrence of trachytic obsidian as a chilled phase at the base of some of the flows. Flow banding and the interbanding of trachyte and obsidian are well exposed at the base of the Middleton's Ridge trachyte.

The western part of the island is formed by a series of basaltic flows and parasitic cones which are generally asymmetrical with the steeper slopes on the windward, south-east, side. Many of the cones have been breached by lava flowing through their less substantial windward flanks. The basalts include aphyric types with or without vesicles and porphyritic types, the principal phenocrysts being plagioclase and/or olivine. Several of the flows have extensive encrustations of white fumarolic minerals which occur preferentially on the leeward side of any projections. The basalt flows, which are generally *aa* or blocky types, display a great variety of structural features including lava tunnels (for example, near Clarke's Beach), spatter cones (for example, Booby Hill), bocas (Horseshoe Crater), hornitos, and lava channels (for example, south of Spoon Crater). The channels or gutters referred to by Daly[1] as having been worn in older rocks by streams of hot lava are in reality the beds of lava streams which have constructed flanking levees by periodic overflowing similar to occurrences on Tristan da Cunha described by Baker and Harris[3]. Further features include lines of hillocks composed of scoriæ and bombs which may represent fragments of a disrupted cone transported on the surface of flowing lava (for example, east of South

...ay, Red Hill), and a small frozen lava lake preserved at a subsidiary centre west of Sister's Peak. There is no historical record of volcanic activity on Ascension, but some of the basaltic flows, for example that from Sister's Peak, are clearly very young, perhaps only a few hundred years old.

The pyroclastic deposits of Ascension Island have previously received little attention. On account of their large volume, extensive distribution and variety of depositional structures they merit detailed examination. Although much of the material is obviously associated with small parasitic centres, a substantial mantle of lapilli and ash covers large areas of Green Mountain and extends for considerable distances beyond. Whereas many of the pyroclastic deposits have resulted directly from subaerial falls or from re-working of such, on Sandy Plain thin beds of pumiceous dust and ash are so finely stratified and so regular over hundreds of square yards that they were probably deposited in an extensive body of water scarcely subject to current action. Local steepening of dips may be ascribed to limited post-depositional movements.

A probable pyroclastic flow is exposed at the roadside on Green Mountain at about 1,800 ft. It comprises at least three units, one of which, approximately 4 ft. thick, shows a gradation from unconsolidated pumice at the top, through lightly welded pumice with lenses of obsidian to a continuous obsidian base. Beneath this lies another unit, 20 ft. thick, consisting of poorly sorted unconsolidated pumice which lacks stratification. Laboratory investigation is required to confirm the origin of this deposit, but should it prove to be a flow it is of particular interest in view of the rarity of such phenomena on islands of the Mid-Atlantic Ridge.

The presence on Ascension of coarse-grained ejected blocks has long been known, and both Darwin and Daly described various types. Olivine-bearing and plagioclase-rich basic types are confined to Dark Slope Crater. These rocks are in many cases laminated and show signs of layering. New localities were discovered for other types of block which include dioritic, syenitic and granitic varieties. The majority of these occur in redistributed agglomeratic deposits.

Certain larger scale structures possibly involving considerable movements were noted by Daly. A problematic structure is Cricket Valley, an elongate depression measuring some 600 yards by 400 yards and about 450 ft. deep. Massive basalt outcrops in the lower part of the near-vertical walls and relatively fine pyroclastic deposits occur round the rim. A fine ash covers the flat floor. Daly ascribed its formation to a series of explosions which threw out the basaltic blocks now found in the immediate vicinity. These blocks are found only on the surface of the pyroclastic deposits south of Cricket Valley and their volume appears quite inadequate to account for the size of the depression. This fact, together with the steep walls of the depression, suggests that subsidence has played a part in the origin of Cricket Valley. The subsidence may have been connected with the protrusion of one or more of the trachytic masses in the area. The nearby Devil's Cauldron has probably had a similar origin. The deep valley between Power's Peak and Weather Post was also believed by Daly to have had an explosive origin, but it seems more likely that the valley remained as a strip of low land between two protruded trachyte masses.

Other structural effects connected with trachytic emplacement are found in Devil's Riding School and Bear's Back. Daly[1] interpreted the former as a basaltic lava cone, the large crater of which was filled by trachyte which flowed out over the rim to the north-east; the trachyte surface within the crater subsided and pyroclastic sediments, some claimed to be lacustrine, were deposited within the basin thus formed; the basining of the sediments was attributed to a continuation of axial subsidence. We consider that a series of near-horizontal basaltic flows was punctured and tilted to a high angle by an injection of trachyte, the surface of which later subsided as suggested by Daly. Bear's Back is probably another instance of a trachyte intrusion up-doming older basaltic rocks but, in this case, just failing to pierce them. A similar situation is found just to the south, where a small area of the upper, brecciated surface of a trachyte dome appears in a gully cut down through tilted basalt flows.

Regarding the general sequence of activity on Ascension it should be emphasized that less than a quarter of the volcanic pile extends above sea-level. The Island has been constructed within relatively recent periods of activity, during which time the volume of trachyte erupted has been notably large. There is no justification, however, for dividing the activity into an earlier trachytic and a later basaltic phase: both rock types have been produced at various periods in the Island's evolution.

We thank the Royal Society for a grant towards this expedition. We thank Prof. L. R. Wager for his advice, and Captain Roy W. Dixon, commanding officer of the U.S.A.A.F. Base on Ascension Island, for his constant and generous assistance. Thanks are also due to many other people who assisted us in a variety of ways.

ENVIRONMENTAL STRESS AND BIOLOGICAL AGEING

By Dr. J. M. ORDY, C. ROLSTEN, Dr. T. SAMORAJSKI and Dr. R. L. COLLINS

Cleveland Psychiatric Institute, Cleveland, Ohio

IT is generally accepted that genetic factors must play a key part in ageing and in determining the life-span of an organism. However, since the average life-span in a selected population can vary in accordance with some extreme environmental fluctuations, it has seemed equally plausible to assume that the external environment may also exert an influence on the rate of ageing and mortality. Although various biological theories of ageing differ in their emphasis on the relative role of genetic and environmental factors in determining the rate of ageing and mortality, numerous experimental observations with animal subjects have indicated that ultra-structural constituents, cells, tissues, organs and the organism itself may show various structural and functional alterations with increasing age[1–4]. However, while some morphological changes may become quite apparent with ageing, various physiological functions may not show alterations with age when observations on functional changes are made under steady-state environmental conditions since the most conspicuous alteration for the organism as a whole with increasing age is generally exemplified by a more gradual reduction in biochemical, physiological and behavioural

capacity to respond to repeated or sustained environmental fluctuations frequently characterized as environmental stress[5,6].

While it may seem obvious that old subjects are less able to withstand repeated exposure to environmental stress, few quantitative multi-disciplinary investigations covering the entire life-span of an organism have been undertaken to isolate and identify interrelationships among genetically determined influences in the rate of ageing and mortality in relation to the effects of specific environmental stressors. While definitive experimental findings based on longitudinal rather than cross-sectional observations are lacking, various experimental findings have suggested that even more subtle environmental influences may result in a decreasing physiological adaptation to stress, and also lead to a possible acceleration of the ageing process and increasing mortality[7]. Whereas various structural and functional alterations have been examined so far in various cell populations and organ systems, it is generally accepted that accumulated biochemical, physiological and behavioural impairments from repeated stress with ageing may be associated most closely with some breakdown in non-dividing neural cell populations in the central nervous system and in integrative neuroendocrine structures and functions of the organism[8].

Numerous previous laboratory investigations with animal subjects have also shown that more extreme changes in environmental temperature and exposure to various noxious stimuli can affect cellular processes, metabolic rate, physiological adaptation to stress, behaviour and mortality[9–12]. However, most previous investigations of ageing in animals have concentrated on general survival curves under more severe environmental changes without an examination of specific interrelationships among morphological, biochemical and behavioural changes in key organ systems. More recently, it has become apparent that appropriate multi-variate statistical designs and the availability of carefully controlled environmental chambers should permit a direct quantitative assessment of the effects of more subtle and specific environmental factors on decreasing adaptation to repeated stress in ageing in relation to morphological and biochemical changes in the central nervous system and neuroendocrines[13]. The multi-disciplinary investigation recorded here was undertaken in an environmental chamber with a pure strain of mice in order to determine some specific effects of repeated temperature, shock and combined temperature and shock exposure to behavioural adjustment to stress with increasing age in relation to concomitant structural and functional alterations in the central nervous system and the pituitary adrenocortical axis.

In order to decrease the genetic variability in the behavioural, biochemical and morphological observations, a highly inbred strain of *C57BL/10* male and female mice were used as subjects. All animals were born, raised and exposed to temperature and shock in the carefully regulated environmental chamber in accordance with a predetermined experimental design. At 100 days of age, groups *A*, *B*, *C*, *D* and *E*, containing 40 males and 40 females each, were subjected to the following stress schedule: all steady-state control groups designated subgroups (*a*) (10 males and 10 females) were placed in cages and maintained without disturbance in the larger chamber at 76° F and 52 per cent relative humidity until they were tested afterwards in a behavioural test battery and then were killed for biochemical and histological evaluations of brain and neuroendocrines.

Electric shock groups (*b*) were maintained in the larger chamber, received shocks 2 h each day for 7 days, followed by no shock for 21 days. All temperature stress groups (*c*) were maintained alternately for 21 days in the larger chamber and the following 7 days in a smaller chamber at 59° F and 52 per cent relative humidity until they were tested and killed. Temperature and shock stress groups (*d*) received alternately temperature and shock stress for two 7-day periods out of 28 days in accordance with a combined temperature and shock stress schedule. For attaining equal intervals in the stress schedules throughout the life-span, each stress cycle was divided into four 7-day intervals. Accordingly, group *A* was exposed to 4, group *B* to 8, group *C* to 12, and group *D* to 16 complete stress cycles. Group *E* was not killed but subjected to the stress cycles until natural death for an evaluation of differential mortality.

The experimental findings on the accumulation of intracellular lipofuscin or age pigments in the central nervous system with increasing age have been reported previously[14]. This article presents a statistical summary of the group *A* behavioural data as well as the stress-induced biochemical and morphological findings on the pituitary–adrenocortical system in group *A* exposed to 4 months of environmental stress. The results obtained with group *A* alone have significant theoretical implications for ageing since they cover 4 critical months of early maturity and presumably an optimum period of biological vigour to adopt to intermittent environmental stress.

Stress Effects on Behaviour

The theoretical basis for the selection of the behavioural tests was to obtain a quantitative assessment of the effects of repeated temperature and shock exposure during ageing on a relatively broad range of adaptive behaviour determined in a test battery consisting of both non-stress and stress conditions. In the standard rodent open-field exploration test, the response measures were: (1) latency in seconds to move from the middle square; (2) number of squares traversed in 2 min. Spontaneous locomotor activity was used as an index of non-stress reactivity and was determined in vertically revolving activity wheels. Wheel rotations were recorded photoelectrically for 1-h periods for 4 consecutive days. Stress reactivity under shock-elicited escape-avoidance conditions was determined in a conditioning apparatus which consisted of an enclosed longitudinally divided galvanized runway measuring 30 in. × 1 in. × 3 in.

An automatic programming unit controlled delivery of shock (*US*), paired light and sound warning signals (*CSs*) which preceded shock by 3 sec, and a timer. A microswitch located at the end of the runway and activated by the escape (*UR*) or conditioned avoidance (*CAR*) responses terminated the *CSs*, *US* and timer. Response measures were percentage of avoidance in 100 learning trials and speed of escape-avoidance running in seconds. Table 1 presents a statistical summary of the group *A* findings on the effects of 4 months of repeated environmental stress on behaviour, biochemistry and morphology. As shown in Table 1, the temperature and shock groups displayed significantly longer open-field latencies, more open-field exploration, decreased spontaneous locomotor activity, and impaired learning as well as running decrements in the shock-elicited escape-avoidance conditioning. In general, the behavioural findings with group *A* indicate that such repeated exposure to intermittent deviations from steady-state conditions as temperature and shock stress (covering even a relatively brief but optimum adaptive period of the entire life-span) resulted in various changes in adaptive behaviour under the non-stress and stress test conditions.

Stress Effects on Biochemistry

After 10 days of behavioural testing, blood was withdrawn from the mice by retrobulbar cavernous sinus punctures for an evaluation of stress-induced changes in serum enzyme- and cholesterol-levels. Enzyme activity was determined by standard assay procedures and transformed into international units (I.U.) for quantitative evaluation[15]. The animals were then killed for histological

Rank sums	19·0	42·0	41·0	58·0		0·001

Kendall's coefficient of concordance for the behavioural, biochemical, and morphological data.
* Group ranks (brackets) in relation to deviation from control group. Rank sums differed significantly from a random expectation; $W = 0{\cdot}60$, $P < 0{\cdot}001$.

examination. The quantitative biochemical comparisons revealed that serum leucine amino-peptidase (LAP) enzyme activity and ascorbic acid-levels of the adrenals were significantly higher in the combined temperature and shock stress groups. However, alkaline phosphatase and serum cholesterol-levels did not differ among groups.

Stress Effects on Neuroendocrine Morphology

In the morphological evaluations, it is interesting to note that body-weights did not differ among the 4 groups. However, pituitary and adrenal weights of the 3 stressed groups were significantly higher than in the controls. In order to obtain some quantitative estimates of the structural changes in the adrenals in response to repeated stress, histological comparisons were made of the size and configuration of the cortex, *X*-zone and medulla in relation to total adrenal area. For these quantitative estimates, the different topographic areas were determined on histological sections of identical magnification by a camera lucida technique and then expressed as a percentage of total area of comparable sections of the adrenals in all groups. Although the cortical area and the *X*-zone did not differ as percentage of total area in the group comparisons, the medullary area was significantly enlarged in the shock- and the temperature-and-shock groups.

As already noted here, numerous circumscribed observations have been made previously on age-correlated alterations in behaviour in relation to some structural and functional changes in the nervous system and the neuroendocrines in response to short-term or acute stress. However, few comprehensive multi-disciplinary ageing investigations have been reported utilizing pure strains, an environmental chamber, as well as behavioural assessment, biochemical assays, histological evaluations, and a statistical analysis of the combined quantitative data in one unified experimental design. As shown in Table 1, in addition to performing a separate statistical analysis of variance procedure for each behavioural, biochemical and histological test, a composite multi-variate statistical ranking was made of the four experimental groups on all 16 variables to determine whether group profiles differed with respect to the effects of temperature, shock, and temperature and shock exposure.

Each group received ranks from 1 to 4 on each variable in relation to the degree of deviation from the steady-state environmental control groups. In all, 160 ranks were assigned. If the ranking was random among the groups, the rank sum expectation of any exposure group would be 40. The rank sums for the groups were as follows: *a*, 19·0; *b*, 42·0; *c*, 41·0; *d*, 58·0. Kendall's statistical coefficient of concordance revealed that these rank sums were significantly different from random expectation ($W = 0{\cdot}60$; P 0·001). Consequently, it may be concluded that repeated temperature, shock and combined temperature and shock exposure in group *A* covering even a 4-month biologically optimum period of the entire life-span resulted in significantly different structural and functional group profiles, and that the most deviant group in behaviour as well as the biochemical and histological findings was group (*d*), which was exposed to both shock and temperature fluctuations.

At the behavioural level it seems relevant to note that the temperature and shock exposure groups displayed various statistically significant differences in behaviour in contrast to the control group. These differences were apparent under both non-stress and stress behavioural test conditions. Previous findings have indicated that exploratory behaviour decreases with increasing age under normal environmental conditions[16]. However, in the work recorded here, open-field exploration was significantly higher in the temperature and shock exposure group. At the biochemical level, decreases in ascorbic acid- and cholesterol-levels have generally been observed in response to acute stress[17]. Various changes in enzymatic activity with increasing age under normal steady-state environmental conditions have been attributed to a possible gradual decrease in such intracellular elements as mitochondria. The stress-induced biochemical findings in this investigation suggest that changes in various enzymatic activities with age may be a sensitive index for biochemical comparisons between young and old subjects since it has also been observed that functional cells in key organs may be replaced by connective tissue in ageing[18].

It has been noted previously that the results of numerous previous investigations with animals have shown a variety of structural and cytological changes in the pituitary and adrenal glands in response to acute stress as well as with increasing age under normal environmental conditions[19–21]. The present morphological findings are in general accordance with those published results on structural changes with ageing. Although the adrenal cortical area and the *X*-zone did not differ as percentage of total area in the multiple group comparisons of group *A* of the present work, the medullary area was already significantly enlarged in the stressed groups. In general support of other reported findings, this morphological enlargement suggests a more direct and prompt activation of the adrenal medulla by repeated stress activation probably involving the hypothalamus and pituitary. Stress-induced morphological alterations in the cortex may be more gradual,

since direct pathways to the adrenal cortex are lacking[22]. In conclusion, it should be emphasized that this article deals only with a summary of the group *A* findings. These significant findings with group *A* make it apparent that large-scale experimental laboratory investigations on the effects of various specific environmental stressors on biological adaptation to repeated stress, rate of ageing and differential mortality have become feasible. When the complete experimental findings of groups *B*, *C*, *D* and *E* covering the entire life-span are completed and analysed, it will be possible to make a direct multi-variate statistical assessment of the relative contributions of specific environmental stressors on decreasing capacity to respond to repeated deviations from environmental steady-state conditions with increasing age, as well as establish a possible acceleration or even inhibition of the ageing process from an evaluation of specific and controlled environmental effects on differential mortality.

This work was supported by a research grant from the U.S. National Institutes of Health.

OBITUARY

Prof. E. F. Freundlich

THE death at Wiesbaden of Prof. E. F. Freundlich on July 25 at the age of seventy-nine has deprived the astronomical world of an impressive personality, and one of the few remaining links with our science in bygone days before the First World War.

Erwin Finlay Freundlich was born at Wiesbaden-Biebrich on May 29, 1885, of mixed German–Scottish parentage, and of a large family in which scientific bent was not unknown; the renowned physical chemist, Herbert Freundlich, being one of his older brothers. His university studies in Göttingen led him first to a doctorate in mathematics as a student of Felix Klein; but it was Klein who deflected his career to astronomy by recommending his young scholar in 1910 to an assistantship at the Royal Observatory at Berlin.

The time when Freundlich joined the ranks of astronomers was a pregnant period in the outgrowth of our science, with the relativity theory approaching the prime of its life; and Freundlich with his mathematical background was particularly well prepared to follow its implications. Somewhat to the consternation of his more conservative contemporaries (including his director, Herrmann Struve), Freundlich joined with enthusiasm the early protagonists of relativity and eventually wrote one of the best expository text-books on it at that time (*Einstein's Relativitäts-Theorie*, Berlin, 1917), an achievement which earned him a lifelong friendship with Sir Arthur Eddington.

Not only did Freundlich set out to defend relativity on theoretical grounds, but he was also one of the first to undertake its experimental verification. To this end, with the support of the Prussian Academy of Sciences, he embarked (with Zurhellen) on the first solar eclipse expedition to measure the light deflexion in the gravitational field of the Sun in Russia, in August 1914. This effort unfortunately came to naught, for the outbreak of the First World War a few weeks before the date of the eclipse caused all equipment to be impounded and the astronomers interned. It was many months before the luckless travellers were eventually repatriated; and the actual detection of the relativistic light deflexion had to await the outcome of the Greenwich expeditions in 1919.

The first decade which followed the First World War marked the high noon in Freundlich's life. It brought him in close touch with Einstein, then himself at the peak of his powers (the large amount of unpublished *Einsteiniana* in Freundlich's possession should constitute invaluable material for future historians of science); and it was largely his efforts and close contacts with German industrial circles which led in 1921 to the foundation, in Potsdam, of the Einstein Institute with its solar tower (later renamed the Institute for Solar Research and amalgamated with the observatory), of which Freundlich became the first director. The work of the distinguished group of investigators (including von den Pahlen, von Klüber, Grotrian, Wurm and others) which Freundlich gathered around him is too well known to need elaboration here. In a study of the *K*-effect, von den Pahlen and Freundlich came (by their detection of the double-wave of the *K*-term in longitude) within an ace of the discovery of galactic rotation. The eclipse expedition to Sumatra of 1929 made up for the abortive one of 1914. and, as a result, Freundlich, von Klüber and von Brunn established the light deflexion at the limb of the Sun to be $2{\cdot}2'' \pm 0{\cdot}1''$—somewhat more than the theoretical prediction of $1{\cdot}75''$. Subsequent work has, on the whole, tended to cluster around the larger value; and this discrepancy (if finally established) may possibly play a similar part in the fate of the relativity theory in years to come as did the secular advance of Mercury's perihelion in Newtonian mechanics.

The advent of the Nazi Government to power in Germany in 1933 interrupted Freundlich's work; and because of his partly Jewish origin he left Potsdam to accept the professorship of astronomy in the University of Istanbul. He remained there for three years (the present Istanbul University Observatory was erected under his direction), and left in 1936 for a similar post in the German University of Prague. The Munich agreement and its aftermath uprooted Freundlich once again after little more than two years of residence in a congenial city and State. This time (declining an invitation to America), at Eddington's initiative he resorted to his Scottish motherland and the University of St. Andrews, where he spent the rest of his active life.

Shortly before that time, the University received a bequest from the late Prof. Gordon Lang for the estab-

lishment of a new university observatory; and Freundlich was entrusted with its erection as the observatory's first director. The outbreak of the Second World War interrupted this work almost immediately; and in the grim years that followed it took all of Freundlich's energy and determination to carry out his mission in the face of protracted material and man-power shortages—not to speak of perennial financial problems caused by the post-war inflation spiral. As the principal instruments for the new observatory—in keeping with St. Andrews's Gregory tradition—Freundlich wished to erect reflectors of the most modern type—the flat-field Schmidts. In collaboration with Linfoot and Waland, he succeeded in commissioning the 19-in. pilot model in regular service in 1949; but it was one of the disappointments of his life that he was unable to render the full-scale 39-in. flat-field Schmidt (the largest telescope of this type in the world) fully operational before his retirement.

On reaching the age of seventy in 1955, Freundlich retired from the Napier chair of astronomy at St. Andrews, but retained directorship of the observatory until 1959, when he finally left Scotland for his native Wiesbaden to spend his years in 'retirement'. If his middle age was often stormy, the evening of his life was calm. In a sense, however, Freundlich never really retired; for until he died he held an honorary professorship in the University of Mainz and his mind continued to remain active. His last book on *Celestial Mechanics* appeared in 1958. In the last decade of his life, Freundlich was much preoccupied with astronomical red shifts and, in particular, with the fate of the photons which may travel from distant galaxies for hundreds of millions of years through empty space to reach us. Do they retain their original energy unimpaired? His last paper on this subject appeared in the *Zeitschrift für Astrophysik* in February of this year.

Death came gently on July 25 to claim the life of a veteran of almost four score years; and his passing is mourned not only by his family but by two generations of grateful students to whom Freundlich gave generous help in various stages of their careers in Germany, Turkey, Czechoslovakia or Britain, and many of whom are scattered all over the world. They will indeed remember him long as a man of forthright character and wide culture (he was an accomplished musician), whose tall stature, unbent by age, and leonine head towered in any gathering over most of his contemporaries. He was always forthright in expressing his views—there was nothing of a politician in him—a true liberal of old vintage and of the type who instinctively evoked also strong feelings in others; very few people who ever met him at a close range remained indifferent to his personality. What greater tribute can a man be paid?

He is survived by his wife, Mrs. K. Freundlich, who shared with her husband more than half a century of common life through troubled times; and by his two children and many grandchildren who have made their home in Britain.

Zdeněk Kopal

NEWS and VIEWS

The Royal Society of London: Medal Awards

The following awards of medals have been made by the President and the Council of the Royal Society: *The Copley Medal*, to Prof. S. Chapman, advisory scientific director of the Geophysical Institute, University of Alaska, for his theoretical contributions to terrestrial and interplanetary magnetism, the ionosphere and the aurora borealis; *The Rumford Medal*, to Prof. H. C. van du Hulst, professor of astronomy in the University of Leiden, for his distinguished work on the scattering processes in the interplanetary medium and his prediction of the 21-cm spectral line from interstellar neutral hydrogen; *The Davy Medal*, to Prof. M. Calvin, professor of chemistry in the University of California and director of the bio-organic chemistry group in the radiation laboratory, for his pioneering work in chemistry and biology, particularly his elucidation of the photosynthetic pathway for the incorporation of carbon dioxide by plants; *The Darwin Medal*, to Prof. K. Mather, professor of genetics in the University of Birmingham and Vice-Chancellor elect of the University of Southampton, for his distinguished contributions to knowledge of cytology and genetics; *The Sylvester Medal*, to Dr. Mary L. Cartwright, Mistress of Girton College and University reader in the theory of functions in the University of Cambridge, for her distinguished contributions to analysis and the theory of functions of a real and complex variable; *The Hughes Medal*, to Prof. A. Salam, professor of theoretical physics at the Imperial College of Science and Technology in the University of London, for his distinguished contributions to quantum mechanics and the theory of fundamental particles.

Director of G.P.O. Research: Mr. R. J. Halsey, C.M.G.

Mr. R. J. Halsey, who retires from the post of director of research at the General Post Office on December 31, was born at Portsmouth in 1902, and was educated at the City and Guilds College on a Royal Scholarship. He took first-class honours degree and diplomas of both the City and Guilds and Imperial College of Science and Technology. He entered the Post Office Engineering Department in 1927, and, until his appointment as assistant engineer-in-chief in 1953, worked at the Post Office Research Station on line transmission. He was in charge of the work that led to the laying of the first-ever repeatered submarine cable, between Anglesey and the Isle of Man, in 1943. As assistant engineer-in-chief he led the Post Office project team on the first Transatlantic telephone cable. He became director of research in 1958, and in 1959 also a director of Cable and Wireless, Ltd. In 1957 he was made a Companion of the Order of St. Michael and St. George.

Dr. G. H. Metson

Dr. G. H. Metson, who has been appointed to succeed Mr. Halsey, was born in London in 1907 and joined the Post Office in 1925 as a youth-in-training. His early years with the Post Office were spent in the physics laboratory working on spectrography. Later he transferred to Northern Ireland, where he carried out research on magnetron oscillations and earned his M.Sc. and Ph.D. at Queen's University, Belfast. During the War he served with the Royal Corps of Signals, and won the M.C. for gallantry. In 1946 he was back at Dollis Hill as a principal scientific officer in charge of the Thermionics Group set up to study the causes of valve failure. Later his Division started to design and manufacture very-long-life valves. He was awarded a D.Sc. in 1958, and in 1962 received the Institution Premium, the highest award made by the Institution of Electrical Engineers, for a paper on an electrical engineering subject. He was appointed deputy director of research in 1962.

Plant Physiology at the University of Sussex: Prof. J. F. Sutcliffe

Prof. J. F. Sutcliffe, who has been appointed professor of plant physiology in the School of Biological Sciences in the University of Sussex, is at present professor of botany at King's College, University of London. Prof. Sutcliffe obtained first-class honours in botany in the University of Leeds in 1947, after his undergraduate career had been interrupted by war service in the Fleet Air Arm. His interests in the solute relationships of plants became evident in the work that he did for his doctorate on the effects of sugar and potassium on the extension growth of roots. Since his move to King's as an assistant lecturer in 1949, he has made the problems of salt uptake his own particular field, in which he is now established as a world authority. He has made many valuable and fundamental contributions to our knowledge of the mechanism of ion uptake, and has written a text-book for university students which is the best of its kind yet to appear. The calibre of his work is shown by the early award of the D.Sc. of the University of London in 1960. He spent one year in the laboratory of Prof. F. C. Steward at the University of Cornell as Rockefeller Foundation Fellow, and it was there that he turned his attention particularly to the coupling of salt uptake with protein metabolism. Prof. Sutcliffe has always been in the forefront of biological society activities. He has been the botanical secretary of the Society of Experimental Biology since 1960, and has served on the Membership Committee of the Institute of Biology since 1961. He was recorder of the Cell Physiology Section at the tenth International Botanical Congress at Edinburgh in August last. He is no narrow physiologist; his wide knowledge and interest in all aspects of plant biology are evident from the fact that he has been president of the Croydon Natural History Society since 1963. In addition to his reputation as a scientist, Prof. Sutcliffe will bring to Sussex a vigour and enthusiasm for both teaching and research which will be an invaluable asset to a new University, particularly in the early days of its development.

Inorganic Chemistry at Queen Mary College, University of London: Prof. D. C. Bradley

Prof. D. C. Bradley, senior professor of chemistry at the University of Western Ontario, Canada, has been appointed as from January 1, 1965, to the chair of inorganic chemistry left vacant by the resignation of Prof. J. Chatt, who has taken a post at the University of Sussex. Prof. Bradley graduated at Birkbeck College, London, where he started research with the late Prof. W. Wardlaw, and was successively lecture demonstrator, assistant lecturer and lecturer. In 1959 he was invited to his present post in Canada, where his responsibilities for the teaching of inorganic chemistry have included the reorganization of courses for the B.Sc. honours degree and the initiation of graduate courses for the M.Sc. and Ph.D. degrees. He has also taken part in general university administration and served on a committee of the Defence Research Board, Department of National Defence, Ottawa. Prof. Bradley's research has developed from his original work on zirconium alkoxides into a general study, by both synthetic and structural methods, of the alkoxides of a wide range of metals. Recently it has been extended to the dialkylamino derivatives of metals of groups IV, V and VI and to inorganic polymers containing transition metal atoms bonded to oxygen, sulphur, nitrogen or phosphorus. It is described in more than eighty scientific papers and many review articles, which have won him international recognition in his chosen field. He returns to the University of London at a time when long-awaited plans for the modernization and expansion of facilities for chemistry are beginning to materialize, and he should find considerable scope in the new buildings now being constructed at Queen Mary College.

The Colwyn Medal

The Colwyn Medal for 1964 is to be awarded to Dr. G. F. Bloomfield, international co-ordinator of Technical Advisory Service, Malayan Rubber Fund Board. The Medal, given by the late Lord Colwyn, a former president of the Institution of the Rubber Industry, is awarded yearly for services of a scientific or technical nature with a bearing on the rubber industry. Dr. Bloomfield began his career in rubber with the Rubber Growers' Association in 1932. After the War he was attached to the Rubber Research Institute of Malaya for some years, assisting in the introduction of the latest research techniques and in the Institute's rehabilitation after the Japanese occupation. He has published many contributions to the subject of rubber research and technology.

Indian Institute of Technology, Delhi

The Indian Institute of Technology at Delhi is the fifth of its kind to be set up in India with foreign aid. Already there is an Institute at Kharagpur which has been mainly equipped by American aid, one at Bombay which has been sponsored by the U.S.S.R., another at Madras sponsored by West Germany, and a fourth at Kanpur which is being equipped by the United States. When it became known six years ago that India was contemplating a College of Engineering and Technology at New Delhi, it was felt that here was an opportunity for H.M. Government to co-operate with British industry in a gesture which would be of long-term advantage to India and Great Britain. In order to meet the cost of British manufactured equipment required by the College, an appeal was launched by Sir Hugh Beaver, the then president of the Federation of British Industries, to which British industry responded with donations totalling more than £260,000. H.R.H. The Duke of Edinburgh laid the foundation stone in January 1959, and the College opened in 1961 with an initial intake of 150 students. In 1963 it was granted independence to confer its own degrees and was renamed the Indian Institute of Technology. It aims eventually to provide five-year residential courses for 1,250 undergraduates and research facilities for 300 postgraduates. At present the teaching staff includes eight British professors and further appointments from the United Kingdom will be made next year. With the attainment of Institute status the equipment programme has been extended. In response to a second appeal launched in December 1963 by Sir Cyril Harrison, chairman of the sponsors and immediate past-president of the Federation, contributions and promises of further support from British industry now exceed £55,000 and it is hoped that an additional £95,000 will be raised by the end of March 1965. (See also *Nature*, 200, 735; 1963.)

Loans of Scientific Apparatus to Schools

Dame Kathleen Lonsdale, professor of chemistry in University College, London, writes: "The Chemistry Department of University College, London, recently made it known, through the Association for Science Education, that certain surplus apparatus, which included potentiometers, resistance boxes, galvanometers and *p*H meters, could be applied for by school science teachers and would be made available on indefinite loan. The result was that nearly ninety applications were received from all over Great Britain, from grammar, technical, secondary modern and independent schools, and a great many teachers had to be disappointed. It seems probable that other colleges and industrial research departments may have, stored away in cupboards, apparatus that they would not like to destroy and cannot continue to store, but for which they have no immediately foreseeable use. The Association for Science Education is willing to act as a clearing house for offers of such apparatus, which

should be in reasonably good or repairable order. Those who are prepared to give or lend apparatus to schools should send a list of what is available to the General Secretary, Association for Science Education, 52 Bateman Street, Cambridge, and should specify what arrangements could be made for its direct handing-over or delivery to those schools which might apply to the Association for it as a result of subsequent publicity".

The Environmental Group

The inaugural meeting of the Environmental Group will be held at the Imperial College of Science and Technology on December 4. The Group has been formed to provide a forum for the discussion of generalized environmental problems. The discussions and meetings of the group are intended to disseminate information, to assist in providing 'feed-back' of information and to promote more fruitful co-operation between the various professions. Membership of the Environmental Group will be open to all those professionally interested in the environment created by buildings. The members of the provisional committee are: *Chairman*, P. Burberry; *Deputy Chairman*, J. S. McCulloch; *Secretary*, P. A. Jay; *Members*, A. Aldersey-Williams, A. Benjamin, T. A. Markus, D. Moizer, D. Poole. Further information can be obtained from Peter Jay, 16 Gloucester Place, London, W.1.

The Classification Society

At a meeting on April 17, 1964, a new society, the Classification Society, was founded, the aims of which are to promote co-operation and interchange of views between those interested in the principles and practice of classification in a wide range of disciplines. In order to carry out these aims it is proposed to produce a bulletin containing references to (and, if possible, summaries of) publications of interest to members, and to arrange meetings. The foundation of the Society follows the holding of a symposium, organized by 'Aslib' on April 6, 1962, entitled "Classification: an Inter-disciplinary Problem", at which it became clear that there are many aspects of classification common to such widely separated disciplines as biology, librarianship, soil science and anthropology, and that opportunities for joint discussion of these aspects would be of value to all the disciplines concerned. Copies of the report of the symposium (price 5*s*.) can be obtained from Aslib, 3 Belgrave Square, London, S.W.1. The annual subscription to the Society is £1, entitling members to receive the *Bulletin* free of charge and to attend and vote at meetings. Further particulars, and a membership application form, can be obtained from the secretary-treasurer, Mr. J. S. L. Gilmour, University Botanic Garden, Cambridge.

Geological Survey of Great Britain and the Museum of Practical Geology

The summary of progress of the Geological Survey of Great Britain and the Museum of Practical Geology for 1963 reports that an area of 1,091 square miles of field survey on the 6-in. scale was completed during the year (Pp. iii+99. London: H.M.S.O., 1964. 6*s*. 6*d*. net). Details are given of the many research activities, in field and laboratory, and of the practical application of the results to many economic and industrial problems. Preliminary research on the geochemistry of British shales shows that many of these rocks have an unusually high natural radioactivity. Since 1955 the Survey has carried out aeromagnetic surveys to investigate changes in the strength of the Earth's magnetic field; the results have provided much information concerning concealed geological structures. A new series of the very useful *Water Supply Reports* is being published to include recent research and records of underground water. Much revision work has been carried out in the Museum, and attendance at lectures and demonstrations reached a total of 15,665.

Institution of Civil Engineers

In his presidential address to the Institution of Civil Engineers on November 3, Mr. R. M. Wynne-Edwards was critical of the Trend Committee's proposals regarding the Department of Scientific and Industrial Research. He thought that the present independence of the Building Research Station and the Road Research Laboratory was an important factor in their value to the community, and that it would be a grave error to transfer them to executive ministries—a view which also found expression in the last report of the Road Research Laboratory. Mr. Wynne-Edwards also stressed the importance of determining the most effective way in which the Institution could make its views known to the Government, and expressed the opinion that one of the most urgent needs was to make full use of British civil engineering knowledge in the underdeveloped countries. To his knowledge, the Department of Technical Co-operation had never yet asked the Institution for its views on any subject. He also instanced the imaginative civil engineering schemes for Morecambe Bay and the Solway as examples of schemes which might fail, not on their merit but for lack of public support, because the community which had to provide the money was insufficiently informed. This demonstrated the need for the Institution to encourage independent thought in these and other topical matters and to find effective means of making them known. There was no room for petty-mindedness or rivalries and he regarded the federation of 13 major professional institutions in the Engineering Institution's Joint Council as a major step towards working together and thinking, speaking and acting as a united profession. Further, the productivity of the construction industries was an immediate challenge to the profession as well as to industry, for in this expenditure and its expansion the engineer and the architect held key positions and were the essential creative force. Whatever reasons might exist for divisions in the construction industry, the profession had a common task in producing the best possible design. He suggested that the engineering content in the construction of a building increased proportionately as its design was adapted to the special needs of its users.

Financial and Management Accounting

United Steel Co., Ltd., has published a lucid account of its financial and management accounting practices. The role of financial accounts in providing a record of the transactions of a business and as a means of conforming to statutory requirements is well presented, but the particular appeal of the booklet lies in the way financial accounts are used as the basis of management accounting in the Company. Current transactions are analysed and compared either with past performance or with predetermined estimates of current performance, in order to provide management with an instrument for the control of efficiency and for future planning. Costing, budgetary control and similar applications of accounting data for the control of industrial activities are well described. The publication would be of considerable use to all accountants who fail to use the information they produce for control purposes and invaluable to all managerial staffs who need to have more than a nodding acquaintance with financial and management accounting; no clearer presentation of this difficult subject has been made. Copies can be obtained, free of charge, from the Secretary, United Steel Co., Ltd., Sheffield.

Radioisotopes, Labelled Compounds and Radiation Sources

The recent edition of the catalogue of radioactive products, issued by the Radiochemical Centre, Amersham, is of greatly enlarged size and scope (*Catalogue of Radioactive Products: Radioisotopes—Labelled Compounds—Radiation Sources*. Pp. 164+13 plates. Amersham: The

Radiochemical Centre, 1964). Two thousand items are listed, and there is a new medical section comprising 76 radioactive chemicals, prepared and tested to pharmacopœial standards, which are in some measure of routine use in medical diagnosis or therapy. In the other sections the classification follows that of previous editions. The facilities are grouped under the headings: radioisotopes and labelled compounds; labelling, irradiation and other services; radiation sources; and radioactive material for instrument calibration. An index and some general information on ordering, registration, packaging and payment, are included. The Centre does not sell radium except in quantities of less than 5 mg, and in the United Kingdom all radium is issued on loan under the terms of a written agreement specifying an annual hire charge, payable six-monthly. The general section on radiochemicals has 1,125 entries, 390 more than in the 1962 edition. Fifty isotopes, mostly cyclotron-produced materials, are listed for the first time. Primary isotopes and labelled compounds are grouped together in a single alphabetical list, the primary isotopes in capital letters. A general trend to labelling at higher specific activities is evident, particularly with compounds with wide biochemical interest such as amino-acids and sugars. Some of the tritium-labelled compounds approach theoretical maxima of specific activity. The number and variety of radiation sources have increased substantially, and the section dealing with these sources consists of two parts—sources for clinical use and sources for the laboratory and factory. Each entry includes a summary of the relevant nuclear data, a description of the method of construction amplified by an illustration where appropriate, and the methods used for testing and measurement. The list of sources for radiotherapy includes new patterns of cobalt-60 ophthalmic applicators, cæsium-137 needles for interstitial use, and improved flexible β-emitting sheet material. For laboratory and industrial use there is an increased range of sources containing americium-241; sources of cæsium-137 for radiography, level gauging or laboratory instruments; and of strontium-90 for thickness gauging, in a ceramic form especially resistant to accidental damage and to high temperatures; and the recently developed cobalt-57 sources for Mössbauer experiments. Technical information on each item in the catalogue is of necessity brief, but more detailed information is given in *The Radiochemical Manual* and in the *Technical Bulletins* issued by the Centre.

X-ray Crystallography

An international summer school in "X-ray Crystallography" was held at Peterhouse College, Cambridge, during August 31—September 12. The course was arranged with twenty one-hour lectures and twenty two-hour periods of exercises involving only drawings and interpretations. Roughly half the work was devoted to the various types of X-ray diffraction photographs, their interpretation and proper use, and the second half to diffractometry and physical aids, other than X-rays, in determining crystal structures. The course was planned so that someone who had little knowledge of many aspects of X-ray crystallography would be able to follow most of the subject-matter. It was also arranged that the most recent developments in each of the matters dealt with were described. The students came from Belgium, Finland, France, Italy and Norway and they all had some knowledge of a part of the subject. Such a course seems appropriate for students of this kind because it enables them to obtain a more comprehensive view of X-ray crystallography. The lectures and demonstrations were given by Dr. W. A. Wooster.

National Institute of Oceanography

Volume 11 of the National Institute of Oceanography's Collected Reprints (published by the Institute, at Godalming, Surrey) contains 62 papers and articles. Classified according to subject, 30 are physical, 20 are biological, six are on the geology or geophysics of the sea-bed, two are chemical and four are general. There are no fewer than 14 papers on waves, providing evidence that this is still one of the main lines of research of the Institute and one in which its workers are keeping in the forefront of activity. Most of these papers deal with the observational and analytical techniques for studying the spectra of ocean waves, particularly the directional spectra. A number of other physical papers are concerned with long waves, internal waves, tides and mean sea level, including one on a comparison of the geodetic reference levels of England and France using oceanographic methods. Among the papers on biological subjects, including fisheries, there is a group of five on whales and whaling (a long-standing interest of the Institute), and six on particular species or groups of marine animals. Several papers describe improved apparatus and techniques, including nets and their closing mechanism. A further group of papers deals with the use of acoustic techniques for the study of various features of the sea bed and of the sediment and rocks below the bottom. The Institute's new research vessel, R.R.S. *Discovery*, was commissioned in December 1962, and the present volume includes descriptions of the ship and her scientific equipment.

Veterinary Non-proprietary Names

The *British Veterinary Codex* Revision Committee has adopted the following non-proprietary names for the veterinary substances indicated:

Non-proprietary name	Other names
Amlcarbalide	*NN'*-di(*m*-amidinophenyl)urea; 3,3'-diamidinocarbanilide. 'Diampron' is the isethionate.
Amprolium	1-(4-amino-2-propylpyrimidin-5-ylmethyl)-2-methylpyridinium chloride. The hydrochloride is an ingredient of 'Amprol', 'Amprolmix', and 'Pancoxin'.
Diminazene	*pp'*-diamidinodiazoaminobenzene. The aceturate is an ingredient of 'Berenil'.
Metriphonate	dimethyl 2,2,2-trichloro-1-hydroxyethylphosphonate; chlorofos; trichlorphon; Bayer *L*13/59; 'Dipterex'; 'Dyvon'; 'Neguvon'; 'Tugon'.
Naphthalophos	*N*-(diethoxyphosphinyloxy)naphthalimide; 'Rametin'.
Thenium	*NN*-dimethyl-*N*-(2-phenoxyethyl)-*N*-(2-thenyl)- ammonium. The closylate is an ingredient of 'Ancaris' and 'Canopar'.
Tylosin	An antibiotic derived from an actinomycete resembling *Streptomyces fradiae*. 'Tylan'.

The non-proprietary names are reported to be free from conflict with trade marks registered in Great Britain and Northern Ireland, and these names, or names resembling them, will not be registered as trade marks for pharmaceutical products or drugs in those countries. Some of the names, other than the chemical names, appearing in the second column above are registered trade marks. The adoption of a non-proprietary name does not necessarily imply that the *British Veterinary Codex* Revision Committee recommends the use of the substance in veterinary medicine or that the substance will be included in the *British Veterinary Codex*, although, if a substance is included, it is intended that the non-proprietary name shall be the title of the monograph. The *British Veterinary Codex* Revision Committee has undertaken, at the request of the Association of the British Pharmaceutical Industry, to provide non-proprietary names for veterinary products, and all requests from manufacturers and other interested persons for the provision of such names should be addressed to the Secretary, *British Veterinary Codex* Revision Committee, the Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, London, W.C.1.

Amendment to List No. 1 (*Nature*, 202, 136; 1964):

Diaveridine	This is an ingredient of 'Darvisul'.

Kootenay National Park, Canada

Kootenay National Park is an area of exceptional scenic beauty consisting of 'rows' of mountains alternating with open valleys. It stretches for more than 60 miles parallel to the north-west-south-east trend of the Rocky Mountains, and, along its width, crosses various mountain

ranges and valleys in a series of 'jogs', from the divide leading to the Bow River valley on the north-east to Columbia River on the south-west. It lies wholly within the Province of British Columbia and consists of four different segments: the northern end comprises the drainage basin at the head of Vermilion River; the middle section is a belt at right angles to the first, following the Vermilion River across the general trend of Vermilion Range and extending into the Mitchell Range in the south-west; the main southern part of the Park is a strip along the Kootenay River valley; and a fourth part includes a 'jog' to westward, which takes in the valley of Sinclair Creek nearly to its junction with Columbia River. An attractive guide to the Park has recently been prepared by the Geological Survey of Canada Department of Mines and Technical Surveys, Ottawa, as Miscellaneous Report No. 9 (*Kootenay National Park—Wild Mountains and Great Valleys*, by David M. Baird. Pp. vi + 94. Ottawa: Queen's Printer, 1964. 1.50 dollars).

Irish Tubificidae

THE study of the Irish Tubificidae has been largely neglected since the publication of a check list by Southern in 1909. The only other person to have concerned himself with them was Friend, whose taxonomic investigations and identifications are in general considered not to be wholly reliable. A complete revision of the Irish tubificids has long been overdue and, in a paper by C. R. Kennedy, of the Department of Zoology, University of Liverpool, an attempt is made to bring knowledge of them up to date and into line with the European species (*Proceedings of the Royal Irish Academy*, 63, Section B, No. 13. Dublin: Hodges, Figgis and Co., Ltd., 1964. 2*s*. 6*d*.). The literature pertaining to the Irish tubificids is reviewed and, in addition, the results of an examination of Southern's specimens are presented together with information gained from visiting sites and making further collections. It has proved possible to confirm or correct the identity of most of the earlier records by an investigation of their descriptions, by examination of specimens or by both, and to bring the nomenclature up to date. As a result of this survey, seventeen species are now recognized as existing in Ireland, six of which are new Irish records. All of these are encountered, more or less commonly, in Britain.

New Medicines

ACCORDING to surveys conducted by Research Services, Ltd., 89 per cent of general practitioners consider that new medicines have been of great importance in recent medical advances in the control of disease, and 80 per cent of both general practitioners and the general public feel that it would be a serious matter if lower profits for pharmaceutical manufacturers were to reduce their work in developing these new medicines (*Attitudes towards the Pharmaceutical Industry amongst Family Doctors and the General Public*, 1962 and 1964). The public in general tended to overestimate the amount spent on National Health Service medicines. Of every £100 of National Health Service expenditure, about £13 went on medicines (in general practice and in hospital); two-thirds of the general public believed the figure to be more than £20, and two-fifths believed it to be more than £30. Moreover, although the proportion of total National Health Service costs spent on medicine has remained constant since 1959, 81 per cent of the general public and 67 per cent of general practitioners had the impression that it was increasing. General practitioners were asked what sources of information they relied on to keep up to date with pharmaceutical discoveries. 71 per cent named articles in medical journals; 36 per cent manufacturers' representatives; 25 per cent discussion with colleagues; 24 per cent manufacturers' literature through the post; 21 per cent the Government-sponsored publication, *Prescribers' Journal*; and 18 per cent advertisements in medical journals. Refresher courses, medical society meetings, the *Monthly Index of Medical Specialities*, discussions with pharmacists, hospitals and consultants were among other sources of information mentioned. The Association of the British Pharmaceutical Industry has a code which bans undesirable marketing practices among its member companies. This was revised recently after consultation with the British Medical Association. Two-thirds of the general practitioners interviewed could not provide examples of cases they felt should have been prevented by this code. The most commonly mentioned type of undesirable practice was price-cutting, mentioned by 5 per cent of doctors. Many of the individual instances related to events which occurred before the existence of the code. 89 per cent of the public said they had confidence in the safety of medicines prescribed for them by the doctor; only 4 per cent said they had not. The reasons given by the majority indicated an overwhelming confidence in their doctor, 71 per cent saying that their confidence was based on faith in their doctor and his prescribing. Copies of the survey are available from the Office of Health Economics, 62 Brompton Road, London, S.W.3.

Announcements

PROF. F. S. DAINTON, at present professor of physical chemistry in the University of Leeds, has been appointed to succeed Dr. B. L. Hallward as Vice-Chancellor of the University of Nottingham as from October 1965.

A MEETING of the Basic Science Section of the British Ceramic Society on "Physics and Chemistry of Ceramic Surfaces" will be held in London during December 15–17. Further information can be obtained from Dr. J. P. Roberts, Houldsworth School of Applied Science, the University, Leeds 2.

A CONFERENCE entitled "A Scientific Basis of Maximum Permissible Levels", arranged by the British Institute of Radiology, will be held in the Edward Lumley Hall, Royal College of Surgeons, London, W.C.2, on December 8. Further information can be obtained from the British Institute of Radiology, 32 Welbeck Street, London, W.1.

THE second annual conference on "Solid-State Physics", arranged by the Institute of Physics and the Physical Society, will be held at the H. H. Wills Physics Laboratory, University of Bristol, during January 5–8. Further information can be obtained from the Administration Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

Two joint meetings of the Western Section of the Society for Analytical Chemistry and the Cardiff and District Section of the Royal Institute of Chemistry will be held at the College of Technology, Newport, and University College, Cardiff, on November 27 and December 11, respectively. At the first meeting, Dr. T. S. West (Imperial College of Science and Technology) will present a paper entitled "Complexometric Methods in Analytical Chemistry", and at the second, Dr. E. V. Truter (University of Leeds) will speak on "Thin-layer Chromatography". Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

A CONFERENCE on "Optics in Process Control", organized by the Optical Group of the Institute of Physics and the Physical Society, will be held at the Manchester College of Science and Technology during January 6–8. The main topics of discussion will include: optical monitoring and inspection; metrology and machine tool applications; optical methods of analysis; control of photographic processes; tracking and ranging devices; optics in the semiconductor industry; optics in computer technology. Further information can be obtained from the Administration Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

UNIVERSITY FINANCE IN BRITAIN

IN issuing *Returns from Universities and University Colleges in receipt of Exchequer Grant, Academic Year 1962–1963**, the Universities Grants Committee, in contrast to the practice of the previous four years, has omitted a general survey of its activities: a separate publication is promised later in the year.

The number of full-time students at university in Britain increased to 119,004, compared with 113,143 in 1961–62, and of these 17,868 were in the Universities of Oxford and Cambridge, 23,338 were in the University of London, 49,464 in other English universities and colleges, 7,761 in the University of Wales and 20,573 in the Scottish universities. There were 13,375 students from overseas, 7,602 of whom were from within the Commonwealth (6,893 of whom were postgraduate); since 1953–54 the proportion of overseas students has risen from 9·9 per cent to 11·3 per cent. Of the full-time students, 29·1 per cent were in colleges or halls of residence, 51·6 per cent in lodgings and 19·3 per cent at home; these figures compare with 28·1, 40·9 and 31·0 per cent, respectively, in 1953–54. The proportions continue to vary widely in different universities and for men and women: in Scotland only 9·4 per cent of men and 18·5 per cent of women are in colleges or halls of residence, while 45·9 per cent of men and 42·1 per cent of women are at home.

Of the 87,654 full-time men students, 24·2 per cent were in arts and 11·8 per cent in social studies; 27·9 per cent in science; 19·0 per cent in technology and 10·9 per cent in medicine; for the 31,350 women students the corresponding figures are: 52·2; 10·4; 23·4; 1·1; and 9·7. Of the 20,793 postgraduate students, 3,755 were taking postgraduate courses in teacher training; the remainder were distributed as follows: arts, 3,691; social studies, 2,144; science, 6,323; technology, 3,027; medicine, 1,251; and agriculture, 429. Of 33,677 full-time students entered for the first time in 1962–63, 32,147 were reading for a first degree and 1,530 for a first diploma; 9,721 were women; 10,791 were in arts and 4,339 in social studies; 9,224 in science; 4,965 in technology and 2,756 in medicine. Over the past 10 years the increases in science and technology have been proportionally almost twice as great as in arts.

The proportion of State-assisted students was 88·4 per cent compared with 87·1 per cent in 1961–62 and 71·9 per cent in 1953–54, ranging from 93·2 per cent for Wales, 92·8 per cent at Cambridge, 90 per cent at Oxford, 92·2 per cent at other English universities and colleges (excluding London) to 82·8 per cent for Scotland. There were 16,424 part-time students (4,890 from overseas) and of those 12,768 were in English and 3,429 in Scottish universities. Of the 23,886 first degrees obtained, 16,435 were honours degrees; of the total 29·2 per cent were in science, 12·5 per cent in applied science, and 8·3 per cent in medicine. Full-time teaching and research staff, excluding Oxford and Cambridge, increased to 13,801 (12,786 in 1961–62) and 27·6 per cent are now in science, 14·3 per cent in technology, 16·2 per cent in medicine and 8·7 per cent in social studies; 11·7 per cent were professors, 6·6 per cent readers, 12·7 per cent senior lecturers and 46·7 per cent lecturers. Including Oxford and Cambridge the full-time academic staff totalled 14,132.

Of the recurrent income of £86,402,542 (£74,112,891 in 1961–62), £60,599,826 was from Treasury grants (70·1 per cent) and £655,150 from grants from Government departments; £8,575,430 (9·9 per cent) from fees; £2,087,756 (2·4 per cent) from endowments; £1,636,623 (1·9 per cent) from local authority grants; £506,820 from donations and subscriptions; £9,522,729 (11·0 per cent; £8,229,163 for 1961–62) from payments for research. For English, Welsh and Scottish institutions the respective totals are: £69,578,663; £4,547,139; and £12,276,940. Non-recurrent Treasury grants amounted to £36,481,214 (£28,638,256 in 1961–62) and of this £22,773,670 was in respect of building work, £3,795,906 professional fees, £8,493,852 furniture and equipment and £1,417,786 site and property purchases. Of the recurrent expenditure of £85,379,145 (£74,119,781 in 1961–62), 6·7 per cent was on administration, 41·9 per cent on salaries and superannuation of teaching staff, 12·0 per cent on departmental wages (technicians and laboratory assistants), 14·5 per cent on departmental and laboratory maintenance, 3·0 per cent on repairs and maintenance of buildings and 11·0 per cent on rates, insurance, heat, light, etc.

RHEOLOGICAL RESEARCH IN BRITAIN

THE science or engineering graduate who enters industry has some understanding of the processes of deformation and flow in solids and liquids, but this is usually restricted to the cases of ideally elastic solids, ideally plastic solids and Newtonian liquids. His knowledge of the creep and plastic flow in real solids and of the elastic and thixotropic effects displayed by non-Newtonian liquids is rudimentary. An understanding of these complex phenomena is essential, however, to the successful development of many industrial processes and to the manufacture of finished products with optimum mechanical characteristics. The situation would be improved by a greater emphasis on rheological topics in university courses, although it may be argued that the experimental techniques and mathematical theory involved are too specialized for extensive treatment in undergraduate teaching.

It cannot be said, however, that improvements in formal teaching will solve the problem entirely, because many of the problems confronting the industrial rheologist involve questions which are still matters of active research; and information on these, if published at all, appears scattered over an enormous range of technical, scientific and mathematical journals. In this connexion, the British Society of Rheology has for many years carried out a useful function by bringing together scientists from industry, the research associations and the universities in order to discuss problems of mutual interest in this field. It has, nevertheless, become apparent that in some directions research is being duplicated by different firms and institutions while in other directions it is almost entirely neglected. The Society, therefore, decided in 1963 to extend its activities by making information on active work more readily available, by ascertaining those directions in which further research is urgently required and by encouraging projects designed to fill the gaps in existing knowledge. It was a fortunate coincidence that at the same time the National Engineering Laboratory was considering the publication of a survey of rheological research in Britain, and the Society was able to co-operate in this work. The

survey has now been published as *Rheological Research in Britain, 1964**. It presents the information obtained by sending out nearly 600 copies of a questionnaire, and the replies give a clear picture of the very large amount of research in progress. Although only a few lines are devoted to each project, the survey runs to more than a hundred pages, being, in fact, the longest report so far published by the National Engineering Laboratory.

In this survey, a total of 226 establishments are listed, divided fairly evenly between universities, Government-owned and Government-aided institutions, and industrial laboratories. There is an index of these establishments and another of the individual research workers. A third index, devoted to materials under investigation, shows the extremely wide range of present-day rheology. It runs through from adhesives to zirconium, via bananas and barytes, coke and cream, earth and eggshells, glaciers and graphite, mud and muscle, plutonium and pesticides, semen and sewage, wheat and wood, and a hundred other substances. The tabulated information has been analysed, and a series of histograms shows the distribution of interest between materials, between phenomena, between methods of approach and between processes. The first of these shows, for example, the predominant interest of industry in polymers and multi-phase materials, while university interest is more generally distributed with some concentration on idealized materials. On the other hand, the interest in phenomena displayed by the universities runs nearly parallel with the industrial interest, although the latter is rather more concentrated on the non-Newtonian viscosity of liquids and the former on the plasticity of solids. Of the methods of approach, that of continuous shear viscometry and rheometry is the most generally used, but this is closely followed by theoretical methods and then by tensile and compressive testing. The extent of the industrial interest in the theoretical approach is quite remarkable, being equal to that shown by the universities. Another surprising feature is the smallness of the interest shown by industry in individual processes (such as extrusion, mixing, flow through pipes and channels) in comparison with the interest in fundamental phenomena.

The present survey is necessarily incomplete, and it would seem that the coverage is weakest in biology and in the study of metals. It is hoped that it will become a regular publication, and the compilers ask that anyone whose work has been overlooked should inform them so that it may be included in the next edition. In this way the survey should become a really comprehensive guide to those who may wish to seek specialized advice and to those who are concerned with the initiation of new research projects with industrial applications.

FAMILIAL TRENDS OF CANCER

SINCE January 1960, the New South Wales State Cancer Council has been conducting a survey of women treated for cancer of the breast in order to determine whether there is a higher incidence of cancer among the relatives of this group than among the relatives of a control group of the same size presumed not to be suffering from cancer. The survey is a sequel to many investigations of hereditary and familial trends of cancer which have been made in Europe, Britain and the United States during the twentieth century.

In the course of the survey carried out by Pamela Siddins*, each of 99 female patients with breast cancer and each of the 99 other women who formed the control group supplied a history of her family. The incidence of cancer among the siblings, parents, aunts, uncles, cousins and grandparents of the women in each group was determined from hospital records and from the cause of death entered on death certificates. A questionnaire was devised, which sought information concerning the age, marital status, geographical situation, socio-economic position, lactation, order of birth, and menstrual and fertility history of patients and control probands.

Incidence of cancer in family histories was taken as that existing at the time of interview. The ages of the patients included in the survey ranged from 33 years 6 months to 74 years 8 months; these consisted of 84 married women with children, 10 married women without children, and five unmarried women. Of the total number of women interviewed, only about 33 per cent were included in the survey. There were many reasons for unsuitability of probands, the chief reason being the fact that few families had lived in Australia for the required three generations. Many who thought that all their grandparents had died in Australia were later excluded from the survey when official records proved otherwise. It was soon realized that the original plan, which had been to locate all relatives back to great-grandparents, would be impracticable.

At first, the findings suggested that breast and other types of cancer occurred more often in the families of the patients with breast cancer than in those of the control probands. For analysis, the types of breast cancer encountered in the survey were divided into the following basic classes: scirrhous, encephaloid or medullary, mucous or colloid, adeno- and duct carcinoma, sarcoma, and Paget's disease of the breast. For 12 patients no histological reports were available, because of loss of records or because no biopsy (or other diagnostic surgical measure) had been performed. Adenocarcinoma and scirrhous carcinoma were the types most frequently encountered. The breast cancer probands included three twins, two belonging to a dizygotic pair and one to a monozygotic pair, but in none of the twins of these patients was there evidence of cancer. No case of cancer of the breast in males was encountered among the relatives of the probands. It occurred, however, in sisters of breast cancer probands in five families and in mothers of three probands.

Cancer occurred less frequently in similar relatives of the control probands. Controls interviewed at medical clinics were not aware that the survey was concerned with the incidence of any one disease. Patients and controls from cancer detection clinics, when asked for the illnesses and operations known in three generations of relatives, tended to emphasize the cancers rather than other diseases. Most frequently the incidence of cancer was incorrectly given by the proband—the number of cancers being exaggerated in those families where several cases were known, and underestimated in families whose attention had never been directed to it for any reason.

The information collected was analysed statistically by S. Chorlton, who found that the number of relations per cancer proband ranged from 18 to 190, with a mean of 70·5. Of these, the mean number for whom some reliable medical history was known was 50·8, or 72·1 per cent. For the controls, the average number of relations was 62·4 (range 14–127), of whom medical history was known for 48, or 77 per cent. The number of relatives with some documented medical history amounted to 5,042 (cancer group) and 4,753 (control group). Some form of cancer occurred in 87 out of the 99 families of patients with the disease—

* New South Wales State Cancer Council Publication No. 9.

breast cancer being found in 21 of these. For the controls, cancer occurred in a total of 80 families, with an incidence of breast cancer in 13.

There is a notable absence of any significant infant mortality rate due to cancer, attributable probably to poor diagnosis in earlier times. Mortality in the early age-groups, particularly in the 0–4 years age-group, is high, but, of 819 deaths of relations for both cancer and control groups, only one death from cancer is reported. This was reflected in a general reduction in the incidence of all cancers in both groups.

The mean age for detection of cancer of the breast in the proband is 47·5 years, and for those families with breast cancer in relatives it is 48·4 years. The mean ages for patients and control groups at the time of the survey were 50·1 ± 13·6 years (cancer group) and 50·4 ± 10·3 years (control group). This means that the cancer group has, on the average, lived 2·6 years since the diagnosis of their disease.

The number of cases of cancer and the types of cancer occurring in the two groups show a similar distribution, except for breast cancer. The highest rate for breast cancer among relatives occurs in maternal aunts. There is a higher incidence of breast cancers and all cancers in female relations of breast cancer patients. With regard to the effect of degree of relationship, there is a high incidence of breast cancer in persons with a coefficient of relationship of one-quarter in the patient group.

EPILEPSY IN AFRICANS

A STUDY of epilepsy in Africans in Southern Rhodesia has been undertaken by Dr. L. F. Levy, Dr. J. I. Forbes and Dr. T. S. Parirenyatwa of Harare Hospital, Salisbury, Southern Rhodesia (*Central African Journal of Medicine*, **10**, No. 7; July, 1964). In a field survey carried out in the Semokwe Reserve, 130 persons admitting to seizures were discovered in a population of approximately 17,500, and these sufferers were interviewed. A parallel group of 100 patients presenting at Harare Hospital with the complaint of seizures was also fully investigated.

The incidence of epilepsy in Africans is probably slightly higher than in Europeans, but African patients tend to present themselves for treatment only when their earning capacity becomes threatened by the disorder. Fits affecting women and children seem to be regarded by patient and parent alike as a misfortune to be accepted, and there must be large numbers of rural sufferers who have never sought medical help. Even allowing for this tolerance of fits, however, the discrepancy between the number of males (161) and females (69) in the combined study seems remarkable and contrasts strongly with the sex distribution reported by other authors.

The age of onset of the disease is similar to that found in other racial groups. Premonitory symptoms vary widely and have no special characteristics. The frequency of attacks in the rural group is interesting because it reflects the pattern of epilepsy which is uncontrolled and allowed to run its natural course. About 10 per cent of the sufferers in the Semokwe Reserve group had fits once a day or more; another 10 per cent had fits several times a month; more than half (56 per cent) had fits once or twice a month, and the remaining 24 per cent had them at intervals of once in two months or longer. A family history of fits was obtained from 65 per cent of the sufferers in the Semokwe Reserve group, but only from 20 per cent of those in the Harare Hospital group. The question of genetic factors in epilepsy should be re-evaluated in all races.

Accidents resulting from fits are common. Twenty-one per cent of the field group and 19 per cent of the hospital group had sustained burns at some time, and, in many cases, the deformity resulting from these was severe. Apart from the physical trauma, epilepsy has a marked effect on the life of the sufferer. In the Semokwe Reserve group 39 per cent of the children up to the age of 14 years were made the butt of humour, and 44 per cent of patients over the age of 15 years were made to feel outcasts by the rest of the community. Twelve male adults and one female had been dismissed from their jobs on account of their seizures. The effects of epilepsy on marital life seem to have no special peculiarities.

Enquiries into tribal beliefs about the ætiology of epilepsy reveal how widespread is superstition and to what extent belief in witchcraft persists. Fifty-nine per cent of Semokwe Reserve sufferers believed their epilepsy resulted from their being 'bewitched'.

The present treatment of epilepsy in such patients is frequently unsatisfactory. The standard anti-convulsant drugs are as effective in controlling their fits as in other races, but, in the first place, sufferers do not make themselves available for treatment; and, secondly, even if they do, the problem of achieving regular and conscientious administration of the selected drug remains. This was also the finding of Hurst *et al.* in the Meadowlands survey. Education and enlightenment of rural Africans will, no doubt, eventually change their present attitude of resignation. In the meantime, it seems that the only way to reach the sufferers would be to send mobile teams into the reserves to seek them out. Once the diagnosis has been made and curable underlying disease excluded, treatment with a long-acting injectionable anti-convulsant would appear to offer the best hope of adequate control.

RECENT REVIEWS OF FOSSIL FISHES

TWO publications of special interest have recently been published on fossil fish: Dr. R. H. Denison has reviewed the Cyathaspididae*, and Dr. C. Patterson† the Mesozoic Acanthopterygia.

Dr. Denison deals with the earliest known family of Agnatha, excluding isolated fragments from earlier strata. The material ranges from the base of the Middle Silurian (Wenlockian) to late Early Devonian (Dittonian). The author describes the anatomy, external and internal, of all forms, which comprise in his interpretation 63 species grouped into 19 genera. The classification adopted for the Cyathaspididae is essentially that of other recent writers, allowing for shifts in the hierarchical status of the taxa. Dr. Denison follows most scholars, Stensiö excepted, in dissociating the Heterostraci from close affinity with the cyclostomes, osteostraci and anaspids. He divides the class Agnatha into two sub-classes, the more primitive Diplorhina with Heterostraci and probably Coelolepida, and the more specialized Monorhina with Myxinoidea and

* Chicago Natural History Museum. *Fieldiana: Geology*. 13, No. 5: *The Cyathaspididae—a Family of Silurian and Devonian Jawless Vertebrates*. By Robert H. Denison. Pp. 309–473. (Chicago: Chicago Natural History Museum, 1964.) 5 dollars.

† *Philosophical Transactions of the Royal Society of London*. Series B: Biological Sciences. No. 739, 247 (July 2, 1964): *A Review of Mesozoic Acanthopterygian Fishes, with special reference to those of the English Chalk*. By C. Patterson. Pp. 212–482 + plates 2–5. (London: Royal Society, 1964.) 105*s*. 15.75 dollars.

with Petromyzonoidea, Osteostraci and Anaspida. All genera in the family are revised, with emphasis on the North American forms and *curricula vitae* given for all species, often with illustrations. In the latter part of his paper, Dr. Denison discusses the habitat, adaptation, evolution, growth and phylogeny of the family. He concludes that they were marine, not highly specialized for benthonic life but well adapted to moving in turbid and poorly lighted waters. He suggests that they were essentially bottom feeders, feeding in a manner similar to that described by Parrington[1] in 1958 for the anaspids. The primitive condition in the cyathaspids is considered to be a shield formed from the fusion of numerous small scales or tesseræ, with the development of large plates in later forms—a view which is consistent with the derivation of the Pteraspididae from the Cyathaspididae.

A review of Mesozoic fishes is long overdue, and Dr. Patterson's study admirably fills the hiatus. While little new material has been added to collections since Smith Woodward[2] produced his monograph on the acanthopterygians, Dr. Patterson has had the inestimable advantage of acid preparations for many of the specimens. Species are now known with a detail and precision impossible half a century ago. The emphasis in the work is on morphology rather than on systematics, and hence isolated scales, teeth and otoliths are omitted, the latter perhaps to be regretted on account of its stratigraphic potential. Dr. Patterson's lengthy review falls into three parts; the first deals with acanthopterygians and ctenothrissiforms of the English Chalk, their systematics and anatomy being discussed in detail; in the second part acanthopterygian faunas of all other Mesozoic deposits are briefly discussed and compared with the British fauna; in the third part the author discusses the morphological, systematic and evolutionary problems arising from his study.

The systematics and morphology of Parts 1 and 2 form the bulk of the work; careful and detailed anatomical descriptions are given accompanied by clear and well-labelled text-figures. The interpretations and deductions are collected into Part 3, which will be read by many not directly concerned with specific details. Dr. Patterson proposes a sub-division of the Beryciformes into three sub-orders; the distinctions are not clear cut and it is doubtful that this truly reflects phylogeny. The author discusses the evolution of the acanthopterygian upper jaw, the origin of the fin spines and the trigemino-facialis chamber. Examining the time span of the Beryciformes, the Cenomanian is seen to contain 19 species in 10 genera, while the Senonian has 22 species in 8 genera. These figures do not reflect the popular picture of rapid radiation of the group during the Mesozoic; they point rather to a pre-Cenomanian deployment, Patterson suggests from Ctenothrissiform stocks, with maintenance of diversity until Senonian times when the Beryciformes are largely replaced by the Perciformes.

In the evolution of the acanthopterygians, three functional trends are defined; increasing manœuvrability, reduction in the buccal dentition accompanied by increase in the pharyngeal dentition, and development of defence mechanisms. Dr. Patterson supports the concept of polyphyletic origin for the Beryciformes and implies the same for the Perciformes. Transitional forms link the two orders and the adaptive advantages of the changes involved—presence or absence of orbitosphenoid, number of pelvic and caudal fin rays—are not apparent. This treatise does not supply answers to all questions on acanthopterygian history; it presents that history clearly and authoritatively, thus enabling us to frame our questions more precisely.

EARLY RECEPTOR POTENTIAL OF THE VERTEBRATE RETINA

A NEW receptor potential of the monkey retina has been reported recently by Brown and Murakami[1]. They observed this new response using an intra-retinal microelectrode and intense stimulus flashes. The latency of the response is very short (less than 0·1 msec), and the amplitude of the response is largest when the tip of the electrode is at the level of the ciliary connexion between the outer and inner segments of the receptors. Brown and Murakami's conclusion that this new response is generated by the receptors is of great significance for visual research; but some additional evidence is still needed to make the support for their conclusion fully convincing. For example, they observed this response in the cone retina of the cynomolgus monkey but could not observe it in the rod retinæ of the night monkey and cat. No attempt was made to directly identify the pigment on which this response depends.

In this communication I wish to report that a quite similar response occurs in the electroretinogram (ERG), and that this ERG response has been observed in every vertebrate eye so far investigated. Furthermore, several lines of evidence given here show that in the all-rod eye of the albino rat this response almost certainly depends on the visual pigment contained in the rod outer segments. Therefore, because the latency of the response is so short, this evidence provides strong and independent support for Brown and Murakami's conclusion that this new response is a receptor potential. Moreover, the amplitude of this new response is linearly proportional to the amount of pigment bleached by the stimulus flash. Thus this new response appears to be more closely linked to initial photochemical events than any other electrical response so far recorded in vertebrate eyes.

In the work recorded here, stimulus flashes were produced by a 65-W-sec photographic strobe lamp (Honewell Strobonar 65*C*) which had a flash duration shorter than 0·7 msec. To minimize electrical and photovoltaic artefacts, the strobe lamp was enclosed in a soft-steel box, and the electrodes, which consisted of saline-soaked cotton wicks leading to Ag-AgCl wires, were partially shielded from the light. With this arrangement, the amplitude of the stimulus artefact was less than 5 μV during the time-interval of interest. A series of simple lenses focused the light from the lamp on to the cornea, forming a roughly 110° Maxwellian view, and the flash energy was adjusted by interposing Wratten neutral density filters. In the rat, the effective flash energy was determined by observing the amplitude of the dark-adapted *b*-wave as a function of flash energy. The resulting curve of amplitude versus energy could then be compared with a calibrated curve previously described[2]. The effective flash energies are, therefore, given in terms of the number of quanta absorbed by the average rod per flash. This energy scale will be abbreviated to read 'quanta/rod'.

Oscilloscope traces of the ERG which exhibit the early response are shown in Fig. 1. Fig. 1*A* shows the ERG of a dark-adapted albino rat (Sprague–Dawley) for a flash with an effective energy of about $1{\cdot}5 \times 10^6$ quanta/rod. There are about 3×10^7 rhodopsin molecules/rod in the rat eye[2], so this flash bleached about 3–5 per cent of the visual pigment. The well-known *a*- and *b*-waves of the ERG are labelled in Fig. 1; at such high energies they have a somewhat unusual appearance. The new response can be seen at the start of the trace. The peak of this response occurs about 1 msec after the start of the flash, and most of the response is over before the *a*-wave begins to appear.

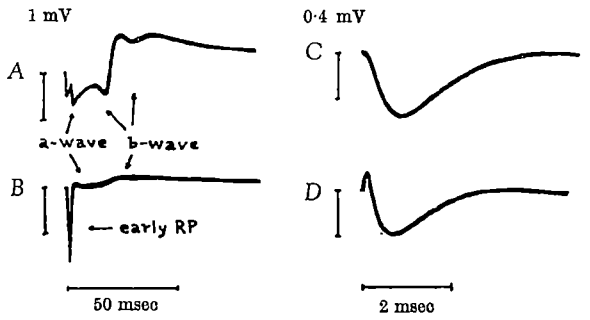

Fig. 1. ERG of the albino rat (*A*, *B*, and *C*), and frog (*D*). In (*A*), a flash with an effective energy of about $1{\cdot}5 \times 10^6$ quanta/rod was presented to the dark-adapted eye. One min later, in (*B*), a maximum energy flash was presented. In (*C*), after 1 more min, a second maximum energy flash was presented. This time the sweep speed and amplification were increased to show more clearly the time-course of the early *RP*. The same sequence of three flashes was presented to the excised eye of a frog, and the response to the third flash is shown in (*D*). Amplifier bandwidth: 0·8–10,000 c/s. Flash duration: 0·7 msec. White light presented in an approximately 110° Maxwellian view. Responses of positive polarity displayed as upward deflexions

Thus the time-course of this early ERG response is similar to that of the early intra-retinal response recorded by Brown and Murakami. In Fig. 1*B*, a flash with the maximum obtainable energy was presented. The eye was still quite light-adapted from the first flash, hence the *b*-wave was much reduced and the *a*-wave almost abolished. On the other hand, the amplitude of the early response considerably increased. This maximum energy flash probably bleached as much pigment as a short flash can bleach in the rat eye. According to recent work by Dowling and Hubbard, this is about 65 per cent of the pigment present[3]. In Fig. 1*C* a second maximum energy flash was then presented. Here, the sweep speed was increased to show more clearly the time-course of the early response. The amplification was also increased because the previous maximum energy flash reduced the amplitude of the early response. With higher sweep speeds the latency of the early response has been found to be definitely less than 60 μsec. The precise lower limit could not be determined with the present strobe lamp because the duration of its flash was much longer than this very short latent period. Even shorter latencies appear to occur in other animals. For example, Fig. 1*D* shows the ERG from an excised eye of a frog (*Rana pipiens*) for a maximum energy flash. Here, the large corneal negative component is preceded by a smaller corneal positive component. A similar wave-form has been observed in the ERG of the cat and the goldfish, and Brown and Murakami have found that the early receptor potential in the cynomolgus monkey has a bi-phasic wave-form (following communication). In every animal, the dominant phase of the early ERG response always has the same polarity as the *a*-wave. Therefore, both the time-course and polarity of the early ERG response are consistent with those of the early response recorded intra-retinally by Brown and Murakami. In the ERG experiments reported here, the early response has been observed in rat, goldfish and cat eyes for more than 3 h after the eyes were excised. This is in accord with the striking resistance to anoxia that Brown and Murakami report for the intra-retinal response[1]. Apparently, they did not detect the early response in the ERG because their maximum flash energy was too small to produce a detectable response. This might also explain why they did not detect the response in the cat or night monkey.

To summarize: the early ERG response is similar to the intra-retinal response recorded by Brown and Murakami because it has about the same very short latency and a similar time-course, its dominant phase has the same polarity as the *a*-wave, it can only be observed with very high flash energies, and it has the same striking resistance to anoxia. Moreover, the early ERG response has been observed in every animal so far investigated and, in particular, it has been observed in the essentially all-rod eye[4] of the rat. Since Brown and Wiesel[5] have already shown that the ERG reflects the same potential changes that are recorded intra-retinally in the local ERG, it is entirely reasonable to assume that the early ERG response is essentially equivalent to the early response described by Brown and Murakami. Accordingly, in the rest of this communication the early ERG response will be called the early *RP* (receptor potential), as suggested by Brown and Murakami[1]. From these results, then, it would appear that the early *RP* probably occurs in all vertebrate eyes, and that it is produced by rod as well as by cone retinæ.

Since the early *RP* has a latency shorter than 60 μsec, it seems clear that this response cannot be generated far from the pigment on which it depends. Consequently, if the early *RP* can be shown to depend on the visual pigment contained in the receptors, a strong argument, which is independent of microelectrode evidence, can be made for considering this response to be a receptor potential. Therefore, a number of critical experiments were performed in an attempt to make a positive identification of the pigment responsible for the early *RP*. In these experiments, the ERG of the albino rat was used because only one visual pigment need be considered, and a minimum number of other pigments are present.

The first experiment consisted of obtaining the approximate spectral sensitivity of the early *RP* by finding the flash energies needed to elicit equal amplitude responses at five different wave-lengths. For comparison, the spectral sensitivity of the dark-adapted *b*-wave was also obtained. Fig. 2 shows the results. The curve in Fig. 2 is redrawn from spectral sensitivity data on the dark-adapted *b*-wave obtained under somewhat better optical conditions by Dodt and Echte[6]. In the present experiment, the results were probably slightly distorted by the chromatic aberration of the simple lenses. Nevertheless, the data for the early *RP* match the curve well enough to indicate that the early *RP* probably depends on rhodopsin. Fortunately, this experiment could be arranged to make a comparison between the spectral sensitivities of the early *RP* and the *b*-wave with high precision. Such a comparison is inde-

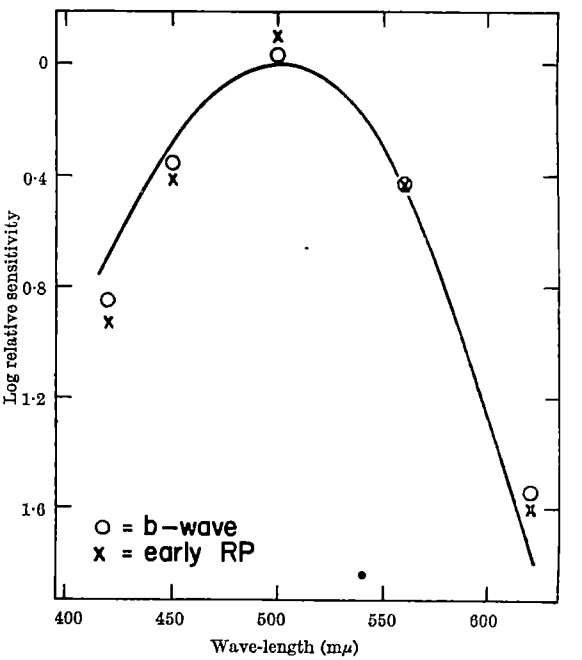

Fig. 2. Comparison of the spectral sensitivities of the early *RP* and the dark-adapted *b*-wave in the albino rat. The sensitivity is the reciprocal of the energy needed to produce a response of a given amplitude. The spectral width of the interference filters at 1/10 transmission was approximately ±6 mμ. Each point is the average of data obtained from four different rats. Data for the early *RP* were taken in a sequence which minimized the effects of pigment bleaching. The solid line is redrawn from data in Fig. 4 of ref. 6

pendent of chromatic aberrations, screening pigments, and changes in the absorption spectrum that occur when pigment is extracted. Furthermore, such a comparison becomes a quite rigorous test when applied to an eye that contains essentially only one visual pigment, such as the eye of the rat. In obtaining the data for Fig. 2, only the stacks of density filters had to be varied, and it is estimated that slight uncertainties in the calibrations of these filters (about $\pm 0{\cdot}7$ density unit for a total density of 6) introduced the limiting source of error. In Fig. 2 it can be seen that at each wave-length the separation between the points is never more than about 0·7 density unit. Thus, to within this experimental precision, these two ERG responses have identical spectral sensitivities. Therefore, the early *RP* in the rat almost certainly arises from the action of light on the visual pigment, rhodopsin.

The foregoing evidence does not necessarily imply that the rhodopsin responsible for the early *RP* is contained in the rods. For example, the early *RP* might be generated by rhodopsin located in the pigment epithelium. But Brown and Murakami have reported evidence which excludes the pigment epithelium as a possible source of the early *RP*[1]. Furthermore, Dowling[7] has shown that no rhodopsin is present in the pigment epithelium of the albino rat. Moreover, I have found that the early *RP* is easily observed in the excised retina of the rat (and also in the excised retina of the goldfish). Therefore, the sources of the early *RP* must reside in the retina, and most or all of the rhodopsin responsible for the early *RP* must be contained in the rod outer segments.

A number of other experiments may be performed on the early *RP* to verify further that it depends on the visual pigment. For example, since strong background light can drastically reduce the amount of visual pigment present in the retina, the amplitude of the early *RP* should be markedly reduced when a strong background light is present. This is, in fact, the case. The amplitude of the early *RP* in the ERG of the rat can be reduced to below the noise-level of the present experimental preparations by applying a sufficiently strong background light. When the background light is turned off, the early *RP* slowly recovers at a rate comparable to the rate of pigment regeneration. Results of another more quantitative experiment are shown in Fig. 1. Since Dowling and Hubbard have shown that a maximum energy flash bleaches about 65 per cent of the rhodopsin in the dark-adapted eye of the rat, the amplitude of the early *RP* for a succeeding flash should be reduced by at least a comparable amount. It can be seen in Figs. 1*B* and 1*C* that the amplitude for the second of two maximum energy flashes is, in fact, about 35 per cent as large as the amplitude for the first flash. This implies that, for a maximum energy flash, the amplitude of the early *RP* is probably linearly proportional to the fraction of pigment present in the eye.

This result suggested that the amplitude of the early *RP* might also be linearly proportional to the amount of pigment bleached by any flash. To check this, the amplitude of the early *RP* was obtained as a function of flash energy taking care to allow for losses of pigment caused by previous flashes. Fig. 3 shows the resulting data on a log log plot. The amplitude scale is labelled directly in millivolts; the flash-energy scale is given in log units of the beam energy, where log (flash energy) = 0 corresponds to the energy at which one quantum is absorbed by the average rod per flash. The light straight line in Fig. 3 has a slope of 1. This line fits the data to within the estimated experimental errors for the first 1·5 log units above threshold. Thus, in this range the amplitude of the early *RP* is linearly proportional to the flash energy. Evidently, the threshold for this linear response is determined by the experimental noise-level. At very high flash energies the amplitude does not increase linearly with flash energy, but this is to be expected because at these flash energies the fraction of pigment bleached by a flash is no longer a linear function of flash energy. Significantly, the shape or time-course of the early *RP* does not change with flash energy; only the amplitude changes.

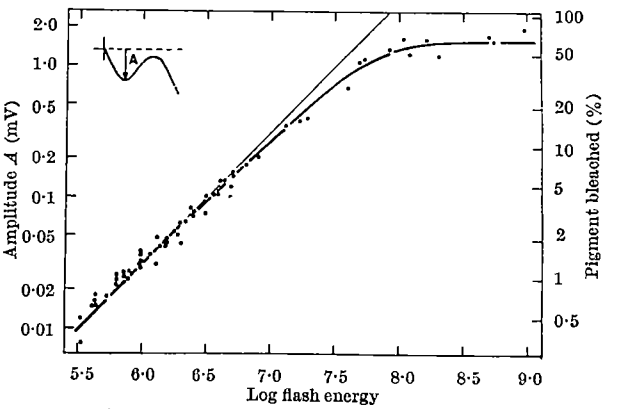

Fig. 3. Amplitude of the early *RP* in the albino rat as a function of flash energy on a log log plot. The flash energy is the energy of the stimulating beam, not the effective flash energy. However, it is calibrated by the method described in the text so that log (flash energy) = 0 is the beam energy at which one quantum is absorbed by the average rod/flash. The curved line shows the calculated fraction of pigment bleached. It is drawn relative to the theoretical scale of pigment bleached shown on the right. This scale is adjusted to make the fraction of pigment bleached by a maximum energy flash equal to 65 per cent. Because significant amounts of pigment must be bleached to obtain these data, in each experiment only five flashes were presented to the initially dark-adapted eye. Four of these flashes were in the range below log (flash energy) = 6·7, and together these four flashes bleached less than about 8 per cent of the pigment. The energy of the fifth flash was selected to obtain a good distribution of points in the high energy range. Thus each point above log (flash energy) = 6·7 was obtained in a separate experiment (15 experiments). Because the absolute amplitude of the response varies somewhat between preparations, the amplitudes of the responses to all five flashes were multiplied by a constant which made the four lowest points best fit the straight line drawn in the figure. All except the three highest-energy points were obtained with a small section of a ping-pong ball placed over the eye to provide uniform illumination of the entire retina[2]

The heavy line in Fig. 3 is a theoretical curve calculated by assuming that the amplitude of the early *RP* is proportional to the fraction of pigment bleached by the flash. The method used to obtain this curve is essentially the same as the method described in detail by Williams[8], who found that it satisfactorily accounts for the photoregeneration of pigment which occurs when intense flashes are applied to frog rhodopsin in solution. On a log log plot, neither the shape nor the slope of the theoretical curve can be altered, but the curve can slide along both axes until it best fits the data. As drawn in Fig. 3, the curve is within the experimental error of every point. Therefore, it appears reasonable to assume that over the entire flash energy-range examined the amplitude of the early *RP* is linearly proportional to the amount of rhodopsin bleached by a flash.

The theoretical scale of the fraction of pigment bleached, shown on the right side of Fig. 3, can be used to predict the number of rhodopsin molecules contained in a rod because the flash energy-scale is calibrated in terms of the number of quanta absorbed per rod. The predicted value depends on the quantum efficiency of bleaching[9], which is known to be between $\frac{1}{2}$ and 1. For this range of the quantum bleaching efficiency, the position of the theoretical scale implies that there are $4-8 \times 10^7$ rhodopsin molecules per rod in the rat eye. This result is in satisfactory agreement with an earlier value, 3×10^7 rhodopsin molecules per rod, obtained by a somewhat more direct method[2]. Therefore, the foregoing theoretical treatment not only adequately describes the amplitude dependence of the early *RP*, but also predicts satisfactorily the number of pigment molecules contained in a rod.

In summary, the foregoing experiments have shown that, in the essentially all-rod eye of the albino rat: (1) The early *RP* has the same spectral sensitivity as the dark-adapted *b*-wave. (2) The early *RP* is present in the excised retina. (3) For a maximum energy flash, the amplitude of the early *RP* is proportional to the rhodopsin present. (4) The amplitude of the early *RP* is linearly proportional to the rhodopsin bleached by a flash. Taken

together, these results provide strong evidence that the rhodopsin contained in the outer segments of the rods is the pigment responsible for the early *RP*. Therefore, on combining the foregoing results with those already reported by Brown and Murakami, it appears that a substantial case can be made for considering this early response to be a potential generated by the visual receptors. This new receptor potential can be expected to provide valuable information on the relation between the photochemical events in the outer segments and the later electrical potentials in the retina. Because the early *RP* appears to be so closely related to the visual pigment, it should provide a means for studying the earliest physicochemical stages of visual excitation, most of which have so far remained almost out of reach.

This work was supported by an Atomic Energy Commission contract with the University of Chicago. I wish to thank Mr. T. G. Ebrey for his assistance; Mr. W. K. Stell for providing goldfish eyes and excising their retinæ; Mr. I. Zucker for providing excised eyes of the cat; and Prof. John R. Platt for his advice.

Biphasic Form of the Early Receptor Potential of the Monkey Retina

FOLLOWING our initial report of the early *RP* (receptor potential) of the monkey retina[1], a detailed paper is being prepared. In response to *Nature's* invitation, however, it is a pleasure to make a few points which relate to Cone's observations recorded in the preceding communication. One point especially should be made at this time, since it seems important for establishing that the response which Cone finds in the ERG by conventional recording methods is the same response which we have detected by intra-retinal recording.

It has been noted that the early *RP* of the monkey retina is biphasic in form, as illustrated in record *A* of Fig. 1. Following the stimulus artefact, there is a small negative phase of the early *RP* which precedes the larger positive phase. The negative phase was not shown in our first report, and it became visible following reduction of the stimulus artefact. The positive phase of the early *RP* is followed by the positive *a*-wave, which is the leading edge of the late *RP*[1,2]. Records *A* and *B* were obtained under the same conditions, except for higher sweep speed in record *B*; this resolves the complex shape of the stimulus artefact, followed by the negative phase of the early *RP*. Record *C* was then obtained after removing the light stimulus from the eye, and record *D* was obtained with the stimulus over the eye but with the electrode withdrawn from the retina; hence these records show only stimulus artefacts. Since both procedures abolish the initial negative phase of the response, it cannot be an electric or photoelectric artefact. It is part of the retinal response to light and may, therefore, be considered as part of the early *RP*.

It was noted in our first report that the latency of the early *RP* did not exceed about 100 μsec[1]. This value was measured to onset of the positive phase of the response. Fig. 1 shows that the negative phase begins immediately at termination of the stimulus artefact, and the latency of the negative phase in record *B* was 45 μsec. Since the

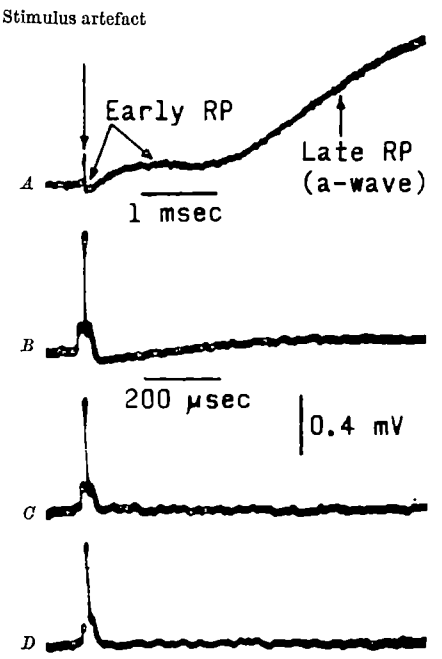

Fig. 1. Records showing the biphasic shape of the early *RP* when recorded by a tungsten micro-electrode in the fovea of the cynomolgus monkey at the retinal level of maximum response amplitude. Reference electrode in vitreous humour. Retinal circulation normal. Stimulus was 20 μsec flash produced by a condenser-discharge lamp (Grass photostimulator) and led to the eye by a fibre optics bundle[1]. Stimulus repeated every 10 sec. Signal amplification was condenser-coupled, with flat frequency response of 1·6–40,000 c/s. Positive signals displayed as upward deflexions. The voltage calibration is for all records; the upper time-scale is only for record *A*, and the lower time-scale is for records *B–D*. Record *A* shows the full time-course of the early *RP*, followed by the rising phase of the late *RP*. Record *B* shows the response under the same conditions but at higher sweep speed. In record *C* the electrode position was unchanged, but the fibre optics bundle was moved away from the eye. This shows only the electric artefact. In record *D* the stimulus was being delivered to the eye as in record *B*, but the electrode was pulled back into the vitreous humour. This procedure should abolish any retinal response, but should not abolish either electric or photoelectric artefacts. Since the initial negative phase of the response was abolished, it is a retinal response and may be considered as an initial phase of the early *RP*

negative response comes smoothly out of the positive stimulus artefact, it is evident that the true latency is less than this. In one experiment the artefact was considerably reduced, and latencies as short as 25 μsec were obtained. This is the shortest so far; but this is still a maximum value, and the artefact must be completely abolished before the true latency can be measured.

Since Cone's responses in the ERG are very similar to our intra-retinal records, in both form and time-course, it seems established that the same type of response is being recorded in the two cases. We have found that responses of small amplitude are more difficult to detect by conventional ERG recording than by intra-retinal recording; thus our failure to detect the early *RP* in the ERG is not surprising, since our intra-retinal signals have not exceeded about 200 μV. We agree with Cone's interpretation that his detection of the early *RP* in the ERG must be due to a more intense light stimulus. The fact that the early *RP* can now be recorded by both methods should prove of considerable value, since each recording method is well adapted to certain problems.

Comparison of Cone's records with ours shows that the early *RP* inverts polarity between the ERG and intra-retinal records. The late *RP* also shows a polarity inversion between the ERG and intra-retinal recording, and it has been shown that this is due to a radially oriented source and sink of the response which occur at different levels of the photoreceptor[2]. It therefore seems likely that the polarity inversion of the early *RP* has a similar basis. When stimulating intensities as high as that used by Cone are applied to intra-retinal recording, the greatly increased signal-levels may make it possible to investigate this problem.

When an electrode is withdrawn from the retina, starting from the retinal side of the pigment epithelium, both the negative and positive phases of the early *RP* increase in amplitude to a maximum which is distinctly removed from the pigment epithelium. Thus the negative phase of the early *RP*, like the positive phase, does not seem to be generated by the pigment epithelium but by the receptors. Since Cone has also observed the biphasic form of the early *RP* in excised retinæ, notably that of the goldfish, this conclusion seems well established. Detailed studies of the early *RP* as a function of electrode depth have now shown that the electrode depth of maximum response amplitude is the same for both the negative and positive phases of the early *RP*, as well as the positive response polarity of the late *RP*. Since all three responses may be plotted during a single electrode track, and since this experiment has been repeated many times, this finding seems secure. The absolute electrode depth of these maximum response amplitudes, however, is difficult to establish. Our initial observations indicated that the level of the photoreceptor at which this occurred was the connecting cilium[1]; but it now appears that the maximum response amplitudes are slightly more proximal, at the level of the inner segment. A hypothetical explanation of these findings has been developed and will be given in a more detailed paper.

Since the early *RP* has now been demonstrated in rods, as well as cones, it seems more likely that the early *RP* represents one of the links in the direct chain of excitatory events in vertebrate photoreceptors. Our comparisons between species indicate, however, that the early *RP* is more difficult to detect from rods than from cones[1]. It is also of interest that the initial phase of the biphasic early *RP*, which we have found larger in the pure cone fovea than in the peripheral retina of cynomolgus, has been noted by Cone only in animals which possess cones; this phase of the response was not found in the pure rod retina of the albino rat, although the response which was recorded had considerable amplitude. Hence these findings suggest that there may be both qualitative and quantitative differences between the early *RP*s of rods and cones; this requires further investigation.

The problems of how the early *RP* is generated, and its functional role in the photoreceptor, seem to be especially important. Cone's finding that the intervening photopigment is rhodopsin, in the rod case, excludes the possibility that the early *RP* may be dependent on some pigment of the photoreceptor other than the visual pigment (such as the chromatin of the cell soma, for example). Although such alternative possibilities seem remote, it remains to be proved that the initial phase of the biphasic early *RP*, in the cone case, is also dependent on the visual pigment. The latency of the second phase of the response is so short that it must be triggered by an isomerization of the photopigment, rather than by a bleaching reaction[1], and the latency of the initial phase is even shorter. In cynomolgus the early *RP* is undiminished 40 min after cessation of artificial respiration, and Cone has now found the response in eyes which have been excised as long as 3 h. It seems unlikely that a response with such high resistance to loss of blood supply, in the case of a mammalian photoreceptor, is due to an alteration of the resting potential of the outer membrane of the cell. This interpretation is also suggested by the fact that the late *RP* may be completely abolished, following cessation of artificial respiration, without affecting the early *RP*[1]. These observations are in agreement with our working hypothesis that the early *RP* is due to activity in the intracellular fibrils of the photoreceptor[1], but do not uniquely support this hypothesis. We have also suggested, on the basis of several striking similarities, that the early *RP* and the cochlear microphonic may be generated in fundamentally the same manner, although triggered by different adequate stimuli. The outer segment of the vertebrate photoreceptor is differentiated from a cilium, the primitive features of which are maintained at the connexion between inner and outer segments[3]; thus the early *RP* and cochlear microphonic may represent a specialized response mechanism of ciliated receptors. Cone's finding that the early *RP* is linearly proportional to light intensity, up to a limit, is of interest in this regard because "The cochlear microphonic is linearly proportional, up to a limit, to the displacement of the cochlear partition . . ." (ref. 3). Hence linearity of response amplitude with stimulus intensity provides a similarity, in addition to those already listed[1], between the early *RP* and the cochlear microphonic.

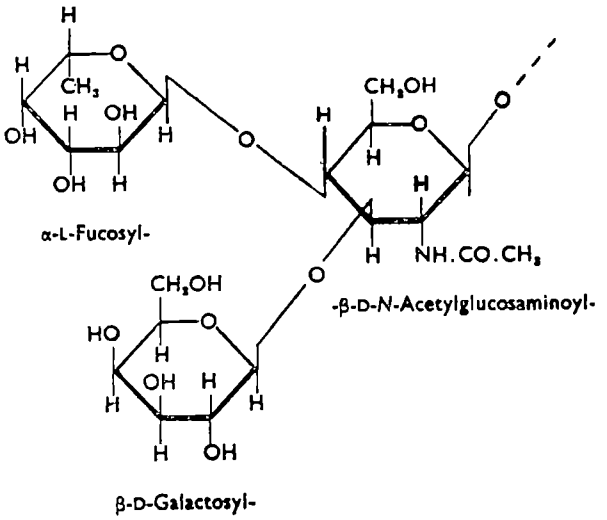
ISOLATION OF A SEROLOGICALLY ACTIVE, FUCOSE-CONTAINING, TRISACCHARIDE FROM HUMAN BLOOD-GROUP Le^a SUBSTANCE

By VAIJAYANTI P. REGE, T. J. PAINTER, WINIFRED M. WATKINS and Prof. W. T. J. MORGAN, C.B.E., F.R.S.

Lister Institute of Preventive Medicine, London, S.W.1



THE first clue to the nature of at least one important component of the Le^a group specific determinant structure was obtained when the inactivation of Le^a substance by an enzyme in *T. foetus* was specifically inhibited by L-fucose[1], one of four sugar components of the carbohydrate chains in the Le^a substance[2]. This result suggested that oligosaccharides containing L-fucose should be examined for their capacity to inhibit the agglutination of Le(a+) red-cells by human anti-Le^a serum, and a number of fucose-containing oligosaccharides, mostly of known structure, were investigated[1]. Of many compounds examined, only two, lacto-*N*-fucopentaose II (ref. 3) and lacto-*N*-difucohexaose II (ref. 4), were active.

α-Fuc
↓ (1→4)
β-Gal-(1→3)-β-GNAc-(1→3)-β-Gal-(1→4)-Glu
Lacto-*N*-fucopentaose II

α-Fuc α-Fuc
↓ (1→4) ↓ (1→3)
β-Gal-(1→3)-β-GNAc-(1→3)-β-Gal-(1→4)-Glu
Lacto-*N*-difucohexaose II

Abbreviations: Fuc = L-fucopyranosyl; Glu = D-glucose; Gal = D-galactopyranosyl; GNAc = *N*-acetyl-D-glucosaminopyranosyl.

Both compounds contained the branched trisaccharide structure:

which was not present in any of the other substances tested. On the basis of the inhibition results it was proposed that this trisaccharide was identical with, or closely related to, the specific determinant structure in the Le^a substance in human secretions. Additional evidence that a non-reducing L-fucose residue was joined at position 4 to *N*-acetyl-D-glucosamine in the Le^a determinant structure was obtained by studies of the specificity requirements of enzymes that destroy the activity of Le^a substance[5]. Thus, one such enzyme removed fucose from lacto-*N*-fucopentaose II, but not from oligosaccharides such as lacto-*N*-fucopentaose I (ref. 6) which contain an α-L-fucosyl residue glycosidically joined at position 2 to galactose.

Although four di- and three tri-saccharides were isolated from the partial acid-hydrolysis products of Le^a substance[7], none of these contained fucose and none was serologically active in the Le^a system. On the basis of the isolated oligosaccharides, however, it was proposed that Le^a substance contains two main types of carbohydrate chain:

(1) β-Gal-(1→3)-β-GNAc-(1→3)-β-Gal-(1→3)-GalNAc-
(2) β-Gal-(1→4)-β-GNAc-(1→3)-β-Gal-(1→3)-GalNAc-

Abbreviations: GalNAc = *N*-acetyl-D-galactosamine. Others, as given before.

The fucose residues were believed to be attached as branching units to these main chains. Evidence for the point of attachment of the fucose residues is difficult to obtain from a study of the partial acid-hydrolysis products owing to the acid-lability of the fucosidic linkages in the blood-group substances. Earlier results, and the isolation of fucose-containing oligosaccharides from *H* substance[8], showed, however, that this evidence is obtainable for the structures occurring at the non-reducing ends of the carbohydrate chains by examining the products of mild alkaline degradation, a procedure that does not readily eliminate fucose from these units. Several years ago, Dr. J. Thomas, at the Lister Institute, isolated from Le^a substance, by alkaline degradation, an Le^a-active trisaccharide that contained fucose, galactose and *N*-acetylglucosamine, but the exact structure of the compound was not determined[9]. The isolation and identification of this active trisaccharide from Le^a substance are now described.

The specific Le^a substance was isolated from a single ovarian cyst fluid[2]. It was treated with hot aqueous methanolic triethylamine, as already described for *H* substance[8], and from 4 g of substance, 2·4 g of dialysable products were obtained. This material was treated in aqueous solution with a mixture (40 ml.; 1 : 1 v/v) of 'Amberlite *IR*-120' (H^+ form) and '*IR*-45' (carbonate form) resins, to remove amino-acids and acidic degradation-products of sugars. The residual material (1·63 g) was adsorbed on a column (17 cm × 3 cm) of charcoal-'Celite' (1 : 1 w/w), and the column was eluted successively with water (5 l.) and aqueous ethanol (5 l. of 1·5 per cent v/v; 3 l. of 2·5 per cent v/v; 7 l. of 5 per cent v/v; 7 l. of 7·5 per cent v/v; 8 l. of 10 per cent v/v; and 9 l. of 15 per cent v/v).

The 5 per cent aqueous ethanolic effluent contained 160 mg of carbohydrate material which, after fractionation on paper chromatograms irrigated with ethyl acetate-pyridine-water (10 : 4 : 3 v/v; solvent *a*), afforded 24 mg of crystalline 4-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine (*N*-acetyl-lactosamine).

The 15 per cent aqueous ethanolic effluent from the column yielded 155 mg of material which contained a component (I) having $R_{lactose} = 0{\cdot}68$ in solvent (*a*) and $M_G = 0{\cdot}22$ in borate buffer at *p*H 10 (ref. 10). After separation on a paper chromatogram and further purification on a small column (3 cm × 1 cm) of charcoal-'Celite' (1 : 1 w/w), about 10 mg of (I) was obtained as a chromatographically and ionophoretically homogeneous syrup, having $[\alpha]_D^{22} = -44° \pm 3°$ ($c = 0{\cdot}3$ in water). This compound (I) gave a negative indirect Ehrlich reaction[11], and reacted rather feebly on paper with silver nitrate-sodium hydroxide reagents[12]. With the benzidine-trichloroacetic acid reagent[13], (I) developed a dark greenish-brown colour similar to that given[14] by 3-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine (lacto-*N*-biose-I)[15].

Chromatography of an acid-hydrolysate of (I) indicated the presence of galactose, fucose and glucosamine, and quantitative analysis[16-18] showed that these sugars were present in approximately equimolar amounts. However, after reduction of (I) with sodium borohydride, its hexosamine content was negligible, whereas the amount of galactose and fucose present was unchanged.

On partial hydrolysis in 0·2-N acetic acid at 85° for 4 h. the trisaccharide (I) yielded free fucose together with a disaccharide which was chromatographically and ionophoretically indistinguishable from lacto-*N*-biose-I. This disaccharide also resembled lacto-*N*-biose-I in giving a strong indirect Ehrlich reaction and a greenish-brown colour with the benzidine-trichloroacetic acid reagent; on alkaline degradation it yielded galactose and free chromogen[15]. Further hydrolysis of the disaccharide (in 0·02 *N*-polystyrene-sulphonic acid[19] at 86°) resulted in the gradual liberation of galactose and *N*-acetylglucosamine.

Oxidation of (I) (0·45 mg) in 0·01 M sodium meta-periodate (2·5 ml.) at 22° led to the consumption of 4·18 mol. of oxidant within 4 h, with the concomitant liberation of 1·98 mol. of formic acid and 0·23 mol. of formaldehyde. Oxidation under the same conditions after borohydride reduction[20] resulted in the uptake of 5·12 moles of periodate within 4 h, with liberation of 0·95 mole of formaldehyde; there was no over-oxidation.

On the basis of this evidence trisaccharide (I) is 3-*O*-β-D-galactopyranosyl-4-*O*-α-L-fucopyranosyl-*N*-acetyl-D-glucosamine, and is, therefore, identical with the structure proposed earlier for the specific determinant in Le^a substance.

From what is known at present about the alkaline degradation of polysaccharides, it appears that, in the absence of residues of uronic acids and sugars containing free keto-groups, degradation always proceeds in a stepwise manner from the reducing end of the chain[21]. Trisaccharide (I) and the *N*-acetyl-lactosamine isolated in the present work should, therefore, represent structures occurring at the non-reducing ends of the carbohydrate chains in Le^a substance. This agrees well with the results of earlier work on the partial acid-hydrolysis products of Le^a substance, on the basis of which the structures (1) and (2) were assigned to the main carbohydrate chains[7]. The structure of trisaccharide (I) indicates that at least some

of the chains of type (1) in the native Le^a substance carry an α-L-fucopyranosyl unit attached as a side-chain to position 4 of the *N*-acetyl-D-glucosamine residue. Similarly, the presence of free *N*-acetyl-lactosamine in the alkaline degradation products implies that at least some of the chains of type (2) do not carry fucose residues attached either to the non-reducing terminal D-galactose residue or to the penultimate *N*-acetyl-D-glucosamine residue. The *N*-acetyl-lactosamine structure is believed to be responsible for the cross-reactivity of the blood-group substances with horse anti-Type XIV pneumococcus serum[22] and, therefore, its occurrence as an unsubstituted non-reducing end unit in Le^a substance is in agreement with the comparatively strong Type XIV cross-reactivity usually observed for undegraded Le^a preparations.

The results in Table 1 show that trisaccharide (I) strongly inhibits the agglutination of Le^a erythrocytes by a human anti-Le^a serum, to a degree only slightly less than that of lacto-*N*-fucopentaose II. This lower inhibitory power may indicate that more than the terminal trisaccharide unit of the main chain of the Le^a determinant structure participates in the antigen-antibody binding reaction. The trisaccharide did not inhibit the agglutination of *O* cells by anti-*H* reagents.

Table 1. Inhibition of Agglutination of Le(a+) Red Cells by Human Anti-Le^a Serum with Fucose-containing Compounds

Inhibiting substances	Minimum amount (μg/0·1 ml.) of substace giving complete inhibition
Human Le^a substance	0·05
L-Fucose	> 1,000
Lacto-*N*-fucopentaose I	> 1,000
Lacto-*N*-fucopentaose II	1
Lacto-*N*-difucohexaose II	2
Trisaccharide (I) isolated from Le^a substance	2

The alkaline degradation products of Le^a substance also contained other oligosaccharides which have not yet been identified. Some of them had fucose residues, and were larger than trisaccharides; it is possible, therefore, that some of the carbohydrate chains in Le^a substance carry additional fucose residues, attached at positions more distant from the non-reducing ends. We were, however, unable to detect either of the *H*-active oligosaccharides, 2-*O*-α-L-fucopyranosyl-D-galactose and *O*-α-L-fucopyranosyl-(1→2)-*O*-β-D-galactopyranosyl-(1→4)-*N*-acetyl-D-glucosamine that were obtained earlier[8] by alkaline degradation of *H* substance. The present work thus provides the first direct chemical evidence for a structural difference between human *H* and Le^a blood-group substances, and confirms the suggestions made earlier[1,5,23] regarding the probable nature of this difference.

This work was supported in part by a grant from the Medical Research Council, to whom we express our thanks.

PHOSPHOGLUCOMUTASE POLYMORPHISM IN MAN

By Dr. N. SPENCER, D. A. HOPKINSON and Prof. HARRY HARRIS

Department of Biochemistry and Medical Research Council Human Biochemical Genetics Research Unit, King's College, London, W.C.2

PHOSPHOGLUCOMUTASE (PGM) is widely distributed in mammalian tissues[1] and plays an important part in carbohydrate metabolism. It is a phosphotransferase (*EC* No. 2.7.5.1) which catalyses the transfer of a phosphate group between the 1- and 6-positions of glucose[2]. In the present article we report a procedure for the detection of the enzyme following starch-gel electrophoresis, and describe the results obtained using human red cell lysates and tissue extracts from different individuals. Several distinct PGM isoenzymes appear to occur in each individual, and clear-cut differences between individuals are also observed. These differences have been shown to be genetically determined and they represent a new human polymorphism.

Horizontal starch-gel electrophoresis using paper inserts (Whatman No. 3) was carried out at 5·5 V/cm for 17 h at +5° C and *p*H 7·4 (bridge buffer: 0·1 M *tris*, 0·1 M maleic acid, 0·01 M EDTA, and 0·01 M $MgCl_2$ adjusted to *p*H 7·4 with NaOH; gel buffer: 1 in 10 dilution of bridge buffer with water). The gel was sliced and then incubated at 37° C for 1 h in a reaction mixture consisting of $4{\cdot}6 \times 10^{-3}$ M glucose-1-phosphate (G1P), about 5×10^{-5} M glucose-1,6-diphosphate (G1,6diP), 10^{-2} M $MgCl_2$, $1{\cdot}2 \times 10^{-4}$ M NADP, about 0·04 unit/ml. glucose-6-phosphate dehydrogenase (G6PD), 0·1 mg/ml. phenazine methosulphate (PMS), 0·1 mg/ml. tetrazolium salt MTT (ref. 3), made up in 0·03 M *tris* buffer *p*H 8·0. This reaction mixture was designed to localize PGM according to the reaction sequence shown in Fig. 1. In the presence of G1P and small amounts of G1,6diP, G6P is formed. This is converted to 6-phosphogluconate (6PG) by G6PD with the concomitant reduction of NADP. The reduced NADP in the presence of PMS, which is thought to act as an electron carrier[4], causes the reduction of MTT to give a blue-coloured insoluble formazan which is deposited at the site of PGM activity.

G1,6diP, a critical ingredient of the reaction mixture, could not be obtained commercially. However, it was found to be present in sufficient amounts as an impurity in some but not all commercial preparations of G1P. It was determined in the various G1P preparations by two different methods. The first method (*A*) involved the enzymatic assay[2] of G6P formed from G1,6diP by brief acid hydrolysis. The G1P sample (10–100 μmoles) was hydrolysed in 0·5 ml. N sulphuric acid for 10 min at 100° C, cooled and then neutralized with 0·5 ml. N sodium hydroxide. To this was added 1·8 ml. 0·19 M *tris* buffer *p*H 8·0, 0·2 ml. 4×10^{-3} M NADP, and 1 unit G6PD (free

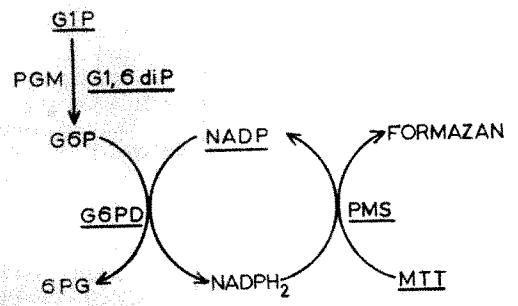

Fig. 1. Sequence of reactions for detection of PGM following starch-gel electrophoresis. The underlined components are contained in the reaction mixture applied to the gel

of 6PG dehydrogenase). The reaction was followed spectrophotometrically at 340 mμ, and the quantity of G6P present estimated from the maximal change in optical density produced by the addition of the enzyme. Correction for any free G6P present in the original G1P sample was made by carrying out a duplicate determination using the unhydrolysed G1P preparation. The second method (*B*) involved the separation of G1,6diP from G1P on an ion-exchange resin[5]. 45 mg of the G1P preparation was applied to a column (17·5 × 0·85 cm) of 'Deacidite *FF*' (2–3 per cent cross-linked) in the formate form. It was eluted with a linear gradient of ammonium formate (mixing flask contained 500 ml. water and donor flask 500 ml. 2 M ammonium formate) at a flow-rate of 20 ml./h; 10 ml. fractions were collected and analysed for total and acid labile phosphate[6]. G1P was eluted at about fractions 16–18, and G1,6diP at about fractions 28–32. Estimates obtained by the two methods of G1,6diP in various commercial preparations of G1P are given in Table 1. Those marked with an asterisk were found to be adequate for the present purpose. The presence of G1,6diP in the various preparations was also confirmed qualitatively by high-voltage filter paper electrophoresis. In general, the results obtained by the various methods were in good agreement.

* Found to be satisfactory for detection and typing of human PGM in the conditions described.
† Obtained from Calbiochem.

When human red cell lysates, prepared either by brief sonication or by freezing and thawing washed red cells, are subjected to the procedure outlined above, at least seven zones of what appear to be PGM activity can be detected. Furthermore, hæmolysates from different individuals can be classified into three distinct types according to the pattern of zones present. These three types, which will be referred to as PGM 1, PGM 2 and PGM 2–1, are shown in Fig. 2. Zones *a* and *c* are present in type 1 and type 2–1 but absent in type 2. Zones *b* and *d* are present in type 2 and type 2–1 but absent in type 1. Zones *e*, *f* and *g* are present in all the types. The pattern of PGM zones observed in type 2–1 appears to include all the components present in both type 1 and type 2, and indeed it was found possible to obtain essentially the same 2–1 pattern by subjecting to electrophoresis an artificial mixture of approximately equal amounts of hæmolysates of type 1 and type 2. In some experiments, one or two rather weak zones with mobility slightly faster than zone *d* were observed in type 1 hæmolysates and it is possible, therefore, that the patterns may be more complex.

Evidence that the zones *a*–*g* shown in Fig. 2 do, indeed, represent PGM activity may be summarized as follows:

(1) If G1P is omitted from the reaction mixture, none of the zones develops.

(2) If G1,6diP is omitted from the reaction mixture, the zones appear only very slowly and are extremely weak. Reaction mixtures without G1,6diP were obtained either by using G1P which had been separated from G1,6diP on an ion-exchange column, or by using one of the preparations of G1P in which no G1,6diP could be detected. If to such a reaction mixture small quantities of G1,6diP are added, full development of the zones is obtained. The requirement for G1,6diP was found to be about 5×10^{-5} M.

(3) If G6PD is omitted from the reaction mixture, only zones *e* and *f* appear. This was found to be due to endogenous G6PD present in the hæmolysate, which migrates in this system as a diffuse zone overlapping zones *e* and *f*.

(4) If NADP or PMS is omitted from the reaction mixture, no zones develop.

(5) It has been shown that PGM activity can be considerably enhanced by Mg^{++} and imidazole or other metal binding agents[7]. In the work recorded here it was found that the inclusion of Mg^{++} and imidazole in the gel resulted in enhancement of the rate of development and intensity of the zones and that an even more striking effect was obtained by the inclusion of Mg^{++} and EDTA.

(6) PGM has been crystallized from rabbit muscle[8]. The procedure described here could therefore be critically tested by a comparison of the results obtained with a crude rabbit muscle extract and a crystalline preparation of purified rabbit muscle PGM. Rabbit muscle was homogenized in an equal volume of water and the supernatant

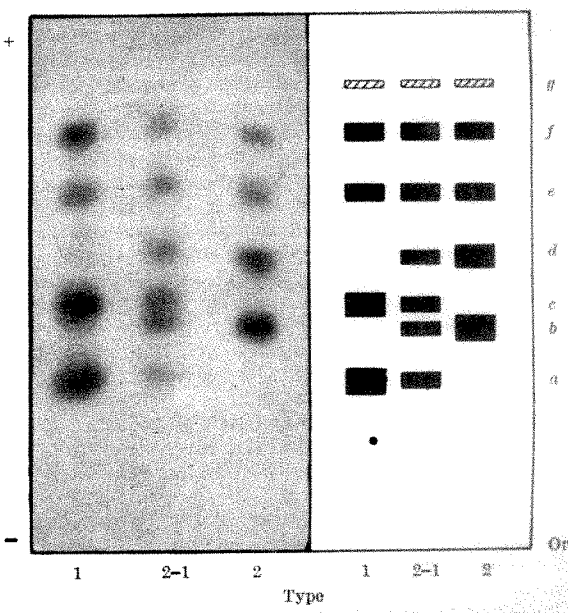

Fig. 2. Photograph and diagram of starch-gel showing components observed in hæmolysates from individuals of PGM types 1, 2–1 and 2

obtained after centrifugation diluted 1 in 50 with gel buffer. This was subjected to starch gel electrophoresis under the foregoing conditions side by side with a suitably diluted solution (about 0·04 mg/ml.) made from a crystalline rabbit muscle PGM preparation obtained commercially. Identical patterns of activity were observed (Fig. 3). There were at least three main zones, the most cathodal having the greatest intensity and the most anodal being much weaker than the others. The three zones had the same mobilities in the two preparations, and were different from those obtained with human material. Quite intense zones were observed with as little as 2γ of the crystalline preparation. Two other crystalline PGM preparations obtained commercially were also examined with the same result.

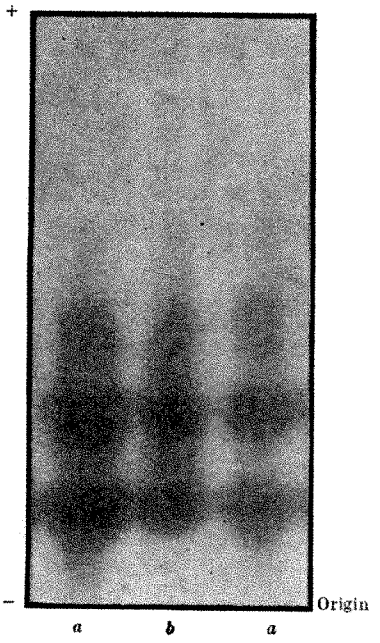

Fig. 3. Electrophoretic patterns of rabbit muscle PGM. (*a*) Solution of crystalline enzyme preparation; (*b*) crude aqueous muscle extract

The multiple zones of activity observed in the human red cell lysates could readily be demonstrated in aqueous extracts of a variety of other tissues. These included leucocytes, liver, kidney, muscle from heart and uterus, brain, skin and placenta. Except for the leucocytes and placenta, the tissue fragments were obtained either at post-mortem or by biopsy. The leucocytes were disrupted by sonication. The other tissues were homogenized in an equal volume of water. All the zones of activity (*a–g*) observed in the hæmolysates were found in the various tissue extracts. Furthermore, the different types of pattern could clearly be identified and, in general, all the tissues examined from any one individual showed the same type. In the case of the placenta, the type observed was in every instance the same as that found in the cord blood, and this was not necessarily the same as that of the mother. In some of the tissue extracts one or more weak zones migrating more rapidly than zone *g* were also observed, but these have not yet been characterized in detail. In general, in all the tissue extracts examined, the degree of activity of the zones was such as to exclude the possibility that they were derived from residual red cells in the tissues.

The characteristic PGM patterns were also demonstrated in extracts of human cells grown in tissue culture. The tissue cultures were established by Dr. M. Glen-Bott and Dr. R. G. Davidson from small skin biopsies. They were maintained in a medium made up of Eagle's[9] minimal essential medium 75 per cent, beef embryo extract ultrafiltrate 5 per cent, and human AB serum 20 per cent. The first passage was generally made after 3–5 weeks, and subsequent passages every 5–14 days when the Petri dishes (6 or 10 cm) were fully sheeted. At varying periods (up to 14 weeks and 10 passages) cells were gathered, washed and disrupted by sonication. The supernatant was subjected to electrophoresis under the standard conditions. A confluent single layer of cells from a small Petri dish (6 cm diameter) gave adequate amounts of material. All the zones observed in the hæmolysates were demonstrable in the tissue culture cell extracts, and the characteristic types were readily identified. In each instance the type of pattern (1, 2–1 or 2) observed in a particular tissue culture preparation corresponded to that found in hæmolysates from the donor whose skin had been used to start the culture.

These findings, and also the observation that repeated blood samples from single individuals over a period of several months were always of the same type, make it clear that the three types represent individual characteristics. The results with placental extracts and with cord bloods indicate that these characteristics are fully developed at birth.

Table 2. Incidence of Different PGM Phenotypes in 338 Unrelated English Adults

PGM phenotype	Males	Females	Totals	Frequency
1	98	88	186	0·550
2–1	65	62	127	0·376
2	19	6	25	0·074
Totals	182	156	338	1·000

Table 2 shows the numbers of each of the types found in 338 unrelated English adults. Table 3 summarizes the results obtained in 80 families in which both parents and at least one child were typed for PGM, and in 53 families in which only one of the parents was available for examination. The familial distribution is clearly non-random and there seems little doubt that the three PGM types are genetically determined. The results can most simply be explained if we suppose that the three types are determined by two autosomal allelic genes PGM^1 and PGM^2, such that homozygotes PGM^1 PGM^1 and PGM^2 PGM^2 are of type 1 and type 2, respectively, while type 2–1 represents the heterozygote PGM^1 PGM^2. All the 262 children in the 133 families shown in Table 3 are of PGM types predicted by the hypothesis, and the segregation ratios are consistent with Mendelian expectations.

Table 3. Distribution of PGM Phenotypes in 133 Families

Type of mating	No. of families	Children 1	2–1	2	Total
1 × 1	30	58	—	—	58
1 × 2–1	26	25	25	—	50
1 × 2	6	—	12	—	12
2–1 × 2–1	12	6	6	8	20
2–1 × 2	4	—	3	7	10
2 × 2	2	—	—	3	3
1 × ?	35	57	12	—	69
2–1 × ?	15	9	20	4	33
2 × ?	3	—	4	3	7
Totals	133	155	82	25	262

Estimates of the gene frequencies p and q of the postulated genes PGM^1 and PGM^2 may be obtained by counting from the population data given in Table 2. The values are $p = 0{\cdot}74$ and $q = 0{\cdot}26$. These estimates may be used to see whether the observed frequencies of the three types in the general population fit the Hardy–Weinberg expectation. The calculation is given in Table 4, and it is apparent that there is good agreement between the observed numbers of the three types in the population sample and the numbers expected assuming random mating and negligible selection.

If the hypothesis is correct, then one must suppose that the components *a* and *c* are determined by PGM^1 and that they are molecular alternatives of components *b* and *d* determined by PGM^2. Presumably a 'structural'

Table 4. EXPECTED AND OBSERVED NUMBERS OF DIFFERENT PGM PHENOTYPES TAKING GENE FREQUENCIES p, 0·74, q, 0·26

PGM genotype	PGM phenotype	Expected frequency		Expected numbers in population sample	Observed numbers in population sample
$PGM^1\ PGM^1$	1	p^2	0·548	185	186
$PGM^1\ PGM^2$	2–1	$2pq$	0·385	130	127
$PGM^2\ PGM^2$	2	q^2	0·068	23	25

locus is involved here, and it is of interest that it apparently does not affect, and may therefore not be concerned in, the determination of components *e*, *f* and *g*. Further elucidation of the molecular interrelationships of these components may be expected to emerge from structural and related investigations. Such investigations will also be of relevance in clarifying the relationship of the phospho- and dephospho-forms[2] of the enzyme to the various components described here.

Apart from the immediate biochemical problems posed by these findings, it is apparent that they will also be of interest for a variety of genetical investigations. In particular, the PGM polymorphism should prove a valuable new genetical marker in population and linkage investigations, and also in human cell genetics.

We thank Dr. J. W. Landells for providing post-mortem material, and Dr. Mary Glen-Bott for her help with the family investigations. Crystalline PGM preparations were obtained from C. F. Boehringer and Soehne and from Sigma Chemical Co. G6PD was obtained from C. F. Boehringer and Soehne, and from L. Light and Co., Ltd.

STRUCTURE OF THE ALVEOLAR LINING FILM OF THE LUNGS

By PROF. JANUSZ GRONIOWSKI and MRS. WIESLAWA BICZYSKOWA
Pathological Anatomy Department, Medical Academy, Warsaw, and Pathological Anatomy Department, Medical Academy, Poznań, Poland

IT has been shown[1] that the alveoli of the lungs are lined with a film formed from a substance of high molecular weight, which lowers the tension of alveolar surface. The alveolar lining film and its surface-active properties have recently been reviewed by Pattle[2]. In human pathology the importance of the lining film is shown in the respiratory distress syndrome of new-borns[3].

For detection of a lining film only indirect physical methods are used[2]. The surface-active material is not detectable in light microscopy, since there is not enough of it to detect histologically. Using the freezing and drying procedure and electron-microscope technique, Chase[4] described a homogeneous surface membrane instead of epithelial lining and postulated the non-cellular nature of the pulmonary alveolar lining. However, so far as we know, until now the alveolar lining film was not visualized directly in the electron microscope image as a separate layer on the epithelial surface.

In work recorded here we have tried to obtain some evidence of the existence of alveolar lining film by means of electron-microscope technique.

The lungs of three rabbits, 6 months to 2 years of age, were examined. The tissue samples taken from living animals were immersed in 0·5 per cent potassium permanganate buffered to *p*H 7·4 in veronal acetate buffer. The samples were fixed for 2 h at 4° C. The dehydration was effected by passing through a series of ethanol solutions of increasing strength (25 per cent, 15 min; 35 per cent, 15 min; 50 per cent, 15 min; 60 per cent, 15 min; 70 per cent, 15 min; 80 per cent, 15 min; 90 per cent, 15 min; 96 per cent, 30 min; 100 per cent, 30 min; 100 per cent, 2 h; 100 per cent, 30 min). Except for the last change, done in room temperature, the dehydration was performed at 4° C. For embedding, 'Araldite *D*' (Ciba) with hardener '964 *B*', dibutyl phthalate and accelerator '964 *C*' were used. Three mixtures were prepared as follows: I, 'Araldite' 15·0, hardener 5·0, dibutyl phthalate 0·5; II, 'Araldite' 10·0, hardener 10·0, dibutyl phthalate 0·5; III, 'Araldite' 10·0, hardener 10·0, dibutyl phthalate 0·5, accelerator 0·5. After dehydration the samples were transferred from absolute ethanol to a 50 : 50 absolute ethanol with the first 'Araldite' mixture (I) for 10 h at 48° C. It was followed by three changes (24 h each) in the first 'Araldite' mixture (I) at 48° C, then by three changes (24 h each) in the second 'Araldite' mixture (II) at 48° C, and finally in the third 'Araldite' mixture (III) at room temperature (24 h). The samples transferred to gelatin capsules condensed at 58° C. Also used for fixing was 1·0 per cent osmium tetroxide in veronal buffer (*p*H 7·4) containing sucrose, while for embedding a mixture of methylmethacrylate and *n*-butylmethacrylate was used.

The ultra-thin sections revealed the well-known pattern of the air-blood barrier consisting of epithelial lining, basement membrane complex and endothelial lining. In sections derived from tissue blocks fixed in potassium permanganate and embedded in 'Araldite' the plasma membrane of epithelial cell of alveoli frequently was closely attached by an irregular layer of diffuse material (Fig. 1). It consisted of more-or-less compact granules facing the lumen of the alveoli. The alveolar side of the layer has no sharp border. However, sometimes it showed a membranous appearance. The thickness of the layer varies greatly: usually it was about 200 Å, but it has reached more than 1000 Å. The discontinuity of the layer was rather a constant event. Often some remnants of the layer were situated more or less perpendicular to the plasma membrane of epithelial cells. The last event, as well as the aforementioned discontinuity of the layer, seems to be artefact. More compact granular material was observed filling some infoldings between the cells of alveolar lining. In the cytoplasm of the epithelial lining, no lamellar inclusions[5] were discerned: instead, some globular agglomerations of granules were observed. The granules were arranged in arrows concentrically or randomly distributed in rather compact clumps. The aforementioned structures showed some resemblances to inclusions described by Campiche[6].

The results presented here were observed in each of the animals examined. The detection of the material, forming here and there a distinct layer on the surface of epithelial lining, was possible only in tissues fixed in potassium permanganate and embedded in 'Araldite'. It seems quite possible that the granular layer on the surface of alveoli described here corresponds in some way to the alveolar lining film as revealed by indirect physical methods. Perhaps the observed granules correspond to a macromolecular component of the surface-tension lowering substance. It should be emphasized that there is some similarity between the granules of the layer attached to the epithelial lining and those observed in

globular structures in epithelial cytoplasm. This suggests some relationship between both structures.

In a further examination of the electron-microscope evidence of the alveolar lining film we have used an adaptation of Mowry's modification of the Hale staining method to electron microscopy, as described recently by Gasic and Berwick[7]. The lungs of five healthy rabbits, aged between 2 weeks and 1 year, were examined. Fresh tissue samples taken from peripheral parts of the lungs were fixed overnight at room temperature in 10 per cent neutral phosphate-buffered formalin. After washing with water, the samples were rinsed in 12 per cent acetic acid, exposed to Müller's colloidal iron solution (*p*H 1·3) for 60 min, rinsed in 12 per cent acetic acid, treated for 20 min in a mixture of 2 per cent hydrochloric acid and 2 per cent potassium ferrocyanide, and finally rinsed in distilled water. Tissue samples which were treated in the same way, except for exposure to colloidal iron, were used as a control. In addition, samples, taken from each lung, were fixed in 1·0 per cent osmium tetroxide in veronal buffer containing sucrose. Methacrylate embedding was used.

In ultra-thin sections the Hale-positive material consists of electron-opaque ferric ferrocyanide crystalline aggregates or coarse mass with no structural details. The Hale-positive material appears as a continuous surface coat of the alveoli, closely attached to the epithelial lining (Figs. 2 and 3), including the alveolar side of the so-called 'granular' or dust cells as well (Fig. 4). Even the microvilli were covered by the Hale-positive material. Some detachment of the opaque layer of the alveoli was only infrequently observed and was interpreted as an artefact. The thickness of the layer varied; usually it was about 300 Å. In the work described here no ultra-structural component belonging to the air-blood barrier, or other structural forms observed, revealed any distinct amount of the Hale-positive material.

The method used gives a good assessment of the existence of lining film by means of the electron-microscope technique. As regards the chemical composition of the lining film, however, the data presented have to be interpreted rather carefully. There is evidence to show that the surface active substance of the alveolar lining is a lipoprotein[8]. The positive Hale reaction, however,

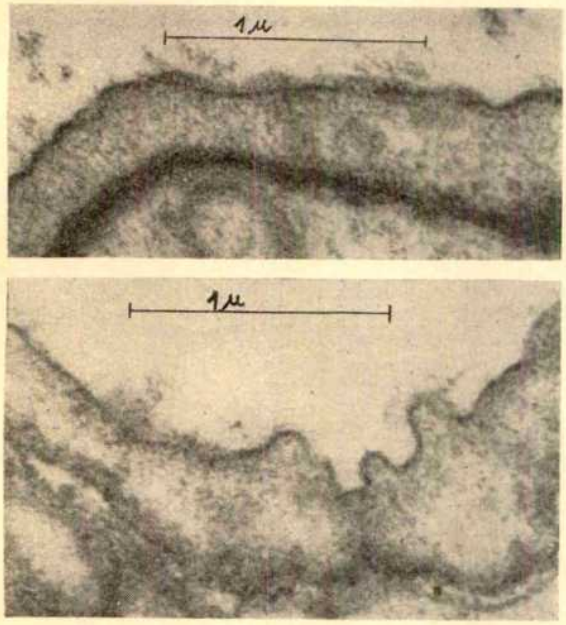

Fig. 1. Epithelial lining after fixation with $KMnO_4$ and embedding in 'Araldite'. At the alveolar side (upper side) some diffuse, granular material attached to cell membrane is observed (*a*). Here and there it presented a membranous appearance (*b*)

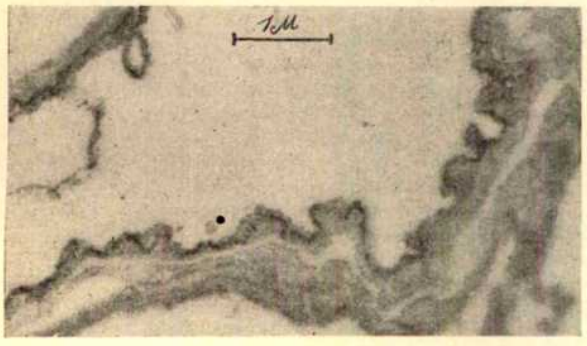

Fig. 2. Section of rabbit lung fixed in formalin and stained by the modified Hale technique. Aggregates of crystals of ferric ferrocyanide coat the alveolar space. Hale-positive material attached closely to the epithelial lining. Basement membrane complex and endothelial lining are also visible

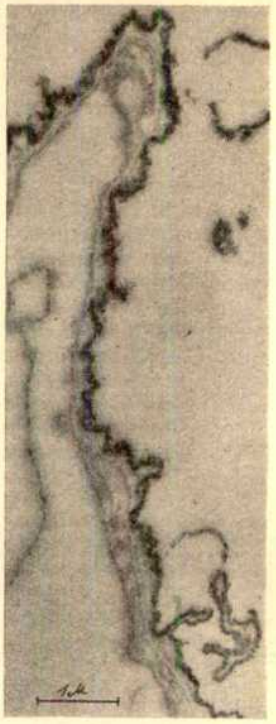

Fig. 3. Prepared as Fig. 2: epithelial lining of alveoli covered by a continuous layer of Hale-positive material. Crystals of ferric ferrocyanide outline the processes of epithelial lining

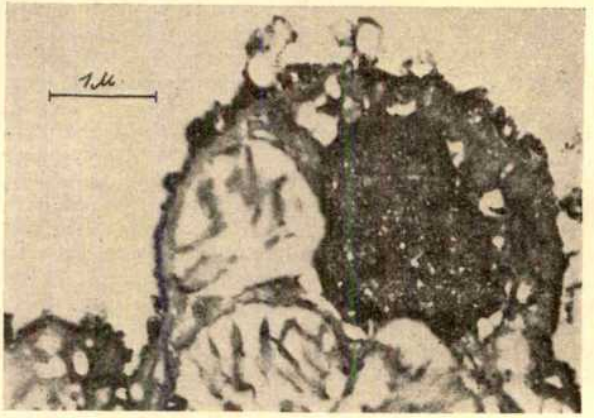

Fig. 4. Prepared as in Fig. 2: a portion of so-called 'granular' cell of the alveolar lining. This cell has a Hale-positive coat similar to that in Fig. 3

could indicate the existence of another component of the acidic mucopolysaccharide nature in the lining film. The comparison of the results obtained from tissue blocks fixed in potassium permanganate, embedded in 'Araldite', and results revealed by means of Hale's method could support the idea of the existence of various chemical components in the alveolar lining film. The granular material observed by us in the alveolar layer had some counterpart in the globular agglomerations of the epithelial cells of alveoli, while the Hale-positive material was found only on the alveolar surface of the cells.

LUNG ALVEOLAR SURFACTANT, LUNG ELASTICITY, AND LUNG STABILITY

By Dr. R. M. MENDENHALL* and A. L MENDENHALL, jun.

U.S. Department of Health, Education and Welfare, Public Health Service, Division of Occupational Health, Cincinnati, Ohio

EVIDENCE exists to show that a highly surface-active mixture of materials lines the alveoli of mammalian lung[1–4]. It is thought to form a 'bimolecular' layer there which is related intimately to the 'unit membrane' of plant and animal cells[5,6]. It is capable of reducing the surface tension markedly at the interface between water or some aqueous solutions and air when its area is diminished steadily[2]. This fact has been used to develop the concept that lung alveolar surfactant confers stability on lung alveoli by adjusting capillary pressure through adjustment of surface tension at their surfaces as their radii of curvature change with breathing movements[2]. In addition, such action is thought to produce a substantial part of the elastic properties of whole lungs[7]. A cogent point in favour of this hypothesis consists in the similar appearance between surface tension-area hysteresis loops obtained from alveolar surfactant on the surface balance and pressure-volume hysteresis loops obtained from excised lungs of various mammals[2,8]. The latter hysteresis loops are largely unaffected when pressures are held constant at the corresponding volumes for periods of up to 40 min, that is to say, under static conditions which are necessary for measurement of elastic properties of matter. The former hysteresis loops, however, have not been observed heretofore under static conditions, leaving the above comparison open to question until suitable evidence is at hand.

Surface tension-area hysteresis loops have been obtained with a specially designed surface balance which permits examination of lung alveolar surfactant at rates of change of area which might be considered similar to those existing in the alveoli of intact lung[3,9]. Under these conditions, the surface tension produced by the lung alveolar surfactant tended to proceed rapidly toward some intermediate value before maximum or minimum area of the surface was attained. Further anomalous behaviour of lung alveolar surfactant was observed when its area on a surface balance was reduced slowly to one-fifth of its initial area, then held constant while surface tension was measured against time. The surface tension rose from about 6 to about 27 dynes/cm in 7 min[10]. This observation indicates that relaxation of 'elastic' properties is slow, but is still much too rapid to agree with the 40 min of substantially unaffected results obtained with excised lungs. It suggests a lack of elasticity in the surface-tension behaviour produced by lung alveolar surfactant.

The area of the lung alveoli has been considered to remain virtually constant during breathing[11]. Under these conditions the lung alveolar surfactant might maintain stability of lung alveoli by producing very low and almost constant surface tensions and so would have little influence on elasticity of the lung. Adequate ventilation of the lungs certainly can be provided without change in their volume or surface area[12]. If the surface tension produced by lung alveolar surfactant *in situ*, under these static conditions, reached the values produced by it under static conditions on the surface balance, then alveolar instability might be expected, but does not result. Stability and elasticity of the lungs, on the other hand, might be due to tissue and not surface forces, or to geometric changes of alveolar surfaces during breathing movements[7,13].

From these observations, divergent hypotheses have arisen regarding the cause of stability and elasticity of lung tissue. It would be well to note that these disparate views have resulted from studies of different model systems, the application of which to events occurring in the living lung *in situ* may be subject to question until direct observations are obtained.

With this understanding of the limitations of model systems, a surface balance was used to re-examine the contribution of lung alveolar surfactant to the elasticity of lung, and to the spacial stability of lung alveoli.

Equipment and methods have been reported, with the exception that the hypophase in the present experiments contained no rinsings of mammalian lung[8,9]. The hysteresis loops presented here are not so smooth as those previously attained with the equipment used[9]. This is due mainly to replacement of the gear drive for control of movement of the barriers of the surface balance with a very slightly erratic chain drive and to the fact that the equipment had been removed to a less stable environment. The significance of the results, however, is believed not to be impaired by these minor artefacts.

Fig. 1 is a photograph of the experimental results from which the least maculate results were chosen for presentation. To obtain data for surface tension-area hysteresis, cycling rates of 14 and 7 cycles/min were used throughout the experiments shown in the top and bottom rows of the figure, respectively. Each of the 10 uninterrupted hysteresis loops shown in Fig. 1 was recorded from the maximum to the minimum and back to the maximum area. At this moment the barriers were arrested virtually instantaneously by shorting the driving electric motor. A large clock which operated at 4 beats/sec was strapped to one of the observer's ears to permit estimation of the duration of each arrest of the barriers. After waiting the number of seconds shown in the lower right corner of each recording, motion of the barriers was resumed until the area designated by each recorded vertical line ('spike') was reached. At this moment the barriers were arrested again for the same period shown. All recordings proceed in a clockwise direction. At each arrest of motion of the barriers, surface tension proceeded abruptly toward what appeared to be some constant value. This value appears to be about 20 dynes/cm for the upper row of data and was attained within 6 sec under static conditions. For the lower row the corresponding values are 27·5 dynes/cm and 8 sec, respectively. The discrepancy between 20 and

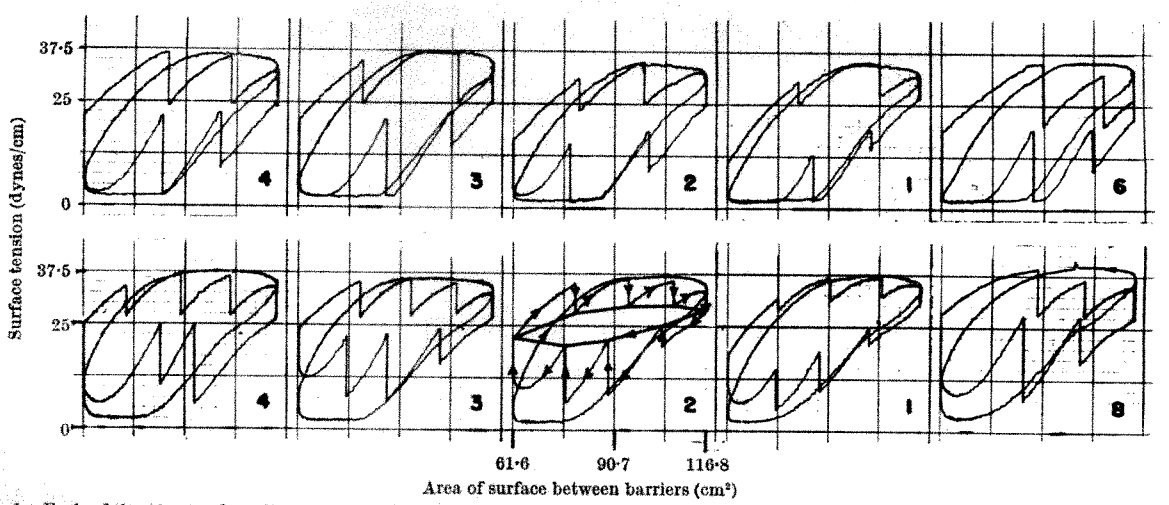

Fig. 1. Each of the 10 sets of results was obtained by first recording one complete hysteresis loop starting from and returning to maximum area clockwise. At this moment the barriers were arrested for the seconds shown at the lower right corner of each set. The same period of arrest of the barriers was repeated at each vertical line in each set. The upper row of sets was recorded at a free cycling rate of 14 cycles/min; the lower at 7/min. One set is labelled to indicate for each set; direction of motion, area bounded by the terminations of the members of each family of vertical lines, area swept by the barriers. The ratio of maximum to minimum area for all sets is the same and is approximately 1·9 : 1

27·5 dynes/cm was produced largely by the greater rate at which surfactant was added to the surface in the former case. This forces the equilibrium position to lower values.

The tips of the spikes formed under static conditions (2 sec) in the central set of data of the bottom row have been connected by straight lines to illustrate the static hysteresis under these conditions. When the free rate of cycling of the barriers was 14 or 7 cycles/min, this static hysteresis virtually disappeared at the end of 6 or 8 sec, respectively.

It would appear from these experiments that lung alveolar surfactant produces little, if any, elasticity of the surface on the surface balance. To the extent that such data can be applied to the mammalian lung, it might be said that elasticity at an aqueous surface produced by lung alveolar surfactant contributes little or nothing to elasticity of the lung. The equilibrium surface tension was also sufficiently great to suggest that lung alveolar surfactant contributes little to the spatial stability of mammalian lung through a mechanism involving a low and constant surface tension, although an increase in stability over that which would be provided by a surface of pure water would be expected.

The concept that lung alveolar surfactant produces stability of lung alveoli by producing a very low and relatively constant surface tension can be only touched on here. Results of examination of such material in the form of bubbles and the present investigations of it with a surface balance appear to be compatible when lung elasticity is considered, but mutually exclusive with regard to stability of the lung. Resolution of this conflicting evidence might depend on future ability to produce very low static surface tensions with lung alveolar surfactant on a surface balance. On the other hand, the question might be resolved by learning what effects the chemical composition and architecture of lung alveolar surfactant have on physical properties and behaviour of bubbles derived from lung alveoli.

THIN-LAYER CHROMATOGRAPHY ON POLYAMIDE LAYERS: SEPARATION OF FAT ANTIOXIDANTS

By Dr. J. W. COPIUS-PEEREBOOM
Government Dairy Station, Leiden

THE use of polyamide powder in column chromatography of phenolic compounds has been introduced, for example, by Carelli[1] and by Grassmann[2]. The work of Hörhammer *et al.*[3–5] especially has shown that this type of chromatographic analysis is very suitable for the separation and identification of many groups of phenolic compounds, flavonoids, etc., occurring in natural products.

Polyamide powders have recently been introduced as support in thin-layer chromatography by Davídek[6,7] and by Egger[8]. This technique has also been applied successfully to the analysis of flavonoids, anthocyanins, glycosides, fat-soluble vitamins, etc.

In column chromatography on polyamide the separation process was found to be highly affected by hydrogen bonding forces between the hydroxyl groups and the CONH groupings in the polyamide molecules[5]. It has been generally assumed that in thin-layer chromatography on polyamide layers hydrogen bonding likewise would play a predominant part.

My investigations concerning polyamide thin-layer chromatography of lipophilic compounds such as antioxidants, fatty acids, esters, however, gave circumstantial evidence as to the conception that in these instances hydrogen bonding is not of great importance, but that the

polyamide layer will act as an apolar support or alternatively in some special cases as a kind of polar stationary phase. The type of stationary phase involved will mainly depend on the composition of the mobile solvent.

On 'loose layers' of polyamide, as were used by Davídek[6], the cross-sections of the spots were about 2 cm, which is somewhat large for obtaining distinct separations (see also ref. 9). I therefore found loose polyamide layers impracticable. Polyamide layers, prepared by mixing the powder with methanol, are also very thin and fragile. The use of an appropriate binding agent like starch or polyvinyl acetate was preferred. Starch-bound polyamide layers were prepared according to the procedure described by Machery and Nagel, by admixing 5 ml. of starch solution (10 per cent) to a slurry of 4·5 g polyamide in 45 ml. methanol–chloroform (3 : 2). Alternatively, I succeeded in preparing firmly bound polyamide layers by adding synthetic glues like polyvinyl acetate as binder. As an example 'Mowilith *CT* 5*a*' (from Messrs. Hoechst) was applied for this purpose. Forty-five millilitres of a 10 per cent solution of this 'Mowilith' in methanol was mixed with 7 g of polyamide powder and this slurry was spread on the glass plates by Stahl's spreader.

Various fat antioxidants, namely, the series of gallic acid esters, BHA, BHT and sesamol, etc., were analysed on starch-bound polyamide layers in the solvent methanol–acetone–water (60 : 20 : 20), according to Davídek[10–12].

As is shown in Table 1, series *A*, and Fig. 2, line *A*, the R_F values of the gallic acid esters decrease with increasing length of the carbon chain. The sterically hindered phenolic compounds BHT and BHA, having strong lipophilic properties, exhibit low R_F values of respectively 0·24 and 0·30. This separation pattern is indeed analogous to that found when analysing these antioxidants with reversed-phase paper chromatography on papers impregnated with vegetable oils or paraffin oil[13–15]. The same correlation between R_F and chain-length was found when analysing the higher fatty acids and their esters on polyamide layers, using the solvent mixtures methanol–acetone–water (40 : 40 : 20) and (30 : 10 : 10) respectively (see Fig. 1, *A* and *B*). These separations are analogous to those achieved in normal reversed-phase systems, for example, by Kaufmann and co-workers[16]. I therefore suppose that in these circumstances the polyamide layer will act as an 'apolar stationary phase'.

A quite different pattern of R_F values was found, however, when using non-aqueous solvent mixtures which contained acetic acid, for example, a mixture of light petroleum–benzene–acetic acid (10 : 10 : 5) (preferably with the addition of 0·25 dimethyl formamide). As is shown in Table 1, series *B*, *C*, and Fig. 2, line *C*, the gallic acid esters with long chain-lengths now display higher R_F values than the lower members of the series. There is a nearly linear correlation between R_M value and the length of the alkyl chain of these esters. In this solvent the lipophilic compounds BHT and BHA have high migration rates. The pattern of the spots is somewhat similar to that obtained in paper chromatographic analysis, for example, in the solvent chloroform–acetic acid (99 : 1) (refs. 17 and 18), where the stationary phase is built up by a cellulose–water complex[19]. This agreement was demonstrated by comparison of the R_F sequences in the series *B*, *C* and *E* in Table 1.

In the case of those solvents containing acetic acid, one should assume a type of partition process between a 'polar stationary phase', built up by acetic acid-imbibed polyamide particles, and the apolar mobile solvent. The

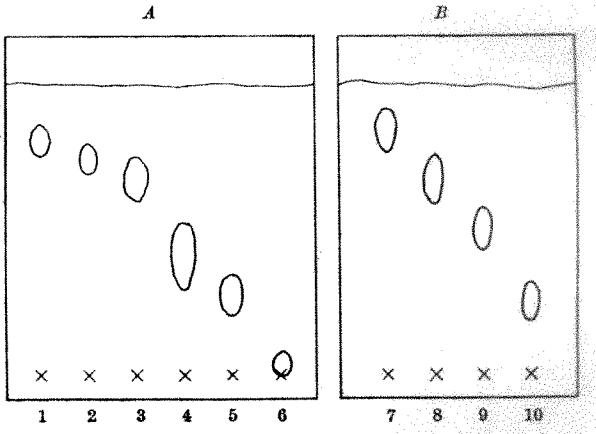

Fig. 1. Separation of lipophilic compounds by thin-layer chromatography on polyamide layers. Polyamide powder (Messrs. Woelm), starch bound. *A*, Separation of the higher fatty acids. Mobile solvent: methanol–acetone–water (40 : 40 : 20). Detection: spraying with 4 N sulphuric acid, eventually followed by a spray with 0·05 per cent rhodamine *B*. Spot 1, capric acid; spot 2, lauric acid; spot 3, myristic acid; spot 4, palmitic acid; spot 5, stearic acid; spot 6, arachinic acid. *B*, Separation of the higher fatty acid esters. Mobile solvent: methanol–acetone–water (30 : 10 : 10). Detection: 2·7-dichlorofluorescein under ultra-violet light. Spot 7, methyl laurate; spot 8, methyl myristate; spot 9, methyl palmitate; spot 10, methyl stearate

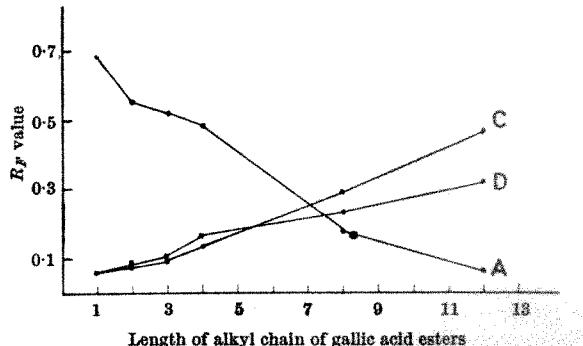

Fig. 2. R_F values of a series gallic acid esters in the systems *A*, polyamide/methanol–acetone–water (60 : 20 : 20); *C*, polyamide/light petroleum–benzene–acetic acid-dimethylformamide (10 : 10 : 5 : 0·25); *D*, 'Silica gel *G*'/light petroleum–benzene–acetic acid (10 : 10 : 5), as given in Table 1

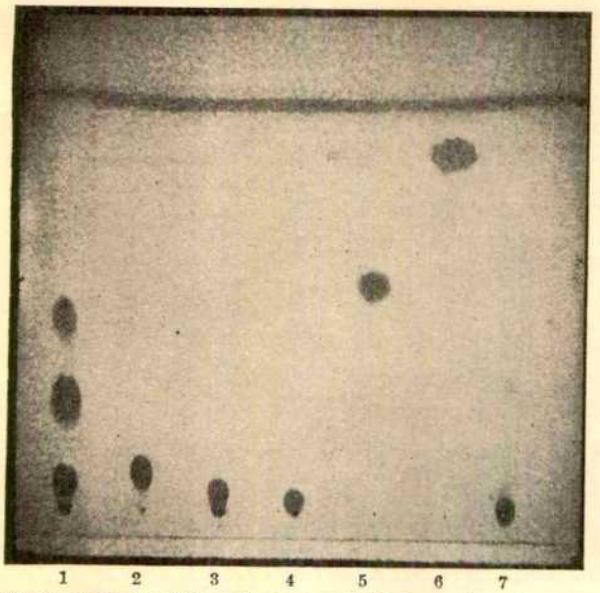

Fig. 3. Separation of fat antioxidants with thin-layer chromatography on polyamide layers. Binding agent: starch. Mobile solvent: light petroleum–benzene–acetic acid–dimethylformamide (10 : 10 : 5 : 0·25). Detection: ferric (III) sulphate–potassium ferricyanide reagent. Spot 1, dodecyl-, octyl-, propyl gallate; spot 2, butyl gallate; spot 3, ethyl gallate; spot 4, methyl gallate; spot 5, sesamol; spot 6, BHA; spot 7, NDGA

polyamide–acetic acid complex is comparable to the cellulose–water complex in paper chromatography. Further evidence of this concept is given by the agreement of the separation pattern of antioxidants on polyamide layers with that on 'Silica gel *G*' layers (compare Table 1, series *C* and *D*). The addition of a small quantity of a non-volatile polar organic liquid like dimethylformamide, ethyl lactate, phenyl cellosolve, etc., will help in building up this complex polar stationary phase and thus prevent the occurrence of tailing effects. The spots of the antioxidants now have a reasonable small cross-section.

The systems *C* and *D* (Table 1) were applied in practice to the separation and identification of common fat antioxidants, namely, gallates, BHA, BHT, NDGA, etc. In margarine and animal fats small amounts of gallates, as low as 0·005 per cent, were determined by using this technique (preferably in system *D*). The estimation of small amounts of BHT in fats with classical methods of analysis previously had encountered great difficulties. On silica gel layers a spot of about 1 μg of BHT could be clearly visualized with a ferric (III) sulphate–potassium ferricyanide colour reagent. By using an appropriate extraction procedure, I could thus determine the presence of quantities of BHT present at as low as 0·0001 per cent in food products like milk powder.

CHARGE-TRANSFER COMPLEX FORMATION, CARCINOGENICITY AND PHOTODYNAMIC ACTIVITY IN POLYCYCLIC COMPOUNDS

By Dr. SAMUEL S. EPSTEIN, INNA BULON, JEFFREY KOPLAN, MYRA SMALL and NATHAN MANTEL

From the Laboratories of Carcinogenesis, the Children's Cancer Research Foundation, and the Department of Pathology, Harvard Medical School, at the Children's Hospital, Boston, Massachusetts, and the Biometry Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

CHARGE-transfer complex formation is a short-range intermolecular interaction involving the transfer of an unpaired electron from donor (*D*) to acceptor (*A*) molecules, yielding a complex which may later dissociate into two free radicals: $D + A \rightleftarrows D \cdot A \cdot \rightleftarrows D \cdot + A \cdot$. An intense new absorption band, characteristic of the complex but of neither component alone, can be detected by spectral difference[1–3], or sometimes by the formation of coloured complexes when donor and acceptor molecules are forced into apposition[4–6]. The concept of involvement of charge transfer from the π pool of carcinogens to intracellular acceptor sites was derived from investigations, on relatively small numbers of compounds *in vitro*, relating carcinogenicity to the formation of certain types of charge-transfer complex[4–6]. An opportunity to determine the general applicability of this theory of charge transfer in carcinogenesis was made possible by the availability of a large series of polycyclic compounds of known carcinogenicity. It was also considered of interest to establish whether complex formation could account for the positive association between carcinogenic and photodynamic properties, recently demonstrated in the same series of compounds[7].

The ability of 107 polycyclic compounds to produce coloured complexes with iodine, chloranil, trinitrobenzene or acridine was determined. Whether the latter affords a true test for the formation of charge transfer, as opposed to other complexes, has been disputed[6,8]. Solutions of all compounds were tested in organic solvents at 0·1 M, using previously described techniques[4–6], briefly presented here.

Iodine test. Strips of Whatman No. 1 paper were moistened with chloroform solutions of the compounds under investigation and exposed to iodine vapour in a stoppered tube containing iodine crystals. In the absence of immediate coloration, observations were extended to 3 min. In addition, this test was also performed by dropping a 0·1-M iodine solution in chloroform on paper previously treated with compound solutions.

Table 1. Results of Colour Reactions with Iodine, Chloranil, Trinitrobenzene and Acridine

The 107 polycyclic compounds tested are classified by grade of carcinogenic activity, and data on photodynamic activity are also given

	Compound and source*	Colour reactions				Photodynamic activity $1/C_{30}$
		Iodine	Chloranil	Trinitrobenzene	Acridine	
	+ + + Carcinogens					
1	7-Methylbenz[*a*]anthracene (1)	Dark brown	Grey	Dark orange	Light yellow	12·50

Table 3. Relative Odds Method for Analysis of Associations

Property II \ Property I	Positive	Negative	Total
Positive	A	B	$A+B$
Negative	C	D	$C+D$
Total	$A+C$	$B+D$	$A+B+C+D$

Relative odds ratio = AD/BC
$AD/BC > 1$ = Positive association
$AD/BC < 1$ = Negative association
$AD/BC \sim 1$ = No association

Chloranil test. Acetonitrile solutions of polycyclics were tested on paper with 0·1-M solution of chloranil in acetonitrile, as described for the iodine paper test.

Trinitrobenzene test. Equal volumes of trinitrobenzene and 0·1-M polycyclic solutions in tetrahydrofuran were mixed on depression slides. Aliquots of water were then added and the colour of any resulting precipitates noted. In addition, this test was also performed in the same way as the iodine paper test.

Acridine test. Acridine solutions in chloroform at 0·1-M were dropped on to filter paper which was then moistened with polycyclic solutions in the same solvent.

The results of the four colour tests are recorded in Table 1, where the compounds are grouped by grade of carcinogenic and photodynamic activities. Photodynamic activity is expressed as $1/C_{30}$, the reciprocal of the concentration, in μg/ml., producing 90 per cent lethality of *Paramecium caudatum* by 30 min, compounds being regarded as having strong activity when $1/C_{30} \geq 2{\cdot}0$ (ref. 8). Under standard conditions, complete reproducibility was found with all the colour tests, irrespective of which technique was used. Erratic results did occur with the iodine test if the moistened paper was allowed to dry before exposure to iodine vapour. Colour production was immediate with the trinitrobenzene slide and all paper tests, but not with the iodine vapour test.

For purposes of statistical analysis, a positive result was scored when a black or dark brown colour was given with iodine, any colour with chloranil, any colour other than yellow with trinitrobenzene, and yellow with acridine[4–6]. The number of compounds positive and negative for each colour test are classified by carcinogenic and photodynamic status in Table 2. The 'relative odds technique'[9] is the method of analysis used to define the associations considered here. Table 3 shows that for T compounds $(A + B + C + D)$ the association of two particular properties, I and II, can be measured by the relative odds ratio AD/BC. Where these properties are not associated, this ratio will approach unity. Positive associations are indicated by ratios greater than unity, while negative associations are indicated by values less than unity. With large numbers of compounds, the relative odds ratio can be considered a reliable measure of the association. However, for smaller samples, the degree of reliability may be lower, necessitating tests for significance. In analyses of the association between any two properties, adjustments may be made for a third property by grouping the compounds into those positive and negative for the third property. Adjustment of this type, perforce, reduces the numbers in each group and results in reduced significance, even if the odds ratio remains unchanged.

Table 4. Inter-association of Four-colour Tests for Complex Formation in 107 Polycyclic Compounds

Colour test A	Colour test B	Test results, No. compounds A+B+	A+B−	A−B+	A−B−	Association Relative odds	χ^2	P
Iodine test	Chloranil test	24	4	50	29	3·5	3·9	< 0·05
	Trinitrobenzene test	25	3	41	38	7·7	8·1	< 0·005
	Acridine test*	20	8	32	46	3·6	6·5	< 0·02
Chloranil test	Trinitrobenzene test	49	25	17	16	1·8	1·5	*N.S.* (> 0·2)†
	Acridine test*	37	36	15	18	1·2	0·1	*N.S.* (> 0·2)†
Trinitrobenzene test	Acridine test*	39	27	13	27	3·0	6·0	< 0·02

* Results for acridine not shown or used in calculations. † *N.S.* = Not significant.

The four colour tests reported here make available individual measures of particular types of charge-transfer complex formation and their results are not strictly comparable. This, in all probability, accounts for the imperfect nature of the positive inter-associations between the results of these tests (Table 4). The inter-associations involving the iodine test are stronger than are those for the other colour tests, suggesting that the iodine test, with relatively few positive results, provided a more stringent measure of strong charge-transfer complex formation. Corresponding stringencies for the other tests might also increase their apparent validity. It is of interest, in this connexion, to note that dark brown, besides black, was scored here as positive with the iodine test (Prof. A. Szent-Györgyi, personal communication), in contrast to the original report on this test which restricted positives to black[5].

Table 5. Association of Carcinogenic and Photodynamic Activities

Associations are shown for all 107 polycyclic compounds, and separately for compounds positive or negative on each of four tests for complex formation

	Relative odds	χ^2	P
All compounds (107)	4·7	12·2	< 0·0005
Compounds positive by:			
Iodine test (28)	2·4	0·6	*N.S.* (> 0·2)
Chloranil test (74)	3·8	6·3	< 0·02
Trinitrobenzene test (66)	5·2	8·3	< 0·005
Acridine test (52)*	6·1	7·6	< 0·01
Compounds negative by:			
Iodine test (79)	5·9	10·4	< 0·002
Chloranil test (33)	∞	5·1	< 0·025
Trinitrobenzene test (41)	3·7	1·9	< 0·2
Acridine test (54)	3·4	2·5	< 0·2

* Results for acridine not used in calculations.

* Results for acridine not used in calculations.

The positive association between carcinogenic and photodynamic activities reported previously[7] cannot be accounted for by the possibility that both activities are associated with complex formation, as the association obtains equally for compounds with and without complex formation (Table 5). A positive but imperfect association between photodynamic activity and each measure of complex formation is expressed in Table 6. There is no systematic indication that this association differs from carcinogens to non-carcinogens. The possible involvement of charge transfer in photodynamic activity has been suggested by the observation that tryptophan gave protection against the photodynamic toxicity of benzo(*a*)-pyrene[10]. In view of recent evidence on the photo-induction of free radicals from charge-transfer complexes[11,12], photodynamic injury might result from the effects of free radicals photo-induced from charge-transfer complexes of photosensitizing polycyclic electron donors and intracellular electron acceptors[7]. The production of free radicals from black complexes of benzo[*a*]pyrene and iodine has been reported[5], but the possibility of photo-induction of these radicals does not appear to have been considered. As can be seen from Table 7, there is no significant association between carcinogenicity and charge-transfer complex formations as indicated by any colour test. The positive association between complex formation and photodynamic activity demonstrated here, together with the photodynamic-carcinogenic association, could induce an apparent statistical association between carcinogenicity and complex formation. In the present data, based on 107 polycyclic compounds, this induced association between complex formation and carcinogenic activity is not significant, but could appear stronger[4–7] in a smaller and more selected group of compounds. For example, restriction of consideration to the results of the iodine test for the + + + carcinogens in Table 1 suggests a degree of association between complex formation and carcinogenicity which, however, disappears when investigations are extended to non-carcinogens and carcinogens of lesser potency.

Application of techniques which provided the original *in vitro* evidence[4–6] for involvement of charge-transfer complex formation in carcinogenesis to a large series of polycyclic compounds has revealed no particular association between complex formation and carcinogenicity, and does not support the recommendation[7] that charge-transfer tests be used to screen for carcinogenicity. On the basis of available evidence, it is now considered unlikely that charge-transfer complex formation plays a significant part in determining the carcinogenicity of polycyclic compounds.

This investigation was supported by U.S. Public Health Service research grant *C*–6516 from the National Cancer Institute.

We thank Prof. A. Szent-Györgyi, Dr. I. Isenberg and Profs. A. and B. Pullman for their helpful comments.

Note added in proof. Our attention has just been directed to an article by N. P. Buu-Hoi and P. Jacquignon (*Experientia*, 13, 375; 1957), who have reached similar conclusions to those reported here.

EFFECT OF ELECTROCONVULSIVE THERAPY ON PLASMA CORTISOL-LEVELS

By Dr. J. R. HODGES and Dr. M. JONES

Royal Free Hospital Medical School, London

AND

Dr. A. ELITHORN and Dr. P. BRIDGES

Royal Free Hospital, London

A NUMBER of investigations of the activity of the adrenal cortex in subjects undergoing emotional and physical stress have been made. Early workers used various indirect measures of adrenal activity, but most recent work has been concerned with the plasma concentration of cortisol, and it has been shown that emotional distress is frequently accompanied by a raised plasma cortisol-level. Raised levels of about 18–22 μg/100 ml. have been reported[1] in relatives accompanying casualties to hospital and in patients awaiting surgery[2]. These levels compare with means of between 12 and 15 μg/100 ml. found in subjects examined under less stressful conditions[3]. Very high values have also been reported[4] in medical students before examinations. The elevation of plasma cortisol-levels has also been ascribed to emotional distress when this is a presumed part of a psychiatric illness such as acute schizophrenia[5], anxiety state[6] or depressive illness[7].

Since almost by definition mental illness implies an abnormal response to emotional stresses, interest in this field has tended to focus on abnormalities of responsiveness. In depressive illness, clinical reports suggest reduced responsiveness to both psychological and physical stress, and many workers consider that one type of depressive illness, called variously endogenous or physiological depression, reflects a failure of hypothalamic centres concerned with instinctive drives and adrenal stress mechanisms, and it has been frequently suggested that E.C.T. acts by stimulating these mid-brain centres. However, early work using various indices of adrenocortical responses to electroconvulsive therapy (E.C.T.) suggested that stress responses to E.C.T. were essentially non-specific.

In some preliminary experiments we made assays of circulating corticotrophin. While it was possible to demonstrate the release of corticotrophin following E.C.T., the method was both cumbersome and expensive. In the work recorded here, therefore, we have examined plasma cortisol-levels before and after E.C.T. in patients diagnosed as suffering from either schizophrenia or depression.

The work was carried out at a large psychiatric hospital in London where a number of patients were receiving E.C.T. The patients examined were those having this treatment with a definite diagnosis of schizophrenia and those who were confidently regarded as not schizophrenic. Each patient was interviewed by one of us (P.B.) and the diagnoses were made on the basis of this interview together with help from the hospital notes and, where necessary, discussion with the consultant in charge of the case. In this way, 23 schizophrenic patients and 23 depressed patients were selected for examination.

The latter group consisted almost entirely of cases of severe depression, but one patient in whom anxiety predominated over depression was included. Cases showing mixed depressive and schizophrenic features were excluded, as were patients in poor physical health and those over 65 years of age.

The mean age of the schizophrenic group was 30·2 years (range 20–53) and of the depressive group 48·0 years (range 21–65). All the schizophrenic patients were having either chlorpromazine or trifluoperazine, and 5 were also having anti-depressant medication. In the depressive group, 13 patients were having phenothiazines and 12 were having anti-depressants; in the case of 7 patients, both drugs were being taken together.

E.C.T. treatments were given between 9.30 a.m. and 11 a.m. Atropine was used as premedication in all cases, and the anæsthetic consisted of intravenous sodium thiopentone. Suxamethonium chloride was used routinely as a relaxant. An initial specimen of 4 ml. of venous blood was collected after the administration of anæsthetic and relaxant, and immediately before the shock was applied. Three subsequent specimens were collected 0·5, 1 and 2 h after the shock. The blood was heparinized and each specimen was centrifuged shortly after collection. The plasma was kept at −20° C until assayed. Plasma cortisol was determined by the spectro-fluorometric method of Zenker and Bernstein[8], the fluorescence being measured 20 min after addition of the fluorescent reagent.

A single set of observations was made on each patient, and these were made at different treatments in the course. Differences in the treatment number were neither marked nor significant for the two groups and, though this variable does influence the effect of E.C.T., it does not affect the issues discussed here. A separate examination of serial observations will be reported later.

The mean cortisol values for the two groups of patients are given in Table 1. The mean change between the pre-treatment value and the 0·5 h reading for the depressed group alone is significant ($P < 0·05$) but not that for the schizophrenic group. The 1 h and 2 h readings are not significantly different from the pre-treatment values for the combined group or for either group taken separately.

Although the depressives have a lower pre-operative mean value and show both a larger absolute and even greater proportionate increase in plasma cortisol following treatment, the differences between the depressive and

Table 1. Mean Plasma Cortisol-levels (μg/100 ml. Plasma) before and after E.C.T.

	Resting	½ h	1 h	2 h
Depressed patients (n, 23)	15·0 ± 7·1	21·0 ± 11·8	17·7 ± 8·2	14·9 ± 7·4
Schizophrenic patients (n, 23)	16·5 ± 8·1	19·2 ± 7·1	17·3 ± 6·1	14·8 ± 5·6

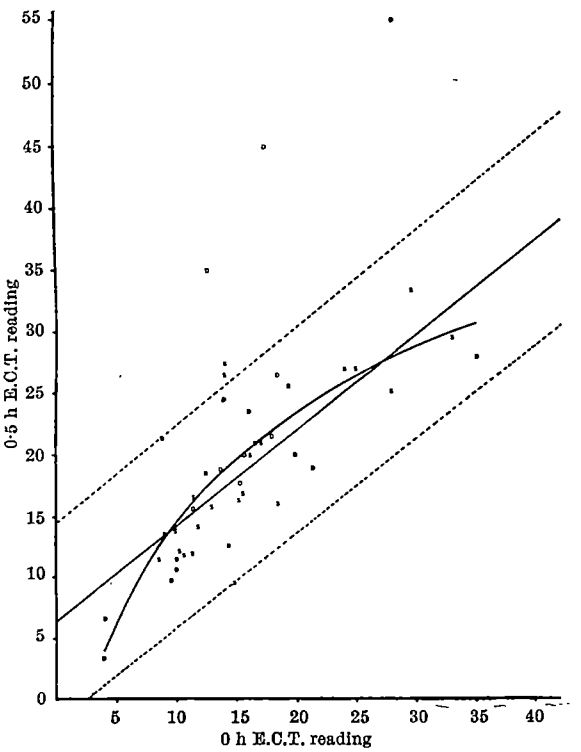

Fig. 1. Scattergram to illustrate the relationship between diagnostic status, pre-E.C.T. and 0·5 h levels of plasma cortisol. Using Chauvenet's criteria, the three aberrant observations have been excluded from these calculations and the straight lines give the resulting linear regression together with its confidence limits. The excluded values are all more than 4 *S.D.* from the regression. The curvilinear regression has the form $y = -16{\cdot}73 - 0{\cdot}632\,x + 11{\cdot}69\sqrt{x}$

schizophrenic groups are not significant using either parametric or non-parametric tests. The differences do not appear to be related to the difference in age between the two groups nor to differences in drug treatment or treatment number.

Inspection of the individual observations (Fig. 1) suggests that three of the depressive patients made markedly aberrant responses to E.C.T. while the remainder formed a homogeneous group with the schizophrenic patients. Using Chauvenet's criterion and Bartlett's test of homogeneity, it is possible to show that these three subjects have normal pre-treatment values and atypical treatment responses, and that the remaining patients, regardless of diagnosis, form a homogeneous group. For this group the linear regression equation $y = 6{\cdot}22 + 0{\cdot}785x$ gives a satisfactory fit for the relationship between the pre- and post-treatment levels. However, since it would be physiologically likely that the responsiveness of the adrenal glands would have an upper limit, it is of interest that the negatively accelerating curvilinear relationship $y = a - bx + c\sqrt{x}$ provides a significantly better fit for the data ($P < 0{\cdot}01$).

The close similarity of the results obtained with schizophrenic and depressive patients is of considerable interest. Pincus and Hoagland[9] reported that in schizophrenia the pituitary-adrenocortical system was relatively unresponsive compared with normal controls. The more recent work of Bliss[5], however, has shown that in schizophrenia the resting cortisol values and the adrenocortical responses as measured by increase in circulating plasma cortisol are essentially similar to those of normal controls. There is less work on stress response in depressive illness, although the observations of Broad *et al.*[10] and those of Gibbons and McHugh[7] are agreed that resting cortisol-levels are high in depression and fall as clinical improvement occurs.

There are two principal differences between the findings of the English and the American workers. First, the Americans found that treatment with E.C.T. produced a sustained rise in plasma cortisol in spite of clinical improvement. Secondly, the final values for the English workers are well below the normal control values reported by the Americans, except that some of the final observations were high because the patients remained depressed. Our own observations throw little light on these two points, but the finding that depressive patients are homogeneous with schizophrenics so far as both resting and post-E.C.T. cortisol-levels are concerned suggests that the sustained elevations observed by other workers reflect a normal hypothalamic-adrenocortical response to the stress of the illness. If this were the case, then it might well be postulated that the physiological stress of E.C.T. is relatively invariate and independent of the psychological stresses of the illness, that the increase in circulating cortisol should be fairly constant, and that the patients who were more stressed by the illness would tend to show a relatively smaller physiological response following E.C.T. The reverse relationship is, in fact, found, and this means that for E.C.T. the resting level of cortisol is a measure of the responsiveness of the patient as well as a possible measure of the degree of subjective stress of the illness. Physiologically it would appear unlikely that responsiveness would increase rectilinearly with resting level if the latter reflected in any way a stress response, that is to say, a ceiling effect should be postulated and the relationship between resting and post-E.C.T. levels should be curvilinear and negatively accelerating. As already mentioned, the data fit a relationship of this type better than a simple linear regression. These findings appear compatible with the findings after traumatic surgery reported by Sandberg *et al.*[11].

The foregoing discussion of the physiological effects of E.C.T. largely ignores the fact that this treatment is a psychological stress as well as a physiological one. It remains possible that a peak of emotional tension is reached immediately prior to the treatment and that this leads to a peak in plasma cortisol between half and one hour later. That this explanation is unlikely to be correct is supported by the preliminary observations carried out on blood corticotrophin. On 7 out of 11 occasions this was found to be increased immediately after treatment compared with the pre-treatment values. The maximum release of corticotrophin has been shown by Hodges and Vernikos[12] to occur within minutes of the imposition of a stress, and these observations suggest that the major stimulus occurs at the time the shock is applied.

With regard to the three atypical subjects, it is clearly very unlikely indeed that these three observations are due to chance variations. That all three are diagnosed as suffering from depressive illness could easily be a chance finding, but is perhaps of some interest. Careful re-examination of the records provides no suggestion of any technical error, and this, together with the fact that the values obtained for the resting pre-treatment cortisol-levels are all within the range for the rest of the subjects, makes it almost certain that these three patients are reacting to E.C.T. in a physiologically different way. This difference bears no discernible relationship to treatment number, outcome of treatment or drug régime. The three patients are at the upper end of the age-group, but previous work shows no marked effect of age on adrenal responsiveness and the correlations of resting plasma cortisol-levels with age in the present study are small and not significant ($r = -0{\cdot}171$ $P < 0{\cdot}3 > 0{\cdot}2$). The correlation with age for the 0·5 h values is even smaller ($r = 0{\cdot}066$ $P < 0{\cdot}7 > 0{\cdot}6$). Although there was no evidence of physical ill-health in any of these patients, it remains possible that this effect could be due to subclinical liver damage—one patient was receiving 'Parstelin', the other two 'Amitriptyline HCl'. In the series reported by Gibbons and McHugh[7], only two patients showed sharp increases in plasma cortisol following treatment. Only one of these received E.C.T., but their observations, as well as

those presented here, support the thesis that depressive illnesses are not physiologically homogeneous[13].

We thank Dr. I. Sutton and the staff of Friern Hospital for their assistance and Mrs. Myfanwy Kerr for help with the statistical analyses. One of us (P.B.) was supported by the Mental Health Research Fund; the others, by the Medical Research Council.

ETHYLENE OXIDE AN ANTAGONIST OF ETHYLENE IN METABOLISM

By MORRIS LIEBERMAN, SAM ASEN and Dr. L. W. MAPSON

U.S. Department of Agriculture, Plant Industry Station, Beltsville, Maryland, and Low Temperature Research Station, Cambridge, England

RECOGNITION of ethylene oxide as an inhibitor of ethylene production in fruit[1] presents new possibilities for exploring both the mode of action of ethylene and its biosynthetic pathway. This report summarizes recent experiments with ethylene oxide, in which reversible antagonism to senescence was observed in a number of different tissues.

When a proper concentration of ethylene oxide is applied to some fruit during the pre-climacteric period, ethylene production is suppressed and ripening is often retarded. Ethylene production and ripening are inhibited (Fig. 1, bottom) only so long as excess ethylene oxide remains in the tissues (Fig. 1, top). After dissipation of the absorbed ethylene oxide, either by expulsion or by reaction within the tissues, the fruit resume production of ethylene and ripening in the normal manner. In this type of inhibitory action, which has been demonstrated with plums and tomatoes, ethylene oxide may be considered a metabolic antagonist to ethylene.

The foregoing statements are based on results of more than two dozen experiments. However, sensitivity to ethylene oxide varies considerably among different fruit tissues, and many tissues are irreversibly injured. The greater the production of ethylene at the time of treatment, the higher the dosage of ethylene oxide required to suppress ethylene and ripening. With high-ethylene-producing fruit, such as the avocado and apple, ethylene production has not, as yet, been suppressed without permanent damage to the tissues.

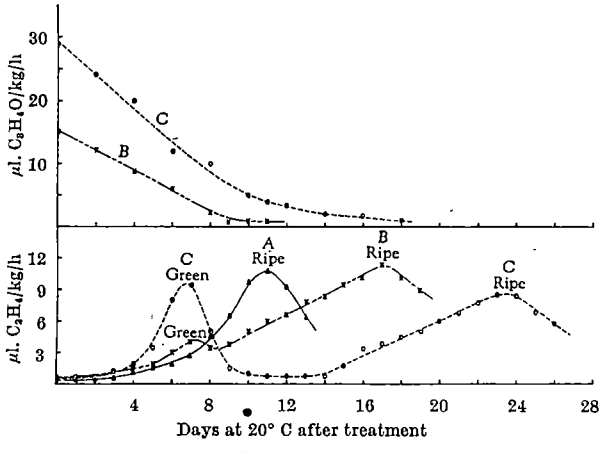

Fig. 1. Bottom, course of ethylene production in tomatoes (var. 'Potentate') at 20° C; (*A*) control; (*B*) ethylene oxide, 0·35 per cent v/v for 20 h; (*C*) ethylene oxide, 0·65 per cent v/v for 20 h. Fruit were mature green at time of treatment. Rise in ethylene production in (*B*) and (*C*) during 5, 6 and 7 days is due to initial stimulation by ethylene oxide. Stage of ripeness shown on ethylene curves was determined by visual observation. Top, course of expulsion of ethylene oxide from tomatoes during holding in enclosed atmosphere. Fruit were removed and atmosphere flushed with air each day before return of fruit to enclosure in air. Ethylene and ethylene oxide were determined by gas chromatography as previously described (ref. 1)

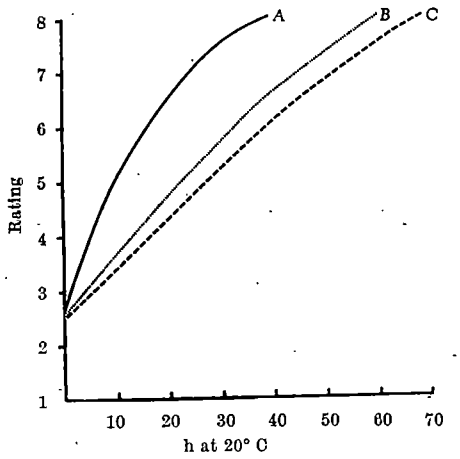
After treatment with relatively high concentrations of ethylene oxide (above 0·5 per cent), some fruit show an initial sharp transitory rise in ethylene production, which may be much greater than the highest point normally reached at the climacteric peak. An extreme form of this phenomenon was found to be associated with subsequent inability of the fruit to ripen properly, and may be related to cellular damage. The result of ethylene stimulation by ethylene oxide may be seen in Fig. 1 (*C*) and (*B*) (bottom) during the 6th and 7th day. Stimulation of this magnitude is comparatively mild. These fruit were not injured, and ripened normally. It appears, therefore, that ethylene oxide inhibits directly at the site of ethylene production, and may also act at the site of ethylene action, judging by its suppression of ripening in fruit already producing ethylene.



The anti-ageing effect of ethylene oxide has also been observed in recent months, in experiments with flowers. Senescence in flowers is associated with ethylene production[2] and may be considered to be a ripening process. Roses (cv. 'Better Times') subjected to 0·25 per cent ethylene oxide (v/v) in an enclosed atmosphere for 20 h at 15° C showed considerably increased longevity after removal to an open environment at 20° C. The buds opened more slowly, and reached full bloom about 30 h later than controls (Fig. 2). The delay in ageing results from absorption of ethylene oxide and lasts as long as ethylene oxide is being released from the tissue. Loss of absorbed ethylene oxide from the floral tissue occurs very rapidly (Fig. 3). However, the rate of release from the rose buds can be retarded further by enclosure, in air, of the ethylene oxide-treated roses, beyond the initial 20-h treatment.

Because roses produce extremely minute amounts of ethylene (less than 0·1 p.p.m.), inhibition of ethylene production in roses treated with ethylene oxide was not clearly demonstrated. With carnations, however, antagonism between ethylene and ethylene oxide was observed. Carnations are extremely sensitive to ethylene and, when exposed, exhibit symptoms known as 'sleepiness'. Sleepiness is characterized by incurving of the petals and closing of fully opened flowers. Exposure to ethylene concentrations of 1 p.p.m. will cause 'sleepiness'[2].

When carnations were exposed to both ethylene (1 p.p.m.) and ethylene oxide (0·1 per cent) simultaneously, 'sleepiness' did not occur (Fig. 4). Ethylene oxide also antagonized loss of water caused by treating carnations

with ethylene (Fig. 5). Loss of water was diminished in the presence of ethylene oxide even when compared to untreated controls (Fig. 5). These and other published results[3–5] suggest that one physiological effect of ethylene is to increase loss of water, by altering permeability of cell membranes. Ethylene oxide appears to counteract this effect. Therefore, the inhibitory action of ethylene oxide appears to strike not only at the source of biosynthesis of ethylene but also at a site of its action.

We have thus observed, in a number of experiments, that different physiological responses to ethylene are antagonized by ethylene oxide. Ripening of fruit, 'sleepiness' and senescence in flowers, and loss of water due to increased cell permeability have all been delayed or

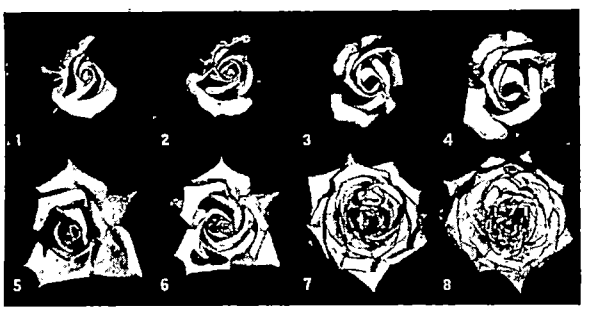


Fig. 2. Rating of roses during holding period at 20° C after treatment; (*A*) control; (*B*) treated with 0·25 per cent ethylene oxide for 20 h at 15° C; (*C*) as (*B*) but held in enclosed atmosphere, after removal from initial 0·25 per cent ethylene oxide atmosphere. Bottom, basis for ratings in Fig. 2

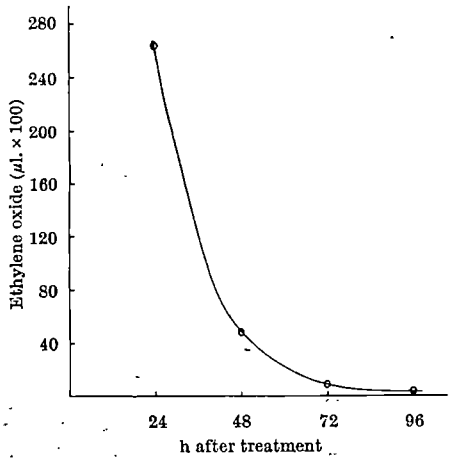

Fig. 3. Expulsion, by roses, of absorbed ethylene oxide into closed atmosphere after initial 20-h exposure to 0·25 per cent ethylene oxide. Chambers were flushed with air each day after assay

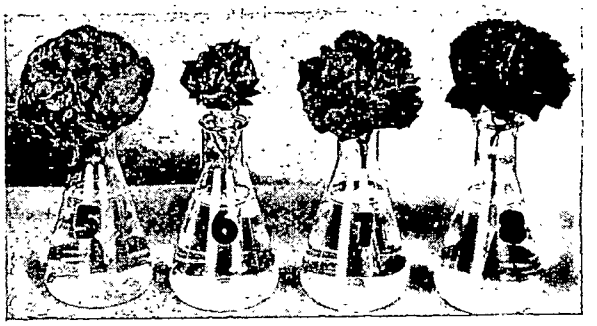

Fig. 4. Effect of ethylene, ethylene oxide, and ethylene and ethylene oxide applied simultaneously, on carnations. Figure shows condition of flowers 2 days after treatment (20 h at 20° C). (5) Control, (6) 1 p.p.m. ethylene, (7) 1 p.p.m. ethylene and 0·1 per cent ethylene oxide, (8) 0·1 per cent ethylene oxide

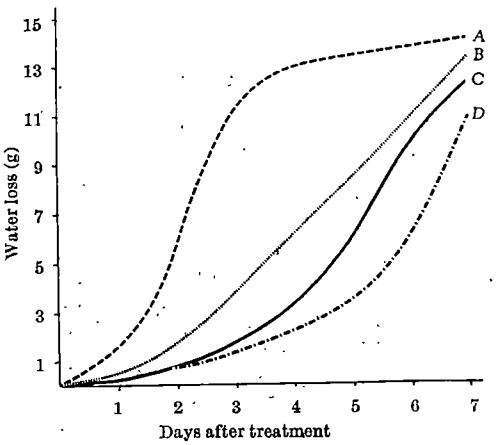

Fig. 5. Acceleration and retardation of water loss by carnations after treatment with ethylene and ethylene oxide respectively. (*A*) 1 p.p.m. ethylene; (*B*) 1 p.p.m. ethylene + 0·1 per cent ethylene oxide; (*C*) control; (*D*) 0·1 per cent ethylene oxide

neutralized by exposure to ethylene oxide. Even the ethylene-induced triple response of etiolated pea seedlings was partially prevented when both ethylene and ethylene oxide were applied simultaneously. Although the etiolated pea seedlings were stunted, they did not show epinasty or swollen growing tips. All these observations, taken together, point to a generalized antagonism of ethylene and ethylene oxide in plant metabolism. The fact that ethylene and ethylene oxide have related structures may be pertinent to their interaction.

If ethylene is a ripening hormone[2], speculation suggests that ethylene oxide may be an anti-ripening or anti-ageing hormone. At any stage in the life of a fruit or flower, the level of ethylene production may be controlled by ethylene oxide. Perhaps minute quantities of ethylene control metabolic events which are important to the young plant. Ethylene oxide may regulate the levels of ethylene in the young plant, thereby preventing excess ethylene and associated catabolic reactions. At the pre-climacteric stage in development of fruit, ethylene metabolism may be released from control by ethylene oxide, and thus allow ageing reactions to go forward at full pace. This may account for the climacteric rise in respiration in fruit metabolism. Suppression of ethylene production by ethylene oxide can be explained by current work which suggests that biosynthesis of ethylene may occur in a reaction sequence, one step of which could be inhibited competitively by ethylene oxide.

Although in earlier work[1] we tentatively identified ethylene oxide in volatiles from cytoplasmic particles from apples, and in volatiles emanating from green tomatoes, this could not be repeated in recent experiments. Therefore, ethylene oxide has not been conclusively identified

as a product of normal metabolism, and, on that account, these speculations on the role of ethylene oxide are not supported. The inability to recognize ethylene oxide in volatiles produced by fruit may be due to its extreme reactivity and solubility, which allow no excess to escape from the fruit tissue. Alternatively, ethylene oxide, produced in the cells, may be immediately converted to acetaldehyde, its less-reactive isomer. Whether or not ethylene oxide is a natural component of plant metabolism, the fact remains that it can act as a reversible anti-ripening or anti-ageing factor. This effect is brought about by suppressing ethylene production and also by directly antagonizing reactions which are stimulated by ethylene.

PRELIMINARY INVESTIGATION OF THE INFLUENCE OF CONTROLLED ATMOSPHERE STORAGE ON THE ORGANIC ACIDS OF APPLES

By DAVID A. KOLLAS

Department of Pomology, Cornell University, Ithaca, New York

IN the procedure described here, apple extract from 'McIntosh' pulp tissue containing 3 m.equiv. of total free acid was separated on 23 cm³ of 'Dowex-1' anion exchange resin into 12 major acid fractions.

The fruit was harvested from a mature tree on two different dates, September 17 and October 5, 1961. The best harvest date, for storage, during this season was September 27. Fruit was put into two commercial-size storage rooms. One was a conventional cold storage room held at 32° F; the other was gas-tight and maintained at 38° F with an atmosphere of 3 per cent oxygen and 5 per cent carbon dioxide. Fruit was analysed at the end of six months' storage in each room. On removal from storage the fruit was frozen at −5° F until the extraction procedure was begun. The frozen fruit was peeled and wedges were cut to the carpels, diced, and dropped (50 g from each of four apples) into 450 ml. of boiling absolute ethanol. This was extracted in a Waring blender and filtered through cheese-cloth; the pulp was re-blended in 250 ml. of 85 per cent ethanol. The filtered juice from the second extraction was combined with the first. Clean-up procedure consisted of evaporation of the alcohol under vacuum at 35° C, centrifugation, and passage over 'Dowex-50' cation exchange resin to remove amino-acids. The use of 'Darco G-60' charcoal, partially deactivated with acetic acid, resulted in the removal of 10 per cent of the total acid from the McIntosh pulp extract. Charcoal treatment was, therefore, not used in these analyses; no problem of resin clogging resulted.

The final column was a shortened 50-ml. burette of 10·5 mm inside diameter, containing 23 cm³ 'Dowex-1' anion exchange resin (200–400 mesh, acetate form) to a height of 25 cm. Sugars were rinsed from the column with 125-ml. distilled, deionized water. Acids were removed from the column by gradient elution with acetic and formic acid. The gradient elution apparatus comprised two polyethylene flasks connected at the bottom by a one-way check valve between the outlets. The principle of the operation of this gradient mixer was similar to one described by Bock and Ling[1]. The system produced a straight-line gradient of acid concentration increase versus volume of eluent run through the column. A flow rate of 1 ml./min was maintained by a pressure head of water and an automatic levelling device[2]. A number of gradient schemes were tested in an effort to obtain good separation of the acids. The scheme that gave the best results is shown in Table 1. Five ml. fractions from the resin column were dried of eluting acid in a vacuum shaker evaporator (Buchler rotary 'Evapo-mix') at 35° C, then dissolved in 5 ml. water and titrated with 0·01 N NaOH.

Table 1. Gradient for 3·0 m.equiv. 'McIntosh' pulp acid

	Mixer flask	Feeder flask	Volume
I	Water	3·0 N acetic	165 ml. each
II	3·0 N acetic	2·3 N formic	145 ml. each
III	4·0 N formic	6·2 N formic	114 ml. each
IV	8·0 N formic		200 ml.

The results, expressed as m.equiv. acid per 100 g fresh tissue, are presented in Table 2. The figures listed are the averages from duplicate samples. Recovery of known acids by this procedure included high values of 120 per cent for quinic and shikimic acids, low values of 58 and 66 per cent for lactic and phosphoric acids, respectively, and values of 91, 93, 95, 100 and 104 per cent for fumaric, glycolic, succinic, citric and malic acids, respectively.

Table 2. Effect of Storage Treatment on Acid Metabolism

Peak	September 17, 1961, pick		October 5, 1961, pick

* Deemed to be significantly different because both the values of the treatment replicates were higher or lower than both the values of the other treatment replicates.

The peak fraction numbers, 1, 2, 3, etc., in Table 2 results indicate the order in which the acids were displaced from the column. Overlapping of adjacent peaks occurred only between peaks 1 and 2 and peaks 3 and 4. However, from the results of one-way paper chromatography it appeared that all the acid peak fractions contained at least two different acids.

The peak fractions of Table 1 were tentatively identified by their R values on the resin column and R_F values on paper chromatograms. It appeared that peaks 2, 3, 7, 8, 10 and 12 included shikimic, quinic, citramalic, malic, citric and phosphoric acids, in that order. Chlorogenic acid was thought to be present and to be eluted from the column between the maxima of peaks 11 and 12. Paper chromatograms of acids from that region produced brilliant blue, yellow, and green colours under ultra-violet light. The sample treated with charcoal did not retain these acids. Similar behaviour was reported for chlorogenic-type acids by Hulmè[3].

Total acid concentration was much greater in fruit from controlled atmosphere storage than in that from air storage. This agrees with earlier reports for total acidity in modified atmospheres[4]. Malic acid, peak 8, accounted for most of the difference in total acid between the two treatments, but there were seven other acid fractions which were found to be greater in fruit stored in the

controlled atmosphere. Quinic and shikimic acids were probably among them. Three acid peak fractions were higher in fruit out of air storage than from 'controlled' storage. These included citric and phosphoric acids.

The differences in the various acid concentrations between treatments could be accounted for by either, or a combination of both, of two ways: either by supposing a difference in the rate of depletion of the acids, or by supposing a greater production of the acids in one storage atmosphere than in the other. Information about the amounts of the acids present at gathering time was not obtained.

If controlled atmosphere conditions simply slowed down the normal processes that occurred in air, one would expect malic acid and quinic acid to be more abundant in the controlled atmosphere, and citric acid and shikimic acid to be lower in the controlled atmosphere. These results would correspond to earlier reports[5-7] that, in air-storage, malic acid decreased at a steady rate, quinic acid decreased during the second half of the storage period after increasing during the first half, citric acid increased slightly in pulp tissue over the storage period, and shikimic acid increased during storage. The actual results reported here agree with these expectations for malic, quinic and citric acid, but not for shikimic acid, since the shikimic peak fraction (peak 2) was greater in the fruit stored in a controlled atmosphere than in air-stored fruit. This peak contained other unidentified acids, however, the relative quantities of which were not determined. It is possible that differences in the unknown acids masked the difference in shikimic acid.

It seems unlikely that the higher malic acid content in fruit stored in a controlled atmosphere could be due to its limited oxidation in low oxygen tensions, since its loss in stored apples has been shown to be independent of oxygen. It was the same in nitrogen as in air[8]. There is evidence that 'McIntosh' apples in air containing 5 per cent carbon dioxide produce malic acid at significant rates by fixation of CO_2 (ref. 9). Thus the higher malic content in applies stored in a controlled atmosphere may have resulted from CO_2 fixation.

The production of citric acid in air-stored fruit[5-7] may be oxygen-dependent. This might account for its higher content in air-stored fruit. Hulme and Arthington[10] have demonstrated that, on oxidation, quinic acid was converted to citric acid and some other acids. Direct evidence for oxidation of quinic acid to citric acid *in vivo* is lacking.

INTERACTION OF PHOSPHORUS-32- AND CARBON-14-LABELLED TRITOLYLPHOSPHATE WITH GLASS SURFACES

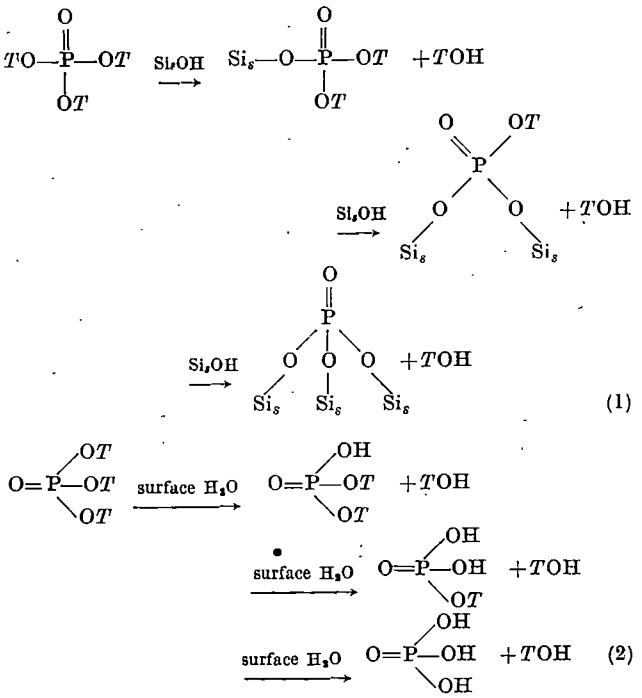
By Dr. MALCOLM E. SCHRADER and IRVING LERNER

U.S. Naval Applied Science Laboratory, Naval Base, Brooklyn, New York

DEPLETION of phosphorus-32 from radioactive phosphate salts of high specific activity has been attributed to adsorption on glass walls[1]. Hensley[1,2] has investigated the adsorption of various anions to glass surfaces. He found that adsorption of these ions occurred only from basic solution under certain conditions. While phosphate ions behaved like the others at room temperature, at moderately high temperatures they exhibited an unexplained unique affinity to the glass surfaces. This indicates a possibility that the phosphate group is capable of forming a stable chemical bond, covalent in nature, with the surface of glass. Since organophosphorus compounds are readily synthesized, chemisorption via the phosphorus functional group may provide a new means of attaching organic groups to glass surfaces. These are useful for various applications, such as coupling agents for glass reinforced plastics or water-repellent coatings. The nature of the interaction of phosphates with glass surfaces is also of importance in the synthesis of radioactive organophosphorus compounds where wall reactions are a serious problem in the use of high specific activity materials.

In the work recorded here an investigation was made of the chemical reactivity of tritolylphosphate (TTP) on the surface of 'Pyrex' and fused silica glasses. In the first series of experiments the TTP was labelled with phosphorus-32, and applied to the surface of 'Pyrex' glass disks from a $1{\cdot}8 \times 10^{-4}$ molar benzene solution. One or more drops of solution were applied to the surface of each disk, the benzene allowed to evaporate, and the radioactivity on the surface counted. The disks were then heated in an oven for various periods of time at various temperatures. Subsequent to determining the radioactivity remaining after heat treatment, the surface layer was extracted with benzene, water, and N hydrochloric acid, successively, and the radioactivity remaining on the surface determined again after each rinsing. In the second series of experiments, the procedure was repeated utilizing carbon-14-labelled TTP. Finally, the procedure was repeated on a pure fused silica surface, at selected times and temperatures, utilizing both phosphorus-32- and carbon-14-labelled TTP.

The 'Pyrex' disks used had a geometric surface area of 2·0 cm^2 and were abraded with dry 120 'Carborundum' paper. To attain optimum reproducibility of adsorption measurements, the abraded surfaces were not polished[1]. The fused silica disks, with a geometric surface area of 3·1 cm^2, were similarly prepared. The phosphorus-32-labelled TTP was a mixture of *ortho*- and *para*-isomers, yielding 420×10^3 c.p.m./μmole in an end window Geiger–Müller counter. The carbon-14-labelled TTP was the *para*-isomer, yielding 228×10^3 c.p.m./μmole in a windowless flow counter.



The radioactivity remaining on the 'Pyrex' disk surfaces after the various treatments is given in Table 1 for phosphorus-32-labelled TTP and in Table 2 for carbon-14-labelled TTP. In both Tables, column 2 gives the total amount of activity applied to the surface as determined after allowing the benzene solvent to evaporate. Column 1 gives the temperature and time of contact of this applied layer with the glass surface. Column 3 gives the activity remaining after contact at the given time and temperature. Columns 4, 5 and 6 show the residual activity on the surface after each of successive rinses in benzene, water, and hydrochloric acid. Table 3 gives these results, at the indicated temperature and time of treatment, for TTP applied to a fused silica surface.

Table 1. Residual Radioactivity on 'Pyrex' Glass Surfaces treated with Phosphorus-32-labelled TTP at Various Temperatures

1 Temperature and time of treatment (°C)	(h)	2 Total activity applied (c.p.m.)	3 Activity remaining after treatment: No rinse	4 Benzene rinse	5 Water rinse after benzene rinse	6 HCl(N) rinse after water rinse
25		3,841		632	14	4
105	0·5	38×10^3	3,549	678	72	36

155	3·0	6,340	2,664	2,004	844	396
155	4·0	7,060	2,724	2,110	844	427
200	1·0	6,355	2,328	2,120	1,040	565
200	2·0	6,414	2,452	2,353	1,218	451
200	3·0	6,810	2,481	2,417	1,446	456
200	4·0	7,211	2,863	2,759	1,476	475

The phosphorus-32 data, taken separately, can be explained according to two general hypotheses, which will henceforth be called I and II. According to I, the TTP which is applied to the surface is partly chemisorbed, with the chemisorbed molecules remaining intact, and the amount of chemisorption increasing with temperature and time of heating. The activity in column 4 represents this chemisorption, while the difference between columns 3 and 4 represents deposited or physically adsorbed material, which is removed with benzene. The action of the water rinse in removing some of the chemisorbed material would then be due to its own hydrolytic action on the chemisorbed TTP to produce phosphoric acid and cresol, followed by removal of the water soluble radioactive phosphoric acid. The phosphorus-32 residue after water extraction would then be that portion of the chemisorbed TTP not hydrolysed by the water wash.

Hypothesis II, on the other hand, assumes that the retention of phosphorus-32 on the glass surface, which is observed to increase with temperature and time of contact, is due to a chemical reaction resulting in fission of the molecule to organic and inorganic fragments. This can result from either of the following two types of reaction:

(1)

(2)

where Si_s is a surface silicon atom, and T is the tolyl radical.

Reaction 1 involves chemical combination of the TTP with a surface silanol group to yield free cresol and a surface silyl phosphate. Reaction 2 consists of hydrolysis of the TTP by surface adsorbed water molecules to yield free cresol and phosphoric acid. The plausibility of reaction 1 is supported by measurements on the adsorption of triethylphosphate to vacuum baked silica powder and *E* glass fibres[3], which gave evidence of the formation of a surface silyl phosphate. Indirect evidence for reaction 2 has been obtained from the wetting properties of smooth silica surfaces treated with tritolylphosphate and other esters[4]. According to hypothesis II, then, the activity in column 4 represents either phosphoric acid (benzene-insoluble) formed according to reaction 2, and/or the surface silyl phosphate formed according to reaction 1. The difference in the values of columns 3 and 4 represents unreacted TTP (benzene-soluble). The water-extraction procedure removes that portion of the activity in column 4 due to phosphoric acid, so that the activity in column 5 represents the surface silyl phosphate formed in reaction 1. The hydrochloric acid hydrolyses part of this surface compound, with the remaining portion accounting for the activity in column 6. It can be seen from column 4, then, that as the temperature or time of heating is increased, the amount of TTP reacting to form either H_3PO_4 or $(Si_sO)_3PO$ increases. From column 5 it is evident that the amount of $(Si_sO)_3PO$ formed increases with temperature or time of heating. A comparison of columns 4 and 5 shows that the ratio of $(Si_sO)_3PO$ to H_3PO_4 increases with increasing temperature. It is interesting to note, at this point, that hypothesis I, unlike II, does not provide an explanation for this increasing ratio of column 5 to column 4 with increasing temperature. Since only one chemisorbed species is postulated in I, there is no particular reason for the amount retained after water extraction to change with increasing temperature of reaction.

The chemical forms of phosphorus represented by the radioactivity values in some of the columns in Table 1 are given in Table 4 for each hypothesis. For simplicity, all product molecules are represented as having undergone reaction at all three functional groups. It can be seen that, according to I, the phosphorus in column 4 remains chemically combined with the tolyl groups. According to II, however, the tolyl groups have split off

Table 2. Residual Radioactivity on 'Pyrex' Glass Surfaces treated with Carbon-14-labelled TTP at Various Temperatures

1 Temperature and time of treatment (°C)	(h)	2 Total activity applied (c.p.m.)	3 Activity remaining after treatment: No rinse	4 Benzene rinse	5 Water rinse after benzene rinse	6 HCl(N) rinse after water rinse

^{14}C	200	1	2,657	21	18	10	5

from the phosphorus portion of the molecule to form cresol, which will no longer be present on the surface due to its solubility in benzene. In column 5, the phosphorus once again retains the organic tolyl groups in the molecule according to I. According to II, however, the tolyl groups are not present. It is apparent, then, that if the experiment wore repeated with carbon-14 labelling, in which case the radioactivity would emanate from the tolyl group, the relative activities in the various columns would remain exactly the same according to I. According to II, however, substantial differences in the relative activities of the various columns must be observed for the two different types of labelling.

Table 4

Column	Chemical forms of phosphorus: Hypothesis I	Hypothesis II
3	TTP + chemisorbed TTP	TTP + H_3PO_4 + $(Si_sO)_3PO$
4	Chemisorbed TTP	H_3PO_4 + $(Si_sO)_3PO$
5	Chemisorbed TTP	$(Si_sO)_3PO$

Examination of the data obtained from carbon-14-labelled TTP, given in Table 2, shows that substantial differences in the activity ratios are indeed obtained. The nature of these differences, furthermore, is in excellent accord with the assumptions of II. For example, a comparison of column 3 with column 2 shows that the amounts of phosphorus-32 activity lost by evaporation increase continually from 8 per cent at 0·5 h and 105° C to approximately 62 per cent for 1 h or more at 200° C. The compound evaporating must be TTP, which has a vapour pressure of 1–10 mm in the range 155–198° C. The increase in evaporation tapers off at higher temperatures and longer times due to the increasing residue of H_3PO_4 and $(Si_sO)_3PO$. The carbon-14 activity in column 3 is lost in equal amounts to phosphorus-32 at low temperatures and short times, where the loss is due essentially to TTP. At higher temperatures and longer times, however, where according to II increasing hydrolysis takes place, the rate of loss of activity increases, in contrast to that of phosphorus-32, which decreases. This is due to the fact that while hydrolysis produces non-volatile phosphorus compounds, resulting in retention on the surface of phosphorus-32, it produces a carbon compound (cresol) more volatile than the original TTP. Consequently, at 200° C where all the TTP is hydrolysed, the carbon-14 activity remaining is only approximately 7 per cent, as compared to 38 per cent for the phosphorus-32 activity. Again, examination of column 4 shows a fairly constant residue of about 5–10 per cent of the activity applied (column 2) at all temperatures. Tentatively taking the residue to be negligible, this is exactly in accordance with II, which assumes the desorption by benzene of all the unhydrolysed TTP, as well as any TOH (cresol) resulting from hydrolysis, which did not already evaporate. The extent to which the surface reaction has taken place does not affect the nearly complete removal by benzene of all remaining carbon-14 activity. According to hypothesis I, of course, the carbon-14 activity would have been present throughout in the same proportions as the phosphorus-32 activity.

The results in Table 3 justify the assumption that reaction of the TTP on 'Pyrex' glass occurs chiefly with the silica network. It is furthermore interesting to note that the residual carbon-14 activity in columns 4 and 5 of Table 2 is no longer present when the reaction occurs on pure silica. This indicates that this activity is due to a small amount of reaction with non-siliceous components of the 'Pyrex' surface.

The simplified representation of hypothesis II in which all product molecules have undergone reaction at all three functional groups is confirmed by the results of the carbon-14 labelling. For example, no more than small amounts, if any, of the compounds $(Si_sO)PO(OT)_2$, or $(Si_sO)_2PO(OT)$, are formed. The results, however, do not preclude formation of the mixed acid-esters $(Si_sO)PO(OH)_2$ and $(Si_sO)_2PO(OH)$ along with, or in place of, $(Si_sO)_3PO$. The formula for the monomeric surface ester postulated is therefore $(Si_sO)_nPO(OH)_m$, where $n=1$, 2, or 3, $m=0$, 1, or 2, and $n+m=3$. The results also do not preclude the possibility of polymerization, which can occur, for example, as follows:

$$(Si_sO)PO(OH)_2 + PO(OT)_2OH \longrightarrow (Si_sO)PO(OH)\text{—}O\text{—}PO(OT)(OH) + TOH$$

where TOH is split off as a result of reaction between a cresyl (OT) group originally present and an acid group present as a result of prior hydrolysis. The same result is also possible, of course, from the splitting off of water between two acid groups.

The reactions of TTP on a 'Pyrex' or fused silica surface may consequently be classified into two overall categories. One involves the formation of a chemisorbed inorganic phosphorus compound joined to the surface by means of an Si_s-O-P linkage. The other consists of hydrolysis of the TTP by water molecules adsorbed at the surface to produce free phosphoric acid and cresol. Ability to form the Si_s-O-P linkage probably accounts for the unusual reactivity of various phosphates with the surface of glass.

HYPERPOLARIZATION OF A NEURONE MEMBRANE BY BARIUM

By Dr. S. NISHI and H. SOEDA

Department of Physiology, Kurume University School of Medicine, Kurume, Japan

The Effect of Barium on the Membrane Potentials of a Neurone Soma

AMONG the divalent cations, barium and strontium are specific in causing some excitable cells to produce an action potential resembling that of cardiac muscle either in the presence or absence of extracellular sodium ions[1–4]. The frog's spinal ganglion cell is such a cell[5], and its action potential is similar in sodium-free barium solution and in solutions of nitrogen compounds of restorative type[6–8]. Tasaki[5] reported that ganglion cells in isotonic barium chloride solution showed the reversed resting potential of +20 to +40 mV or the ordinary resting potential of −40 to −70 mV, and that these potentials could be switched back and forth between the two stable levels by delivering anodal and cathodal pulses alternately. This communication deals with the membrane potentials of the toad's spinal ganglion cells perfused with barium solutions of varying ionic composition. The perfusion was performed in a small chamber in which the solution could be changed in a fraction of a second by a multiple tap. Membrane potentials were

recorded between an ordinary intracellular microelectrode and an indifferent agar–3M KCl electrode.

By substituting the isotonic barium solution ($BaCl_2$, 80 mM; KCl, 2·0 mM; $CaCl_2$, 1·8 mM; and $KHCO_3$, 0·5 mM) for Ringer's solution (Fig. 1, *A*), the resting potential increased approximately 20 mV in less than 15 sec. The increased potential level was maintained almost constant for 2 min, then tended toward a progressive decrease with a slope of 6–10 mV/min, so that the phase of hyperpolarization usually lasted for 5 min. The action potential induced by antidromic stimulation was initially heightened and suddenly fractionated into a smaller spike which eventually disappeared as time advanced. When the succeeding slow depolarization reached the level of about −10 mV, there appeared a sudden reversal of membrane potential (spontaneous firing of the membrane) reaching a level of +80 mV. The reversed potential declined very slowly down to approximately +20 mV, forming a plateau lasting 1–5 min, then abruptly returned to the level of −10 to −20 mV. This level was maintained so long as the flow of barium solution was continued or sometimes a similar potential reversal was repeated. When Ringer's solution was restored the decreased membrane potential returned to the original value with a slope of 3–7 mV/min and the antidromic action potential which had disappeared also recovered.

The reduction of barium concentration down to 40 mM by replacing barium chloride with an osmotically equivalent quantity of sodium chloride did not appreciably change the initial hyperpolarization. On the other hand, the slope of the succeeding depolarization and the height of spontaneous firing were considerably reduced. Further reduction of barium concentration decreased the hyperpolarization and almost none was observable in barium solutions less than 24 mM. The lowering of the peak level of spontaneous firings was fairly logarithmic against the reduction in barium concentration and showed a slope of 45 mV per ten-fold change of barium concentration. A similar relation was also observed when barium chloride was replaced stepwise with an equimolar amount of sucrose.

An increase of potassium concentration up to 10 mM, by replacing barium chloride with potassium chloride, did not alter the hyperpolarization. Further increase in potassium concentration reduced the hyperpolarization and eventually changed it to a depolarization. However, the resulting depolarizations during the first several min in potassium-rich barium solutions were always much smaller than those in potassium-rich Ringer's solutions.

The electrotonic potentials of both hyperpolarizing and depolarizing directions were greatly augmented in barium solutions. The augmentation was usually completed within the first 15 sec of barium flow. The augmented tonic potentials thereafter maintained the same magnitude regardless of the progressive decrease in the resting potential. During the spontaneous firing, however, the magnitude of tonic potentials was greatly reduced and was always smaller than that in Ringer's solution. The tonic potentials in 32, 56 and 80 mM barium solutions were respectively about 2·5, 3·7 and 4 times the initial values in Ringer's solution. The V–I curves obtained from the tonic potentials extended almost in a straight line up to the absolute membrane potential of −20 mV, indicating a marked decrease of the rectifying property of the membrane to outward currents. Thus, barium produced a marked reduction of membrane conductance which might be largely brought about by the decrease of membrane permeability to potassium ions. This is in keeping with the experimental fact that the barium-treated cells became remarkably insensitive to the change in the external potassium concentration.

These results indicate that the diffusion potentials of potassium and sodium ions are not directly involved in the initiation of Ba-hyperpolarization, since the hyperpolarization was independent of external sodium concentration and was unaffected by an increase of potassium concentration. It appears therefore that if the hyperpolarization is entirely due to the change in diffusion potentials across the cell membrane, chloride ion alone would then be responsible for Ba-hyperpolarization. In fact, E_{Cl} across the cell membrane is theoretically increased in parallel with the increase of barium concentration.

To check this hypothesis the preparation was first perfused with chloride-free sodium glutamate solution (Na-glutamate, 112 mM; Ca-glutamate, 1·8 mM; K-glutamate, 2·0 mM; $KHCO_3$, 0·5 mM), and then with the isotonic barium glutamate solution (Ba-glutamate, 80 mM; K-glutamate, 2·0 mM; Ca-glutamate, 1·8 mM; $KHCO_3$, 0·5 mM). In spite of the complete depletion of chloride ion with such a large anion, the cell membrane in this barium solution was hyperpolarized to the same extent as in the isotonic barium chloride solution. The only difference noticed was that the succeeding depolarization in barium glutamate solution appeared slightly earlier, and its slope was greater. Furthermore, the perfusion of the preparation, which was pre-incubated in 10 mM K-Ringer's solution having the same [K] [Cl] product as that of ordinary Ringer's solution, with 10 mM K and 32 mM Ba solution also having the same [K] [Cl] product ($BaCl_2$, 8·2 mM; Ba-glutamate, 23·8 mM; Na-glutamate, 16·0 mM; KCl, 9·5 mM; $CaCl_2$, 1·8 mM; sucrose, 85·0 mM; $KHCO_3$, 0·5 mM) produced a hyperpolarization as large as in the isotonic barium chloride solution (Fig. 1, *B*). The hyperpolarization obtained after pre-incubation in potassium-rich media was thus always larger than that induced without pre-incubation. In fact, pre-incubation of the preparation into potassium-free Ringer's solution markedly suppressed or even nullified the hyperpolarization.

The Mechanism of the Hyperpolarization Effect

It can be concluded from these results that so far as the establishment of Ba-hyperpolarization is concerned the diffusion potential of ions across the cell membrane is not directly involved. Some other process, possibly an active extrusion of some cation or an active intrusion of some anion, is evidently responsible for the hyperpolarization. The most probable mechanism, on the basis of present information, is the active extrusion of sodium ion, since acceleration of the hyperpolarization by pre-incubation in potassium-rich Ringer's solution and its depression by pre-incubation in potassium-free Ringer's solution are well in accord with the property of active sodium extrusion[9,10]. The succeeding slow depolarization and the spontaneous potential reversal were quite dependent on barium concentration, and the latter showed a specific logarithmic relation with barium concentration. The spontaneous potential reversal, therefore, seems to be due to the sudden inrush of barium ion into the cell and its peak level may be determined by the electrochemical potential difference of this ion across the membrane. The succeeding depolarization might be brought about mainly by the decrease in P_K and the passive inward movement of barium ion.

We have now to present more direct evidence in support of this interpretation. First, the relation between the temperature of the perfusing barium solution and the membrane potential was investigated. The preparation was perfused with Ringer's solution, at the same temperature as the barium solution, for more than 10 min before the application of barium solution. The results obtained with isotonic barium chloride solution (Fig. 2) may be summarized as follows: At around 0° C, hyperpolarization was not visible and a slow progressive depolarization occurred immediately after the beginning of barium flow. At around 10° C, hyperpolarization was usually induced, but its magnitude was less than 5 mV. Typical

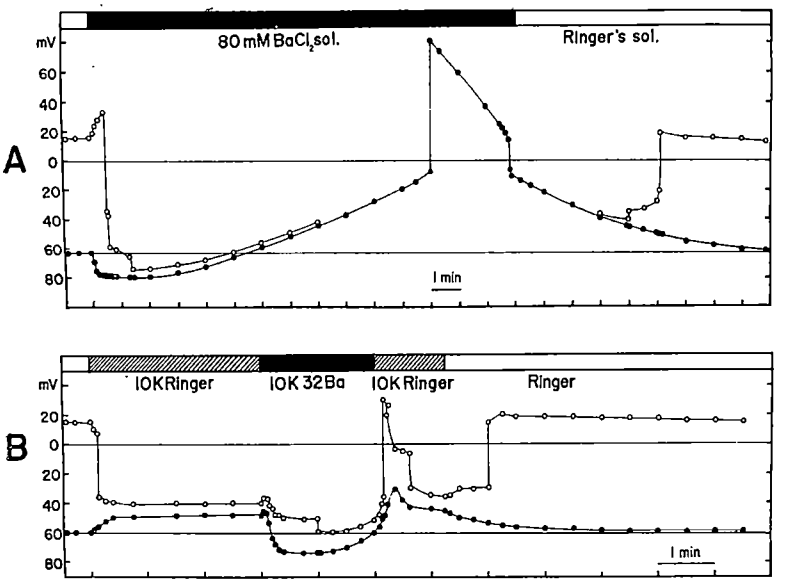

Fig. 1. Alterations in resting potential (solid circles) and the height of antidromic action potentials (open circles) of the toad's spinal ganglion cells perfused with barium solutions. In *A* an isotonic barium chloride solution was substituted for Ringer's solution. In *B* the preparation was perfused with a potassium-rich Ringer's solution before perfusion with a potassium-rich barium solution. The [K][Cl] product of these two solutions was kept the same as that of Ringer's solution

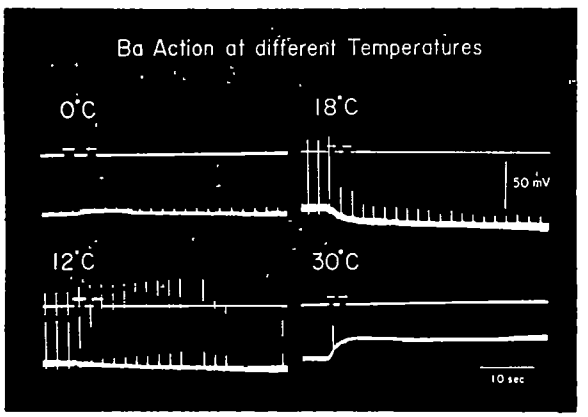

Fig. 2. The effect of isotonic barium solution at different temperatures on the resting potential of the toad's spinal ganglion cells. Barium solution was substituted for Ringer's solution at the beginning of the first rectangular pulse on the zero potential line. Antidromic responses were evoked every 2 sec except under perfusion with barium solution at 30° C. With solution at 0° C the antidromic conduction was blocked at M–NM junction in that particular case (left upper), so that merely M spikes are seen

hyperpolarization was observed in a temperature range between 18° and 22° C. When the temperature of the barium solution was raised to 30° C or more, there was usually no sign of hyperpolarization and the cell membrane was immediately depolarized. The rate of slow depolarization was considerably reduced at a temperature below 5° C and was appreciably increased at 30° C. At all temperatures we have examined, however, the changes in the succeeding depolarization, and the spontaneous firing, were apparently smaller than the alteration in the hyperpolarization. Actually, the Q_{10} of the latter was approximately 3·0 in a temperature range between 0° and 20° C. Such a dependency on the temperature clearly indicates that some chemical process is involved in the initiation of barium hyperpolarization. The conversion of the hyperpolarizing action of barium at around 30° C is difficult to explain at present. However, at such a high temperature the physicochemical nature of the membrane might be made more sensitive to the depolarizing action of barium, or possibly the destruction of some enzyme reduces the chemical force.

Next, the effect of a metabolic inhibitor on the barium action was examined by perfusing the preparation with Ringer's solution containing 2,4-dinitrophenol before applying the barium solution. The membrane potential of the cells perfused with 1 mM dinitrophenol Ringer's solution for 5–10 min usually showed a decrease of up to 5 mV at 20° C. The application to such a cell of barium at the same temperature immediately resulted in a further depolarization. Thus, pre-incubation in a dinitrophenol solution always caused a complete disappearance of hyperpolarization even at the optimal temperature. At around 30° C, similar pre-incubation accelerated the slow depolarization, but the threshold for spontaneous firing was considerably raised. These potential changes were completely reversible when the normal Ringer's solution was substituted for barium solution. The disappearance of the hyperpolarization with the metabolic inhibitor also supports the suggestion that the process underlying the Ba-hyperpolarization has some direct relation to cell metabolism.

It has been reported that the active sodium efflux is roughly proportional to the intracellular concentration of sodium ion[10]. Increase of the intracellular sodium ions must augment Ba-hyperpolarization, if it is associated with the active extrusion of sodium ions. Sodium ions were therefore electrophoretically injected into the cell through the recording microelectrode[7] filled with 3M NaCl before the perfusion of the cell with barium solution. The injection of sodium ions with an outward current of approximately 1×10^{-8} amp for 1–2 min depolarized the cell membrane by 5–40 mV during perfusion with Ringer's solution at around 20° C. By applying isotonic barium solution at the same temperature immediately after the injection, the membrane potential was usually increased by 30 mV or sometimes more than 40 mV. As previously mentioned, the cell membrane is depolarized by the isotonic barium solution at around 30° C. Even at such a high temperature, the membrane potential of the cells which received the sodium injection was increased as much as 20 mV or more by perfusion with barium solution (Fig. 3). The magnitude of the potential increase induced at such a high temperature was usually smaller than at 20° C, but the slope of the succeeding depolarization was markedly reduced in comparison with those induced without sodium injection. These observations may sufficiently prove that Ba-hyperpolarization is accompanied by the active efflux of the intracellular sodium ions.

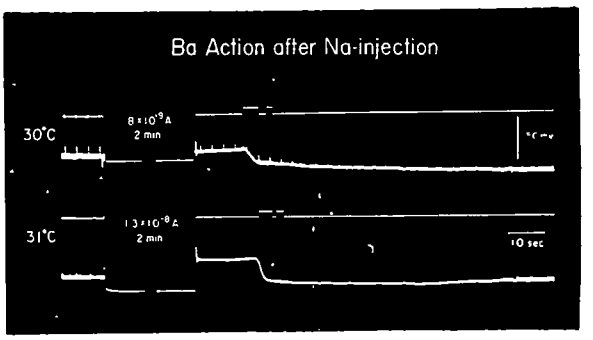

Fig. 3. The effect of barium solution at a high temperature on the cells which received electrophoretic injection of sodium ions through the recording microelectrode. The temperature of perfusing solutions, and the intensity and duration of outward currents used for sodium injection, were indicated on each record. Barium solution was substituted for Ringer's solution at the beginning of the first rectangular pulse on the zero potential line

In the normal Ringer's solution, the potential associated with the active efflux of sodium ions may be totally or partially neutralized by the coupled active uptake of potassium ions[10]. Even if it is not perfectly neutralized its contribution to the resting potential may be negligibly small, since the diffusion potentials of potassium and chloride ions will entirely cover such a potential. However, in barium solution, membrane permeability to normal diffusible ions seemed to be markedly reduced. Moreover, the marked reduction of delayed rectification and the remarkable prolongation of action potentials in barium solution suggest that the potassium-carrying system is markedly suppressed in barium solutions. This again seems to indicate that in barium solution there might occur an uncoupling of sodium–potassium pumping by the suppression of the inward movement of potassium ions. In such a state, the potential accompanied by the active efflux of sodium ions may be unmasked and become large enough to be recorded.

SHOCK-INDUCED FREEZING OF 'ACTIVATED' SUPERCOOLED WATER

By Wm. H. FISCHER and C. ROBERT PERDUE

National Center for Atmospheric Research, Boulder, Colorado

PROF. G. PICCARDI has reported that a mercury bulb (a hollow glass sphere containing a drop of mercury in neon at reduced pressure) "activates" water[1]. Water so treated has properties subtly different from untreated water. The mercury bulb when agitated emits very small quantities of electromagnetic radiation. An examination of this radiation has been reported by Halla and Nowotny[2], and further investigations are being carried out here.

Work on the shock-induced freezing of supercooled water is also under way at this laboratory. It was decided to investigate the effect of 'activation' of water on shock-induced freezing. The cooled shock-tube has been described elsewhere[3] so that full details will not be given here. Suffice it to state that the shock-tube was maintained at −10° C, that the 0·5-c.c. samples were held in glass tubes 2 in. long by 1/4 in. outer and 1/8 in. internal diameter and that a 1·1 lb./in.^{2} over pressure shock wave lasting 2 milliseconds was administered by bursting a 'Cellophane' diaphragm with 15 lb./in.^{2} air pressure.

The water samples consisted of three types. The de-ionized water samples received no treatment. The water had been de-ionized, distilled, and stored in polyethylene carboys. It was withdrawn into a covered beaker and submitted to test.

Blank water samples were subjected to agitation with a bulb containing no mercury. Such a bulb does not emit radiation.

'Activated' water samples were subjected to agitation with a mercury bulb. The agitation in both cases consisted of making a fixed number of revolutions with the bulb in the beaker in a fixed length of time.

The samples were submitted blind so that the shock-tube operator did not know which type of water sample he was handling until after the daily tests were completed. Freezing was carried out within half an hour after agitation.

Table 1 lists the experimental results. Examining the freezing temperature of those samples not receiving a shock and those receiving a shock at one temperature but freezing at a lower temperature (shock ineffective), it is apparent that the recorded natural freezing temperatures were originally in the neighbourhood of −7° C, then rose to about −3° C, and then sharply dropped back to about the original freezing temperature, as shown in Fig. 1 (the line was drawn by eye and should not be regarded as quantitative, but only as indicating the time-temperature trend). The reason for this behaviour is not known, but, with one exception which will be given here, it does not prevent useful analysis of the data.

If a shock is effective in inducing freezing, the sample freezes instantaneously on administration of the shock and the freezing temperature is that at which the shock is administered. If the shock is ineffective, the sample continues to cool in the shocktube until it spontaneously freezes. Fig. 2 is a plot of the temperature at which the shock was administered versus the freezing temperature of the sample. The line is the locus of the points at which shock temperature equals freezing temperature. If the shock is ineffective, the freezing temperature will be below the shock temperature and the plotted point will fall below the line.

Two de-ionized water samples were shocked at −5·5° C, but both froze at colder temperatures, indicating that the shock was not effective despite the relatively low temperature at which it was administered. Other work[3] has shown that there is a threshold temperature, about 2° C above the spontaneous freezing temperature, above which

Table 1. Experimental Results

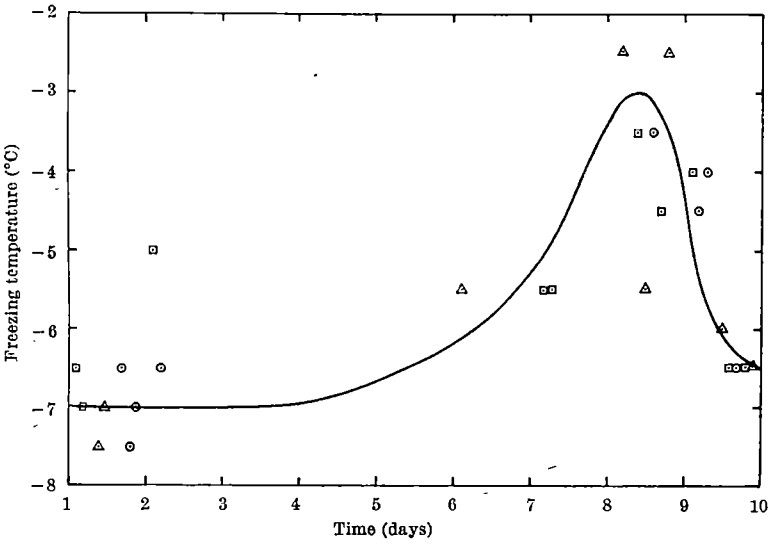

Fig. 1. Time trend of spontaneous freezing temperature of treated water. ○, De-ionized; □, blank; △, activated

shocks are always ineffective. Possibly −5·5° C is in the neighbourhood of this threshold temperature for de-ionized water.

Six blank water samples were shocked. Three exhibited shock-induced freezing, two at the high temperature of −3·5° C. However, another two were not affected at this temperature. The final blank sample was shocked at the intermediate temperature of −4·5° C but was not affected or only slightly affected, freezing at −5° C. These results indicate that agitation alone sensitizes the water to freezing at elevated temperatures induced by administering a shock.

Seven 'activated' water samples were shocked. Only one was shock insensitive—the one shocked at −3° C, the highest shock temperature tried. Possibly −3° C is above the previously mentioned threshold temperature for the 'activated' water. A second 'activated' sample was shocked at −5·5° C and froze at that temperature. The remaining 'activated' samples were all found to be affected by the shock at −3·5° C, a temperature where only 0·5 of the blank samples were affected. These results indicate that the activation process also sensitizes the water to shock-induced freezing and is even more sensitizing than the agitation alone. Water is probably

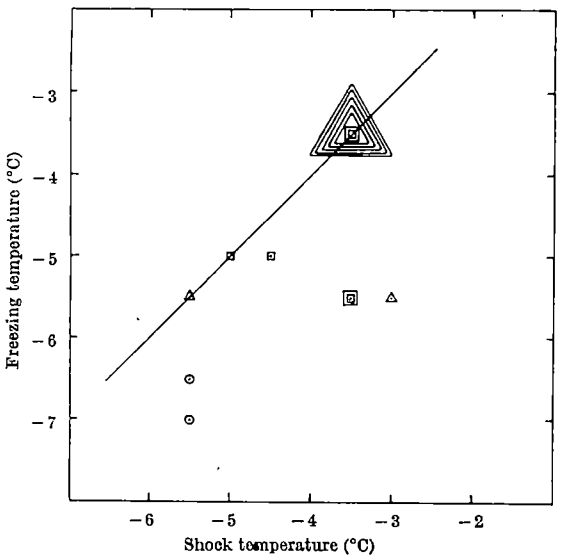

Fig. 2. Effect of shock on freezing temperature of treated water. ○, De-ionized; □, blank; △, activated

sensitized by agitation because air and dust motes are beaten into it, and these then presumably act as freezing nuclei in the presence of shock. The activation sensitization must include this process but also must have an additional effect, functioning at still higher shock administration temperatures, due to the electro-magnetic radiation. At present, the second effect is not understood in a mechanistic sense.

The distribution of the samples is given in Table 2. The paucity of shocked samples of the de-ionized water is due to the extensive study of shock-induced freezing of water to be reported on by others[3]. Comparison of the number of blank and 'activated' water samples affected by shock versus those subjected to shock indicates that 'activation' has a greater effect than agitation alone, in that a higher proportion of 'activated' samples are affected by the shocks.

The actual mean temperatures involved are given in Table 3. The natural freezing temperature in the absence of shock is practically identical for all three samples, indicating that the treatments do not introduce freezing nuclei that are active in the absence of shock at temperatures above those at which nuclei originally present in the de-ionized water samples are active.

Table 2. Distribution of Samples

Sample	No shock	Shocked	Shock effective
De-ionized	6	2	0
Blank	7	6	3
Active	7	7	6

Table 3. Effect of Shock on Freezing Temperature of Supercooled Treated Water

Sample	Freezing temperature (° C) No. shock	Shocked	Shock effective
De-ionized	−5·4	−6·8	—
Blank	−5·5	−4·7	−4·0
Activated	−5·4	−4·1	−3·8

The treatments caused the water to freeze at higher temperatures when subjected to shock. For the blank samples this is probably explainable on the basis of introducing (additional ?) air and dust motes as previously noted. Again, however, the 'activated' water samples are more shock sensitive as shown by their even higher shock-induced freezing temperatures. The lowering of the shock-induced freezing temperatures of the shocked de-ionized water samples must be disregarded as previously mentioned in the discussion of Fig. 1, since this result is based on only two samples, both tested on day 1 when the natural freezing temperature was low and thus does not include samples from subsequent days when the natural freezing temperature was some 4° C higher (Fig. 1). All the other data in Table 3 contain samples obtained throughout the test period and thus reflect an average over all the various natural freezing temperatures.

The last column of Table 3 gives the average freezing temperatures of only those samples whose freezing was induced by shock. It indicates that activation is somewhat more effective than agitation.

This work shows that the electromagnetic radiation from a mercury bulb raises the temperature at which shock-induced freezing occurs in supercooled water.

We wish to thank Dr. G. G. Goyer for making the shock-tube available for this work.

ASTROPHYSICS

Detection of an Interstellar Flux of Gamma-Rays

The intensity and energy distribution of radiation produced by astrophysical processes is important to an understanding of stellar evolution and the mechanism of cosmic ray production and acceleration. Previous efforts to detect a γ-ray flux have been confined to balloon and rocket flights, close to extraneous sources of radiation in the atmosphere and the radiation belts. Although measurable fluxes have been observed in such experiments, only γ-ray fluxes accompanying solar flares have been identified as extraterrestrial in origin[1]. In this communication, we report γ-ray measurements at distances of 7×10^4 km to 4×10^5 km from the Earth, far enough to make contributions from the Earth negligible. The experiment involved operation of a spectrometer on two flights of the *Ranger* spacecraft with the primary purpose of monitoring surface radiation from the Moon. Results obtained in cislunar space point to the detection of a substantial interstellar flux of γ-rays.

The scintillation spectrometer consisted of a 2·75-in. bevelled cæsium iodide (Tl) scintillation crystal, with a plastic scintillator phoswich for the rejection of charged particles[2]. The mass surrounding the inorganic scintillator crystal has a mean value of approximately 2·5 gm/cm², the half-thickness for radiation of 60 keV. Output pulses from the phototube were amplified and analysed in a kicksorter of 32 channels, the last of which counted all pulses above a given level. The detector system was housed in a thin aluminium shell at the end of an extensible 6-ft. boom. The boom was provided to reduce the background of spacecraft-generated secondary γ-rays, and was programmed to extend after operation for 12 h in a stowed position. Data transmission from the earlier flight spanned a period of 40 h; 5 h of results were received from the second flight with the boom in the stowed position only. The combined energy spectra of the two flights cover a range of 70 keV–4·4 MeV.

An initial report on the flux observed between 0·4 and 2 MeV on the earlier flight has appeared previously[3]. The results from this flight have been refined and extended to include the full energy range scanned, as well as the stowed position mode of operation. The contributions from calibration sources of cobalt-57 and mercury-203, and of two extraneous radiation sources have been removed. Data from the second flight have been similarly reduced. In the second flight, the spacecraft was passing through the fringe of the outer radiation belt when the spectrometer began to operate. Therefore, only results received during the last hour of flight, when the reproducibility of successive readouts indicates that the belts had been passed, are considered here.

The observed fluxes from *Ranger* 3 with the detector stowed and extended, and *Ranger* 5 stowed, are shown in Fig. 1. Extension of the boom reduces the contribution of cosmic-ray-induced secondary counts by a geometrical factor of 13. Fig. 1 shows that the actual reduction was much less. From this it is deduced that the contribution of the interstellar flux predominates in the extended position.

The spectra of the two flights in the stowed position are seen to be in reasonably good agreement, although the absolute values differ by about 20 per cent. This difference may or may not be significant.

The upper channels of the *Ranger* 3 extended spectrum appear high since the cross-section for the production of secondary γ-rays is not expected to decrease abruptly above 1 MeV. These count rates were also accompanied by an anomalously high count rate in the overflow channel which appears to have been due to a partial malfunction in the instrument. The differential spectrum varies roughly as $E^{-2.3}$ for the extended case and $E^{-1.7}$ for the stowed. The instrumental response has not yet been unfolded.

Small peaks at 0·51 MeV in both stowed spectra can be attributed to secondary production. The absence of peaks at 0·51 MeV in the extended position, and at 2·23 MeV in the stowed position, of both *Ranger* 3 and *Ranger* 5 sets upper limits for these lines which are generated by pair production and neutron–proton reactions respectively. Based on the *Ranger* 3 results, where long periods of stable performance were measured, these become 0·014 γ/cm² sec for the 0·51-MeV line and 0·005 γ/cm² sec for the 2·23-MeV line.

The integrated fluxes observed are 3·1 counts/cm² sec for 0·09–4·3 MeV on *Ranger* 5, 3·2 counts/cm² sec for 0·12–2·5 MeV on *Ranger* 3 (detector stowed), and 3·1 counts/cm² sec between 0·07 and 1·2 MeV on *Ranger* 3 (detector extended).

The Sun has been eliminated as the source of the observed flux by the lack of any significant change in count-rate response after the *Ranger* 3 spacecraft performed an orientation manœuvre which carried the detector through an angle of 145° with respect to the Sun. Laboratory tests have shown that the detector possesses sufficient anisotropy of response to have produced detect-

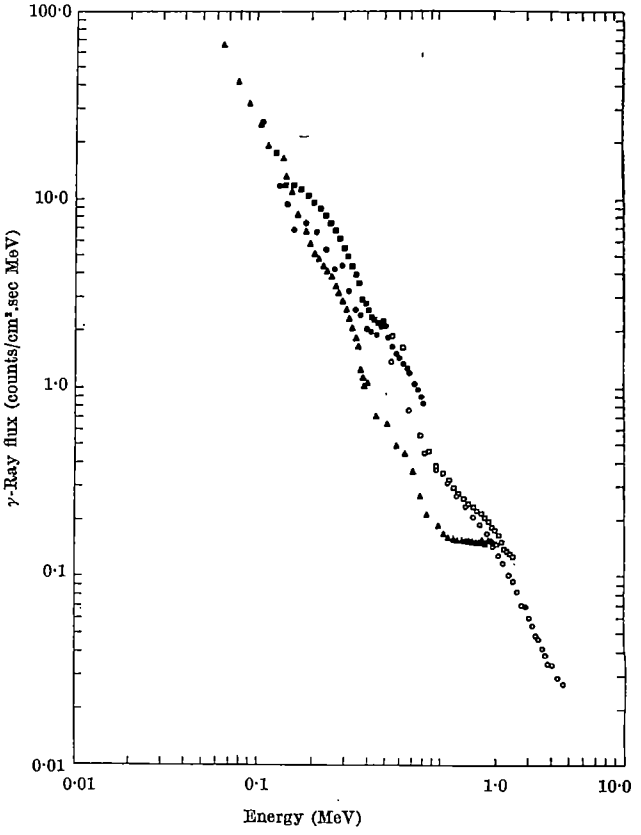

Fig. 1. Energy spectra obtained in cislunar space by the γ-ray spectrometers on *Ranger* 3 and *Ranger* 5. *Ranger* 3, detector stowed; ■, high gain; □, low gain. *Ranger* 3, detector extended; ▲, high gain; △, low gain. *Ranger* 5, detector stowed; ●, high gain; ○, low gain

able changes in count rates at the low-energy end if 25 per cent or more of the flux were solar in origin.

The primary γ-ray flux detected in these experiments is evidently an interstellar flux because of: (1) the distance of the instrument from the Earth and the constancy of count rate with change in distance once the radiation belts are left behind; (2) the comparatively small reduction in counting rate with extension of the detector from the spacecraft, much less than if this were entirely the result of cosmic-ray secondary production; (3) the ability to eliminate the Sun as the prime source.

The intensity of the flux makes a synchrotron origin very unlikely, while the absence of a line at 0·51 MeV makes it unlikely that the flux has been produced by nuclear interactions of high-energy particles. The mechanisms of bremsstrahlung and inverse Compton scattering which have been suggested recently are more promising[4].

Extrapolation of these results to the mean energy of the X-ray flux detected in rocket flights[5] indicates a general agreement. If the agreement is meaningful, certain mechanisms for the production of this X-ray flux such as line transitions and synchrotron emission can be eliminated.

On Intergalactic Gas as a Possible Absorber of Extragalactic Radio Noise

IT has recently been pointed out by Smith[1] that most of the background radiation at low frequencies (< 10 Mc/s) is probably of extragalactic origin. The intensity of this radiation increases with decreasing frequency until about 3 Mc/s where it turns over sharply[1–3]. This turnover is probably due to absorption by ionized hydrogen, the required emission measure being about 4 cm^{-6} pc (for an electron temperature of 10^4 °K). It was suggested by Hoyle and Ellis[4] that the ionized hydrogen lies in a slab parallel to the galactic plane, with an electron concentration $n_e \sim 0{\cdot}15$ cm^{-3} and a thickness ~200 pc. This model has been ruled out by the rocket and satellite observations of Walsh *et al.*[3] and Smith[1], which show that even when integrated over a hemisphere the radiation has a very sharp turnover in its spectrum, corresponding to the emission measure being nearly isotropic around us. These authors suggest[5] that we are surrounded by a more or less spherical *H* II region with, say, $n_e \sim 1$ cm^{-3} and radius ~4 pc (parameters which would not lead to unreasonably large Faraday rotation effects).

This explanation has the unattractive feature that we are required to be near the centre of this region, since otherwise again the turnover would not be sharp. We would like to direct attention to an alternative explanation which avoids this difficulty. This explanation becomes possible if most of the radiation at these low frequencies is indeed extragalactic. According to some cosmological theories extragalactic space is filled with ionized hydrogen of electron density in the range 10^{-5} to 10^{-4} g cm^{-3}. Indirect arguments suggest[6] that the temperature of this gas is in the neighbourhood of 10^5 °K, but these arguments may not be correct, and the temperature may in fact be close to 10^4 °K. In this case the emission measure of the gas out to a Hubble radius lies in the range 0·3 to 30 cm^{-6} pc. Since most of the extragalactic radiation has a path-length of about a Hubble radius the intergalactic gas might be responsible for the absorption. This suggestion has the advantage of providing an immediate explanation for the isotropy of the absorbing region around us.

A detailed calculation of the spectrum expected on various cosmological models leads to rather awkward integrals, and until the observations are more reliable it does not seem worth attempting to fit them closely. However, we can easily make the estimate of the last paragraph somewhat more precise. For simplicity we shall consider only the Einstein–de Sitter and steady state models. The density of the gas in the Einstein–de Sitter model is 2×10^{-29} g cm^{-3} for a Hubble constant τ of 10^{10} years. Its temperature is usually considered to be low (say, a few degrees absolute), but the heating effects of galaxies[6] could raise it to 10^4 °K so that it would then be ionized (which would also avoid difficulties with the 21 cm observations[7–10]). Now in this model 5 per cent of the extragalactic radiation (assumed to have a constant source strength) was emitted at epochs before 10^9 years (on the usual Robertson–Walker time-scale). At that epoch the electron concentration was greater than it is to-day (because of the expansion of the universe). When allowance is made for this, and for the red shift, the effective path-length for this part of the radiation is about 20 $c\tau$. Since the present electron concentration in the Einstein–de Sitter model is 10^{-5} cm^{-3}, this part of the radiation reaches us through a region with emission measure ~6 cm^{-6} pc (on the favourable assumption that the temperature was 10^4 °K over the whole path-length). The corresponding optical depth is unity at about 2 Mc/s. Thus we would expect the intensity to drop by about 5 per cent in the region of 2 Mc/s, as is in fact observed. Owing to the rapidity with which absorption sets in once it has started, this crude calculation suffices to show that the intergalactic gas of the Einstein–de Sitter model could have the required opacity.

In the steady-state model the temperature of the gas is constant, by hypothesis, and again we take it to be 10^4 °K. In this model 5 per cent of the extragalactic radiation was emitted more than 10^{10} years ago. The electron concentration n_e is now constant and because of the red shift the effective path-length for this part of the radiation is less than 10^{10} light years, and is in fact half this quantity. The theoretical value of n_e is uncertain, but if we take the value favoured by me[6], formerly (due to Pirani[11]) of 5×10^{-5} cm^{-3}, the corresponding emission measure is 4 cm^{-6} pc, which again is in satisfactory agreement with observation.

Further observations may make it possible to distinguish between the local and the cosmological explanation for the absorption. Measurements with greater angular resolution would enable tighter limits to be placed on the degree of isotropy of the absorbing region. If the galactic contribution to the background could be detected by its anisotropy it would show the same absorption behaviour as the extragalactic background on the local explanation but not on the cosmological one. A more difficult but more decisive method would be to observe the low-frequency spectra of discrete radio sources, which again should reveal whether the absorbing *H* II region is local or universal. Whichever explanation turns out to be correct these considerations provide

valuable constraints on the possible density and physical state of the intergalactic gas.

Note added in proof. Since this letter was written some new ground-based observations of the low-frequency background have been published: Ellis, G. R. A., *Nature*, 204, 171 (1964); Ellis, G. R. A., and Hamilton, P. A., *Nature*, 204, 272 (1964). These observations appear to support the local explanation of the absorption. However, a final decision awaits confirmation by observations from above the ionosphere.

PHYSICS

Standard Date Periods with Declination Limits

A system of dividing the year into 16 periods, each defined by certain solar declination values having numerically equal positive and negative magnitudes, has been discussed by me in an earlier paper[1]. Research has been continued on the selection of the most suitable declination values and the corresponding dates by examination of ephemerides for the Sun during 1952–64 (ref. 2), resulting in slight modifications of the original selections. Such a system would have many advantages in solar engineering research, where bright Sun conditions are of predominant importance, the computation of solar angles of incidence on variously inclined surfaces being greatly facilitated by the limitation to the five standard numerical declination values shown in the fourth column of Table 1.

The ideal system for sub-division of the year would comply with the following conditions: (1) limiting declination values having numerically equal positive and negative magnitudes; (2) a uniform system of dates for all years in the cycle of four years between successive leap years; (3) the same number of days in each period.

The yearly cycle of the Sun's apparent motion is asymmetrical because of the eccentricity of the Earth's orbit and the inclination of the ecliptic, there being 186·4 days from the spring equinox through summer to the autumnal equinox and 178·8 days from the autumnal equinox through winter to the spring equinox. Hence conditions (1) and (3) are mutually incompatible and condition (3) is quite impossible to fulfil if condition (1) is retained. Conditions (1) and (2) can be closely approximated for non-leap years, but for strict correlation a different sequence of dates should be used for leap years, though this would constitute an undesirable complication of the system. It was decided that condition (2) should be the dominating one for all years, even though this involved deviations of a few minutes of angle on certain dates from the declination values set out in Table 1, which shows the proposed standard dates, limiting declination values and mean declinations for the 16 periods. Declination values are at local apparent noon and the dates are for the meridian of Greenwich (0° long.). No significant change is needed over the range ±3 h International Time Zones, but beyond this range there are a few modifications. The length of period 4*A* must be increased by one day in leap years.

Table 1. System of Dates for Standard Declination Periods

Period	Limiting dates	No. of days	Decln. limits	Mean decln.	No. of days	Limiting dates	Period
1*A*	Dec. 22 Jan. 13[2]	23	−23°27′ −21°30′	−22°47′	22	Dec. 21 Nov. 30[1]	1*B*
2*A*	Jan. 14[2] Feb. 4[1]	22	−21°30′ −16°15′	−19°05′	23	Nov. 29[1] Nov. 7[3]	2*B*
3*A*	Feb. 5[1] Feb. 26	22	−16°15′ − 8°45′	−12°34′	22	Nov. 6[3] Oct. 16[1]	3*B*
4*A*	Feb. 27 Mar. 20	22[5]	− 8°45′ 0	− 4°23′	23	Oct. 15[4] Sept. 23[3]	4*B*
5*A*	Mar. 21 Apr. 12[2]	23	0 8°45′	4°23′	23	Sept. 22[3] Aug. 31[3]	5*B*
6*A*	Apr. 13[2] May 5[2]	23	8°45′ 16°15′	12°34′	23	Aug. 30[3] Aug. 8[3]	6*B*
7*A*	May 6[2] May 28	23	16°15′ 21°30′	19°05′	23	Aug. 7[3] July 16	7*B*
8*A*	May 29 Jun. 21	24	21°30′ 23°27′	22°47′	24	July 15 Jun. 22	8*B*

The above dates are for International Time Zones +3 to −3 h (45°W.–45°E. long.). (1) Retard date by one day for Int. Time Zones +9 to +12 h (135°W.–180°W. long.). (2) Retard date by one day for Int. Time Zones +3 to +12 h (45°W.–180°W. long.). (3) Advance date by one day for Int. Time Zones −3 to −12 h (45°E.–180°E. long.). (4) Advance date by one day for Int. Time Zones −9 to −12 h (135°E.–180°E. long.). (5.) Add one day to period for leap years

The *A* and *B* periods of corresponding number may usually be combined for the purpose of collating data on solar energy utilization, especially as periods of bright sunshine are mainly concerned. This does not imply that the total sunshine hours are equal in the *A* and *B* periods and allowance must be made separately for the relative duration of bright Sun conditions. The system has been found satisfactory for evaluating research on solar engineering applications, and if more widely adopted would facilitate comparisons between different research work as well as simplifying any computation involved.

Propagation of Stress Waves in Liquids

The underlying assumption implicit in work concerned with the propagation of stress waves in liquids is that any pressure disturbance originating at some point in the liquid travels unchanged in form with a velocity $c = \sqrt{(dp/d\rho)}$, which is independent of the density. Such a wave is an 'acoustic' wave, and it is well known that this assumption is amply justified for the small variations of density and pressure usually developed by sound sources under water. But is it justified when the pressure at a point in a liquid rises suddenly by 200 atmospheres (say) due to the passage of a transient stress pulse? The purpose of this communication is to consider this question on the basis of the type of conditions prevailing in previous experiments described by me and other workers[1–3].

Consider unit mass of water at a temperature of 15° C. The initial pressure before the arrival of the stress wave is 1 atmosphere and we require to find the fractional decrease in volume occurring when the pressure rises rapidly by 200 atmospheres. Strictly speaking, we should treat the change as an adiabatic one; but since the adiabatic and isothermal bulk moduli for water differ by so little, we shall obtain a sufficiently good approximation if we assume that the change is isothermal and use the equation:

$$K = V_0 \frac{\Delta p}{\Delta V}$$

Here K, the bulk modulus, is taken to be $2{\cdot}13 \times 10^{10}$ dynes cm^{-2}; V_0 is the volume at 15° C, that is, 1 cm^3; Δp is 200 atmospheres and ΔV the decrease in volume of the unit mass under consideration. This gives us $\Delta V/V_0 = 9{\cdot}46 \times 10^{-3}$, that is, a decrease in volume of about 1 per cent. If ρ_0 and ρ are respectively the initial and final densities then we have, with sufficient accuracy,

$\Delta\rho/\rho_0 = \Delta V/V_0$ and $\rho = 1{\cdot}00946\ \rho_0$. Thus the sudden rise in pressure is accompanied by a density increase of about 1 per cent.

The velocity of propagation U at this higher pressure may, as a first approximation, be estimated by assuming that the pressure changes from its initial value to its final value in an extremely short time, that is, the pressure change approximates to a step-function such as we have in a shock wave. In such a case the value of U is given by the well-known equation of Rankine and Hugoniot, namely:

$$U^2 = \frac{\rho}{\rho_0}\left[\frac{p - p_0}{\rho - \rho_0}\right]$$

In the present case this gives:

$$U^2 = 1{\cdot}00946\left[\frac{p - p_0}{\rho - \rho_0}\right]$$
$$= 1{\cdot}00946\ c^2$$

where c is the acoustic velocity. Thus $(U-c)/c = 0{\cdot}0047$, which is a fractional increase of a little less than 0·5 per cent.

We therefore see that the velocity of propagation U in the regions of higher pressure is only about a half per cent greater than the velocity c of the acoustic waves. Thus the usual assumption that stress wave propagation in a liquid is of the acoustic type appears to be justified and represents a very close approximation to what actually happens.

Fast Flux Reversal in Laminated Nickel–Iron Thin Films

This communication deals with fast flux reversal in 80–20 nickel–iron films laminated with silicon monoxide. The magnetization curves of such films were shown by Clow[1] to be characterized by very low coercive forces. The laminated film used in this measurement consisted of ten laminations of nickel–iron, each 200 Å thick, separated by silicon monoxide of about half the nickel–iron thickness. The silicon monoxide and nickel–iron layers were deposited alternately using a differential shutter. A control film was deposited at the same time but screened from the silicon monoxide, and therefore was essentially a solid film of nickel–iron 2000 Å thick. The films were 1 cm diameter spots evaporated on to glass substrates at 320° C in a pressure of about 1×10^{-5} mm mercury. The nickel–iron deposition rate was 25 Å/sec. The laminated films had an easy direction coercivity, $H_c = 0{\cdot}17$ œrsteds, and an anisotropy field, $H_K = 3{\cdot}9$ œrsteds, while the control films had $H_c = 0{\cdot}76$ œrsteds and $H_K = 3{\cdot}4$ œrsteds.

The flux reversal measurements were made in a 50 Ω strip line section with a centre member 2·5 cm wide to ensure a uniform field at the sample. The current pulse was obtained by discharging a cable through a coaxial relay with mercury wet contacts. The field pulse had a rise of less than 0·5 nsec with a duration of 1 μsec and was continuously variable in amplitude. The flux change was observed with a single turn loop around the centre of the film arranged as a bridge in conjunction with another loop, with provision to balance the inductive voltage in both amplitude and time. The flux change was observed by integrating the induced voltage with an active integrator with a response time of 1·25 nsec, a decay time of 12 μsec and an effective gain of 1 V-μsec for 0·5 V output.

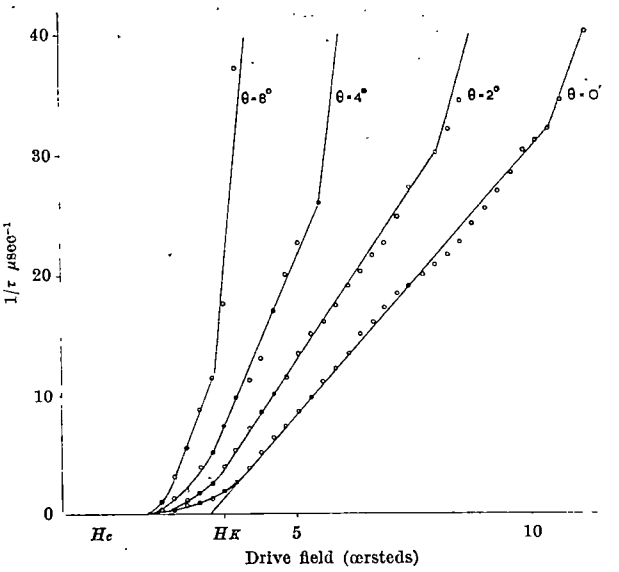

Fig. 1. Inverse reversal time as a function of drive field, with the initial angle as a parameter, for a thin nickel–iron film used as a control when the laminated film was made

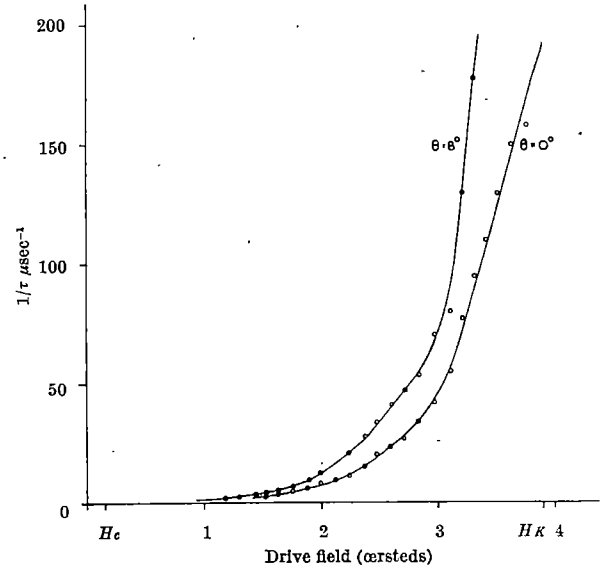

Fig. 2. Inverse reversal time as a function of drive field, with the initial angle as a parameter, for a laminated nickel–iron film.

The output of the integrator was observed using a conventional sampling oscilloscope with a response time of 0·6 nsec. The reversal time, τ, was measured as the time from 10–90 per cent of the integrated flux. Various coils were arranged around the sample to provide the reset field, transverse field and Earth's field bucking.

Fig. 1 is a plot of the inverse of the 180° reversal time as a function of the pulsed driving field in the presence of a static transverse field $H_\perp$. The parameter shown is the initial angle, θ, calculated as $\sin^{-1} H_\perp/H_K$, assuming single domain behaviour. This result is typical of films where three characteristic regions[2] are observed. The intermediate drive region (for $\theta = 0$) is linear and has a slope of about 5 (μsec œrsted)$^{-1}$ with an extrapolated intercept for infinite reversal time of about H_K. The sensitivity to initial angle is also typical.

Fig. 2 gives the results for the layered film (note the change of scale from Fig. 1). To preserve the single domain character of the film when the demagnetizing field was large compared with the coercive force, a constant field of 0·2 œrsteds was applied parallel to the easy

axis in opposition to the pulsed driving field. All results have been corrected for this field. It can be seen that the linear portions of the plot have disappeared, that the sensitivity to initial angle has disappeared and that reversal times as short as 2 nsec were obtained for fields less than H_K. This character can be ascribed to the layered nature of the films since other films of essentially the same low coercive force, and single films with thicknesses about 200 Å, exhibit reversal character similar to Fig. 1.

Single Sweep Oscillograph Traces of Sonoluminescence

It has been reported[1–7] that sonoluminescence, which is a weak light emission accompanying ultrasonic cavitation in certain liquids, occurs as a discrete flash once every cycle of the stimulating acoustic field. However, I have recently obtained photographs of single-sweep oscillograph traces of the anode current of a photomultiplier used to observe sonoluminescence, and these photographs show that whereas sonoluminescence does occur as pulses always at roughly the same phase of the sound field, the pulses do not occur with every cycle (Figs. 1 and 2. The upper member of each of the pairs of traces shown in these photographs is the sound field).

Cavitation was produced in tap-water with a magnetostrictive window type transducer coupled to a double quarter wave velocity transformer, the system being capable of delivering a total of about 10-W acoustic power at a frequency of 21·2 kc/s over an area of about 0·3 cm². The sonoluminescence trace was obtained by inserting a 5 k ohm resistor in the anode lead of a 15-stage E.M.I. photomultiplier and displaying on a 'Tektronix' oscilloscope. Figs. 1 and 2 were photographed on 'Polaroid' film of 3,000 A.S.A. rating.

It might appear that the probability of a sonoluminescence pulse arising during a given cycle of the sound field (about one-fifth in this investigation) is linearly related to the probability of a suitable nucleus being present in the volume of water where the sound pressure exceeds the threshold value and during the interval that this condition is fulfilled. It would then be reasonable to expect

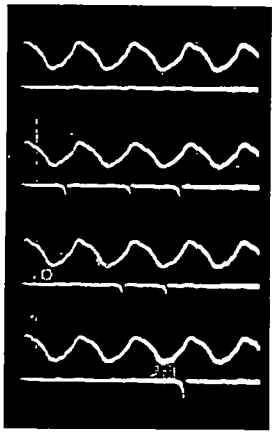

Fig. 1. Oscillograph traces of pick-up voltage and photomultiplier anode voltage (single sweep)

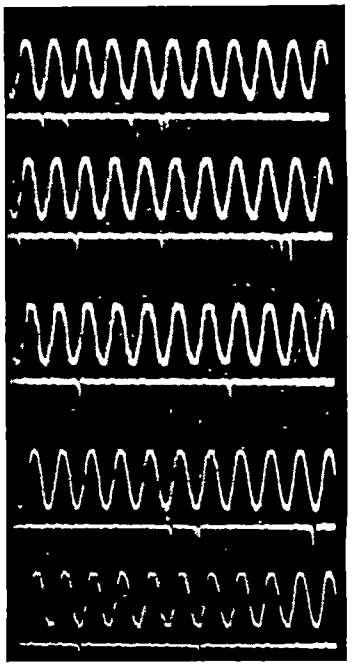

Fig. 2. Oscillograph traces of pick-up voltage and photomultiplier anode voltage (single sweep)

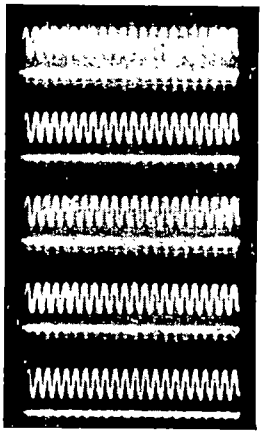

Fig. 3. Oscillograph traces of pick-up voltage and photomultiplier anode voltage (many sweep)

many sweep oscillograms to show an averaging effect whereby the sonoluminescence seems to occur as a flash with every sound cycle (Fig. 3).

Fig. 2 shows that occasionally more than one pulse occurs at about the same time. The frequency of such events is consistent with the chances of two nuclei being present almost simultaneously in the sensitive region during the prescribed interval (about 1/25). The possibility of two pulses arising from the rebound or disintegration of a single nucleus must also be admitted, however.

Variation in the Ratio of Strontium-89 to Strontium-90 in Precipitation Samples with Sampling Height

It was shown that during March–December 1959 (ref. 1) the specific activities of fission products from fall-out in precipitation increased with sampling height. Some evidence was also found for an increase in the ratio $^{89}Sr/^{90}Sr$ with sampling height, but this increase was not significant ($P \sim 90$ per cent).

(where y is the transformed $^{89}Sr/^{90}Sr$ ratio, and x is the sampling height).

An analysis of variance showed significant differences between the slopes for dry and wet months for both group I ($P \sim 99$ per cent) and group II ($P > 99$ per cent) (Tables 2 and 3).

Hence, it is evident that in 'dry' months the slope was significantly steeper than in the 'wet' months, that is, the $^{89}Sr/^{90}Sr$ ratios in 'dry' months were significantly higher in the upper precipitation collectors than in the lower. An

about lines	0·4147	57	$0·7275 \times 10^{-2}$	
between slopes	$0·5045 \times 10^{-1}$	1	$0·5045 \times 10^{-1}$	6·94

Table 3. Comparison of the Lines in Group II. Analysis of Variance

Variation	Sum of squares of deviations	Degrees of freedom	Variance	Test
about lines	$0·7378 \times 10^{-1}$	114	$0·6472 \times 10^{-3}$	
between slopes	$0·4952 \times 10^{-3}$	1	$0·4952 \times 10^{-3}$	7·65

After the resumption of large-scale nuclear testing in September 1961, it became possible to repeat the experiment over a longer period. The $^{89}Sr/^{90}Sr$ ratios were determined in precipitation collected at eight different heights in the meteorological mast at Risö after the principles used in 1959 (ref. 1).

Table 1 shows the results for the 24-month period: October 1961–September 1963.

The $^{89}Sr/^{90}Sr$ ratios in Table 1 were treated as follows. The ratios were converted to the logarithms, because the figures were logarithmically distributed. The converted ratios for each month were divided by the corresponding (converted) mean ratio for the month. The purpose of this operation was to eliminate the effect of the time variation of the $^{89}Sr/^{90}Sr$ ratios. The months were separated into two groups, one with high variance (I) and one with low (II). This was necessary for the performance of a regression analysis, where the differences in the variances have to be insignificant. The two groups of months were each sub-divided into two sub-groups, one representing 'dry' month (*d*), that is, months with less than 25 mm precipitation and another representing 'wet' month (*w*), that is, months with 25 mm and more precipitation (Table 1).

The following regression lines were calculated:

$$y = 1 + 0·1040 \times 10^{-2} (x - 46·55) \quad (Id)$$

$$y = 1 - 0·4452 \times 10^{-3} (x - 52·13) \quad (Iw)$$

$$y = 1 + 0·4050 \times 10^{-3} (x - 52·13) \quad (IId)$$

$$y = 1 + 0·6857 \times 10^{-5} (x - 52·39) \quad (IIw)$$

explanation for this phenomenon has been proposed earlier[1]: it is assumed that the dry deposit, which yields the higher concentrations in the upper precipitation collectors, is of greater particle-size than the deposit from rain. Larger and heavier particles will be deposited more readily than fine particles, and consequently the coarse particles will consist of younger fission products (greater $^{89}Sr/^{90}Sr$ ratio) than the fine ones.

I thank Mr. Heinz Hansen for his advice concerning the statistics.

Equivalence of the Schroedinger and Heisenberg Pictures

In a recent re-examination[1] of the foundations of quantum mechanics, Dirac asserts, *inter alia*, that the Heisenberg and Schroedinger pictures in quantum electrodynamics are not equivalent because the unitary operator which connects both pictures, namely $e^{iHt/\hbar}$, where $H = H_{\text{Dirac field}} + H_{\text{Maxwell field}} + H_{\text{interaction}}$, is the total Hamiltonian in the Schroedinger picture, does not exist. It is the purpose of this communication to question this assertion.

It is assumed from the outset that H is, in common with all observables in quantum mechanics, self-adjoint; that is, $H = H\dagger$ and $\mathfrak{D}_H = \mathfrak{D}_{H\dagger}$, where $\mathfrak{D}_H$ and $\mathfrak{D}_{H\dagger}$ are the domains of H and its adjoint in the Hilbert space $\mathfrak{H}$ of the system. Accordingly, if $\{E(\lambda)\}$ are the projectors comprising the resolution of the identity belonging to H and if $F(\lambda)$ is an arbitrary complex-valued function of λ, then the operator $F(H)$, with the domain $\mathfrak{D}_F$, is defined[2] by the Radon–Stieltjes integral:

$$< \Phi|F(H)|\Psi > = \int_{-\infty}^{+} F(\lambda)\mathrm{d}(< \Phi|E(\lambda)|\Psi >)$$

for all $|\Phi>$ in $\mathfrak{H}$ and all $|\Psi>$ in the set $\mathfrak{D}_F$ of all vectors in $\mathfrak{H}$ such that $\int_{-\infty}^{+\infty} |F(\lambda)|^2\mathrm{d}(||E(\lambda)|\Psi>||^2)$ exists. Hence, if $F(\lambda) \equiv e^{i\lambda t/\hbar}$, then $\mathfrak{D}_F$ is the set of all vectors $|\Psi>$ in $\mathfrak{H}$ such that $\int_{-\infty}^{+\infty} \mathrm{d}(||E(\lambda)|\Psi>||^2)$ exists. And since $\lim_{\lambda\to-\infty} E(\lambda)|\Psi> = |0>$ and $\lim_{\lambda\to+\infty} E(\lambda)|\Psi> = |\Psi>$ for all $|\Psi>$ in $\mathfrak{H}$, it is clear that $\mathfrak{D}_F = \mathfrak{H} \supset \mathfrak{D}_H$, so that $e^{iHt/\hbar}$ certainly exists. Also, using[2]

$$< \Phi|G\dagger(H)F(H)|\Psi > = \int_{-\infty}^{+\infty} G^*(\lambda)F(\lambda)\mathrm{d}(< \Phi|E(\lambda)|\Psi >)$$

it is evident that $e^{iHt/\hbar}$ is unitary and that H is identical in both pictures.

Thus the Schroedinger and Heisenberg pictures are equivalent, provided merely that H is self-adjoint.

H. S. Perlman

H. S. Perlman assumes that H is a self-adjoint operator, operating in Hilbert space. This assumption is not valid in quantum electrodynamics. H, like the other dynamical variables, then operates on vectors in some kind of space, larger than a Hilbert space, the nature of which is unknown.

GEOLOGY

Kink-bands and Related Geological Structures

Dr T. B. Anderson[1] considers that kink-bands are symmetrically distributed about a planar anisotropy caused by cleavage, and that this is indicative of the major principal pressure acting within the cleavage. This is not justified since in rocks with strong planar anisotropism there is no basis for interpreting "a component parallel to the strike of the *s*-surface"[1,2] as the maximum principal pressure. Indeed, according to Hoeppener[3], the view that the maximum principal stress bisects the obtuse dihedral angle may be fallacious.

However, permitting Anderson's assumption, it is apparent from his values that the kink-bands are not symmetrically arrayed about the modal cleavage. This asymmetry may be explained in terms of a small discrepancy in the modal cleavage value; but it probably reflects true variations in the orientation of the kink-bands since, although the dextral kink-bands are very consistent in their orientation, it would appear from Anderson's statement that the sinistral ones are less so. Further, the two kink-bands in Anderson's Fig. 2, because they do not intersect, are not truly conjugate and may be explained in terms of a first-order shear on which a second-order shear has developed. One must, therefore, question that Anderson's kink-band system is the product of irrotational strain as would be the case where P_{max} is contained within the cleavage. This is critical, for should P_{max} not be contained within the cleavage of strongly planar-anisotropic rocks the strain will be rotational, P_{max} will not bisect the obtuse dihedral angle and the kink-bands will not be symmetrically disposed about the *s*-surface.

It is important to Anderson's theory that, as stated by him, "The orientation of the kink-band itself does not change". However, in a summary of work from the Rhenish Schiefergebirge, Hoeppener[4] concluded that relative rotation between the rock and the shear-planes must occur. Similarly, in the Start Point area[5], South Devon, where steeply dipping kink-bands cross a sub-vertical cleavage, I observed in plan view and on the cleavage face kink-bands of the same movement-sense crossing each other, bifurcating and converging.

For the orientation of the kink-bands to be consequential on the rotational movements on the foliation surfaces between the kink-planes, as suggested by Anderson, it is implicit that the direction of shear paralleling the kink-bands is also consequential. In south Devon, however, I have traced a kink-band along its strike into a single kink-plane with associated pinnate tension joints[6], in turn passing into a strip of tension gashes *en echelon* (Fig. 1). Similar associations are figured by Engels[7], and in all cases the movement-sense is consistent throughout the association. Thus, the direction of shear paralleling the kink-band must be the primary displacement, while rotational movement on the foliation surfaces between the kink-planes is secondary.

Although greater variation in the angle of internal friction (φ) might occur, it is generally thought to lie between 25° and 35° (ref. 8). According to Anderson's theory this would place limiting values of 115° and 125° on the dihedral angle between conjugate kink-bands containing P_{max}. However, Hoeppener[3] recorded values ranging between 105° and 140°, Ramsay[9] reported values of less than 90°, and I have noted values of less than 90°

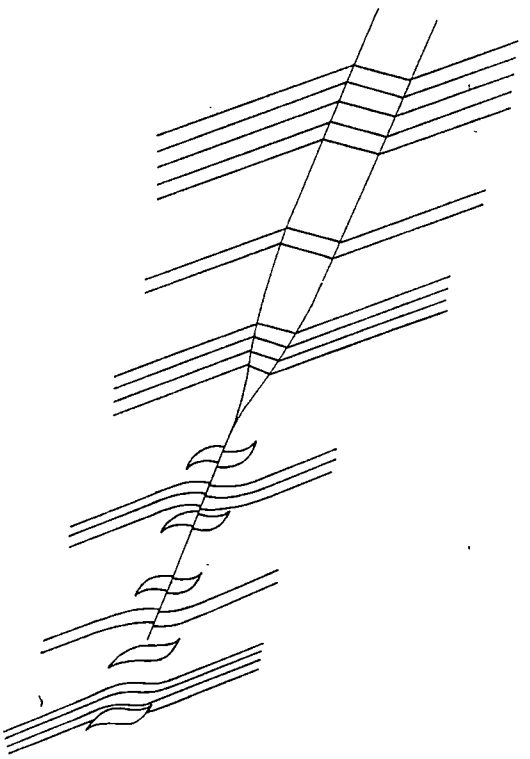

Fig. 1. Diagrammatic association of kink-band, pinnate tension joints, and tension gashes

ranging up to 140°. Therefore, although an extreme value of φ (= 50°) might be advocated to account for the 140° dihedral angle, the less than 90° values are inexplicable by Anderson's hypothesis.

Where regional data are evaluated statistically, the angular spreads of the kink-bands and cleavage about their modal values should be given. This will permit a fuller understanding of the behaviour of the kink-bands with respect to the cleavage. For example, given that the modal values indicate an approximately symmetrical distribution of kink-bands about the cleavage, should the dextral kink-band exhibit a wide angular spread while the cleavage and sinistral one have narrow values, it will be apparent that the regional relationship between the kink-bands and the cleavage has a degree of asymmetry.

In conclusion, I fully support Anderson's view that kink-banding is an incipient strain-slip cleavage, but would not exclude other geneses of this structure.

[9] Ramsay, J. G., *Geol. Mag.*, 99, 525 (1962).

MARSHALL's statement that I considered "that kink-bands are symmetrically distributed about a planar anisotropy caused by cleavage" is scarcely a fair synopsis of the sentences: "In any one area the kink-bands may all be roughly parallel and all may have the same sense of displacement. However, conjugate sets, composed of kink-bands in two different orientations with complementary displacements, are not uncommon"[1]. Clearly I fully realized that kink-band systems are not all symmetrical about the foliation and that the symmetrically arranged conjugate set is a special case.

The clause "there is no basis for interpreting 'a component parallel to the strike of the *s*-surface' as the maximum principal pressure" is vague and uses its quotation out of context. In fact, I followed Flinn[2] in stating that kink-bands are "the expression of a movement which can have a component parallel to the strike of the *s*-surface"[1]. I also said that "kink-bands effect a shortening parallel to the original foliation" and may be "interpreted as a response to a major principal stress acting in a direction contained in, *or close to*, the original foliation"[1]. This obviously does not imply that kink-bands are necessarily produced by a maximum principal pressure acting exactly along the foliation.

Marshall goes on to allege that the kink-bands I described from the Ards Peninsula[1] were "not symmetrically arrayed about the modal cleavage". The modal values given[1] were: dextral kink-bands, N.15° E.; sinistral kink-bands, E.40° S.; modal cleavage plane, N.70° E., all planes being approximately vertical. The modal cleavage plane was therefore within 2·5 degrees of exactly bisecting the obtuse angle between the kink-bands. This, as Marshall must know, is very well within the limits of experimental error in the measurement of the orientation of small planar structures in a structurally complex area. The deviation from perfect symmetry is negligibly small.

Marshall also alleges that the two kink-bands shown in my Fig. 2 "because they do not intersect, are not truly conjugate". In his paper on conjugate folds Ramsay[3] states "conjugate folds may be defined as sets of paired reversed folds whose axial planes are inclined toward one another". In this accepted sense the kink-bands shown are conjugate. Marshall clearly has his own definition.

Marshall contends that the two kink-bands in Fig. 2 "may be explained in terms of a first-order shear on which a second-order shear has developed". In fact neither kink-band is a shear plane, nor is it parallel to a shear plane. However, treating the two structures as shear planes of opposite sense, one first-order, the other second-order, measuring the angle between and using the formula in McKinstry's paper[4], to which Marshall refers, a value for φ of either 9° or 51° is obtained. Both of these are well outside the range of possible φ values Marshall himself quotes.

Marshall's observation of kink-bands of the same movement-sense crossing each other, bifurcating and converging does not conflict with my view that during the formation of a single kink-band the orientation of the band does not change. The sentence he quotes is again taken out of context. Taking the simplest analogy, the fact that faults may cross-cut, bifurcate and converge does not mean that each fault-plane changed its orientation during faulting.

I fail to see how a kink-band, defined essentially by two kink-planes, can pass "along its strike into a single kink-plane", the axial surface of a single fold. Certainly Marshall's Fig. 1 does not show this phenomenon. The two kink-planes of the kink-band illustrated converge and pass into a shear plane, not a kink-plane. Unfortunately, the critical transition point is not adequately illustrated.

Marshall argues from Fig. 1: "the direction of shear paralleling the kink-band must be the primary displacement, while rotational movement on the foliation surfaces between the kink-planes is secondary". Since the displacement effected by the kink-band is a product of the shear movements on the foliation and the one cannot exist without the other this is a circular argument. In many kink-bands there is no "shear paralleling the kink-band". The displacement across the band is effected by folding alone and the foliation planes are continuous. Without a primary shear plane the movement on the foliation planes can hardly be described as secondary.

Marshall states that the angle of internal friction (φ) is "generally thought to lie between 25° and 35°" and refers to a paper by Hubbert[8]. In fact, Hubbert[8] (p. 364) states: "Thus from fault data . . . the angle of internal friction would lie between 10° and 50°". Substituting these values for those quoted by Marshall neatly accounts for the range of 'dihedral angles' reported by Hoeppener[6], and, in fact, the mid-point of Hoeppener's range (122°) coincides almost exactly with the prediction (120°) obtained by taking the mid-point (30°) of either of the φ ranges quoted as a basis for calculation. I would accept this as a support rather than a contradiction of the angular relationship I outlined.

While conjugate faults usually enclose an angle of less than 90° about the direction of maximum principal pressure[7], field geologists occasionally observe pairs of conjugate faults which are apparently exceptions to this rule, implying negative values of φ, though these are comparatively rare and do not affect the correctness of E. M. Anderson's[7] conclusions when modal orientations calculated from adequate data are considered. A very similar situation seems to obtain in the geometry of conjugate pairs of kink-bands. Here values of less than 90° for the same angle are as exceptional as values of more than 90° among conjugate fault systems.

Finally, it appears that Marshall has not considered the recent experimental work of Paterson and Weiss[9]. These authors produced kink-bands by compressing cylinders of phyllite under high confining pressure. "In the specimens compressed parallel to the foliation, the kink-bands are in symmetrically oriented conjugate sets". Individual bands "appear at approximately 50° to the direction of shortening", that is, making in conjugate

pairs an angle of 100° about the maximum principal pressure. In cylinders inclined at small angles (less than 25°) to the foliation asymmetrical conjugate sets developed. At angles of 25°–45° only one set of kink-bands appeared and at greater inclinations of the foliation to the cylinder axis, and hence to the maximum principal pressure, the deformation took other forms. No mention is made of any change in orientation of the kink-bands during growth.

These experimental results are in good agreement with the geometrical relationships and mechanisms of formation I outlined, particularly with the statement that kink-bands "may be interpreted as a response to a major principal stress acting in a direction contained in, or close to, the foliation".

Live and Dead Foraminifera between the Sarns, Cardigan Bay

The Sarns of Cardigan Bay are submarine ridges of boulders, cobbles and pebbles, running out to sea at right angles to the coast. The longest, Sarn Badrig or St. Patrick's Causeway, is more than 13 miles long. These striking features, and the areas of finer sediment between them, are being investigated. During the summer of 1961 samples were collected from sand areas in shallow, near-shore waters above the five fathom line, off Aberystwyth, off Clarach and off Borth in Cardigan Bay. These samples were surface skims of sediment obtained by use of 'Normalair' aqualung equipment from a rubber boat. Dr. T. D. Adams and Mr. W. Barrett assisted with this work. Analysis of the fauna in these samples by the standard rose bengal staining technique[1] revealed that all the foraminifera were dead, and many of the shells were abraded and worn.

In late 1962 the Department acquired the research vessel, *Antur*, and systematic bottom sampling of the whole area between Sarn Cynfelyn and Sarn Badrig was undertaken. This work was done in co-operation with Dr. H. A. Jones and Mr. J. R. Moore, III, the object being to map recent sediment distribution and its relation to living and dead foraminifera, and to other forms of marine life. Most of the samples were collected with the Holmes vacuum grab, others with the Van Veen grab. Boat operations were continued through the winter of 1962/63 and an area of about 200 square miles was sampled at approximately one-mile intervals. This survey covered the area between the Sarns down to the 10-fathom line and made it possible to compare samples collected at different seasons.

Petrological work by Mr. Moore shows that the predominant sediments in this area are fine sands ($\frac{1}{4}$–$\frac{1}{8}$ mm) with subsidiary patches of coarse sands and sandy gravels. Living specimens of foraminifera are absent from these sediments—not only from samples collected by the Van Veen grab, where it could be argued that surface sediment was swamped by subsurface material, but also in vacuum grab samples of less than 50 ml. where the sediment included a high proportion of surface material.

As was shown by Herdman and Lomas[2] the net current movement, and thus transport of sediment, in the shallow parts of the eastern Irish Sea, is landwards. Admiralty charts show that currents up to 1 knot obtain in the area between the Sarns. These speeds are quite sufficient to transport smaller foraminifera, average size between 0·1 and 0·5 mm (ref. 3). This indication that the dead foraminifera are moving with the sediment is strongly supported by their marked size sorting. In the fine sand areas they fall mainly on the 100 mesh (152 microns) sieve. In the coarse sand and gravel areas the majority are found in the 60 mesh (251 microns) sieve with some well-grown forms on the 30 mesh (500 microns) sieve.

Clues to the origin of at least some of the species found dead in the current-swept sand of the bay are provided by samples from the Sarns themselves. Parts of the Sarns are awash at low spring tides. They are thus shallow banks providing convenient anchorage for many kinds of marine algae and associated life forms. Cobbles and boulders obtained with the Van Veen grab, particularly from Sarn Bwch, carry a rich assemblage of algae, hydroids, tunicates and bryozoans with associated molluscs and foraminifera. Most of the foraminifera are living, and include not only fixed forms, such as *Cibicides*, but also numerous members of the Miliolidae. When they die these forms are undoubtedly swept into the sands. Foraminifera also live on the surface of the relatively small areas of mud deposition in the Bay, such as in the 'trawling grounds' south of Sarn Cynfelyn. It is unlikely that specimens from these quiet areas are worked into the sands (though the muds include specimens which may have been winnowed from the sands). There are, however, many forms in the dead assemblage that occur neither on the Sarns nor, living, on the mud. These include *Bolivina* and *Lagena* as well as *Globigerina*, and are presumably swept in from the deeper parts of St. George's Channel, or beyond.

Carter[4], in his work on the East Anglian crags, has shown that the foraminifera are size-sorted. The sands between the Sarns are likewise the product of a rapidly advancing transgressive sea. Identification of such current-swept microfaunas as occur in these sands may thus assist in the identification of similar sedimentary bodies, above unconformities, in the sub-surface.

The work described here is part of a research project concerning the geological history of Cardigan Bay, directed by Prof. Alan Wood. The diving equipment was supplied by the College and the research vessel financed by the Department of Scientific and Industrial Research.

M_2 Component at Hyderabad

In an earlier paper[1] the authors reported the recording and analysis of the gravity variation with time in the month of December, 1961, at Hyderabad (long. 78° 27′ E and lat. 17° 26′ N). The record was continued for another six months in 1962 and the data were analysed only for the main lunar semidiurnal tidal component M_2, as it was found that this was the most consistent and dependable component. It is found desirable to check the calibration of the photographic recording paper (in milligals) frequently. The theoretical amplitude is 0·069 milligals for Hyderabad.

In Table 1 the gravimetric factor G is the ratio of the observed amplitude (A) in milligals to the theoretical amplitude. From this factor the characteristic numbers Love (h, k,) and Shida (l) are calculated.

Table 1

Month	A	G	h	k	l
Jan.	0·0815	1·18	0·64	0·31	0·08
Feb.	0·0807	1·17	0·61	0·29	0·08
Apr.	0·0830	1·20	0·71	0·34	0·09
May	0·0839	1·21	0·75	0·36	0·10
June	0·0812	1·18	0·64	0·31	0·08

Taking the average values of f from the equation $h=\frac{5f}{2f+1}$ for different months as 0·180, the rigidity value of the Earth $\mu=gd\rho/19f$ (where g is 978·5 dynes/sec², d, density 5·52 g/c.c. and ρ = distance from the centre of the Earth to the observation point = 6375·567 km) is found to be $1{\cdot}1\times10^{12}$ dynes/cm², which value is in general agreement with those obtained by other workers.

CRYSTALLOGRAPHY

New Representatives of the $NbAs_2$ and $ZrAs_2$ Structures

The monoclinic unit cell and the space group of $NbAs_2$ and isomorphous $TaAs_2$ have recently been determined by Saini *et al.*[1]. In the course of an examination of transition-element polycompounds I observed this structure also in VP_2, VAs_2, NbP_2, TaP_2, $MoAs_2$, α–WP_2 (low-temperature modification) and WAs_2. The titanium-group phosphides TiP_2, ZrP_2 and HfP_2, on the other hand, were found to be isostructural with the orthorhombic $ZrAs_2$ (ref. 2) and $HfAs_2$ (ref. 3). This structure is referred to as $PbCl_2$ (C23) type. However, in these titanium-group pnictides anion–anion bonds seem to be important so that I prefer to distinguish this variety from the ionic $PbCl_2$ type by using a different name. The lattice constants, as derived from powder patterns, are listed in Table 1.

Table 1. Lattice Constants of Orthorhombic $ZrAs_2$-type and Monoclinic $NbAs_2$-type Phases

	a (Å)	b (Å)	c (Å)	β
TiP_2	6·181 ± 3	8·256 ± 3	3·346 ± 3	
ZrP_2	6·494 ± 3	8·744 ± 3	3·513 ± 3	
HfP_2	6·467 ± 3	8·646 ± 3	3·497 ± 3	
VP_2	8·466 ± 9	3·106 ± 2	7·170 ± 8	119° 16′ ± 4′
VAs_2	9·059 ± 7	3·272 ± 2	7·481 ± 7	119° 47′ ± 4′
NbP_2	8·878 ± 9	3·266 ± 2	7·529 ± 9	119° 8′ ± 5′
TaP_2	8·870 ± 8	3·267 ± 2	7·497 ± 7	119° 24′ ± 4′
$MoAs_2$	9·064 ± 6	3·295 ± 2	7·715 ± 8	119° 22′ ± 3′
α–WP_2	8·501 ± 9	3·167 ± 2	7·471 ± 8	119° 20′ ± 4′
WAs_2	9·079 ± 5	3·318 ± 2	7·692 ± 5	119° 26′ ± 3′

My samples all showed metallic conductivity and a positive thermoelectric power of 10–25 μV/° C. I do not know at present whether the metallic conductivity is an intrinsic property of all these compounds or if it is due only to impurities or to a deviation from stoichiometry. In the $ZrAs_2$-type compounds the tendency to saturate all bonds is obvious. All anions form pairs which would suggest an ionic formula $Zr^{4+}(As_2)^{4-}$. The probability for the occurrence of semiconducting properties should be greatest in the 5d compound HfP_2. If a parallelism between corresponding $d\varepsilon^6$ and d^0 compounds

$$\begin{array}{ccc} PtS_2 & ----- & PtP_2 \\ \downarrow & & \downarrow \\ HfS_2 & ----- & HfP_2 \end{array}$$

is postulated we would expect a rather large energy gap in the case of HfP_2. The As–As distance 2·58 Å (ref. 3) reported for $HfAs_2$, on the other hand, is somewhat large for a saturated anion–anion bond (As–As single-bond distance 2·42 Å (ref. 4)), indicating the possibility that a small fraction of the cation electrons are left in a metallic d band.

Though the detailed structure of $NbAs_2$ is not known*, we suppose that the anions also form pairs in this type of structure. In the vanadium-group phases one then expects to find a similar metallic d band as in the corresponding dichalcogenides VSe_2, NbS_2, TaS_2, etc. It is interesting that $MoAs_2$, α–WP_2 and WAs_2 also crystallize in the $NbAs_2$ structure. In these latter compounds two extra d electrons of the cation would be sufficient to fill a d^2 band supposing the cation to have a trigonal prismatic environment. In this case, then, diamagnetism and non-metallic properties would be possible as in MoS_2, WS_2, etc. In the high-temperature modification β-WP_2, which crystallizes in the MoP_2 structure[5], anion pairs are still present (P – P = 2·17 Å, corresponding to a single bond). The cation has in fact six P neighbours forming a trigonal prism but a seventh W–P bond occurs and this additional bond may explain the observed metallic behaviour of MoP_2 and β–WP_2.

I thank Miss Elfriede Rittershaus and Mr. H. U. Boelsterli for assistance in sample preparation and X-ray work.

* *Note added in proof.* Meanwhile, the structure of $NbAs_2$ and of isomorphous $NbSb_2$ has been determined[6]. Since only half of the As atoms form pairs (As_{II} – As_{II} = 2·45 Å, whereas As_I – As_I = 2·98 Å) the structure would allow $NbAs_2$ to be a diamagnetic semiconductor with ionic formula $Nb_2^{5+}(As_2)^{4-}As_2^{3-}$. The observed metallic properties, therefore, are due to an accidental overlapping of bands as occurs in $TiTe_2$ and $PdSb_2$. $TaSb_2$ is isomorphous with $NbSb_2$ and has the following lattice constants: a = 10·22 ± 2 Å; b = 3·644 ± 4 Å; c = 8·29 ± 2 Å; β = 120° 24 ± 8′.

CHEMISTRY

Water Structure around Silver Iodide Sol Particles

In order to explain lower values of differential capacity at the negative silver iodide/solution interface than at the mercury/solution interface, Lyklema[1] proposed that the Stern layer in the former may be of icelike (tetrahedral) structure, and pointed out that this would also explain the greater specificity of cations in the silver iodide case. More recently Levine and Bell[2] have commented that such structure would tend to remove the distinction between inner and outer Helmholtz planes so that the fluctuation potential would become small, this making the maximum in the outer Helmholtz plane potential much less marked. This effect would then explain the relative constancy of the flocculation concentration for silver iodide sols at high (negative) potentials[3,4] compared with those of silver bromide and silver chloride sols, which have been reported[5] to decrease at high negative potentials. The hypothesis is supported by the well-known epitaxis of ice on silver iodide which is more effective near the zero point of charge[6].

The purpose of this note is to report further evidence of such structure both from pulsed proton nuclear magnetic resonance (spin-echo[7]) measurements on negative silver iodide sols and from studies on the rates of rapid flocculation of these sols at varying surface potential by excess electrolyte.

For the spin-echo measurements (using a spectrometer constructed by Mr. W. E. Porter of this department) silver iodide sols were prepared by the addition of 0·1 M silver nitrate solution to 0·11 M potassium iodide solution followed by dialysis in 'Cellophane' tubing against constantly renewed distilled water at 25° C for about 10 days. This procedure reduces the excess iodide concentration to about 10^{-5} M (pI 5) or below. For measurements at

pI 3, the sols were made 10^{-3} M with respect to iodide ions by the addition of the appropriate small quantity of concentrated potassium iodide solution from an 'Agla' syringe. In order that sols at different pI could be compared at the same sol concentration an identical quantity of distilled water was added to the sol as dialysed. In one experiment, in order to increase the magnitude of the observed effect, the sol concentration was increased by light centrifugation before division into two parts and adjustment of pI.

Table 1. Relaxation Times from Spin-Echo Measurements on Silver Iodide Sols

		T_2 (sec)			T_1 (sec)		
	sol conc.	pI ~ 5	pI 3	Water	pI ~ 5	pI 3	Water
Sol *A*	0·05 M	2·21	2·30	2·43	2·38	2·61	2·69
Sol *B*	0·05 M	2·18	2·53	2·61			
Sol *C*	0·05 M	2·09	2·35	2·44			
Sol *D*	*	1·07	2·18	2·61			

* Sol initially at 0·05 M concentrated by light centrifugation.

Table 1 shows the values of the transverse relaxation time T_2 and the longitudinal (spin-lattice) relaxation time T_1, obtained from spin-echo measurements on sols as dialysed (pI ~ 5) and at pI 3. The relaxation times for pure water, measured at the same time as those for the sol, are included in each case.

It can be seen from Table 1 that both T_2 and T_1 reduce in the order water > pI 3 > pI ~ 5 with the T_1/T_2 ratio equal to 1·1. The reduction is due to an increase in the correlation time for molecular motion[8] which is indicative of a corresponding increase of water structure.

The effect cannot be due simply to a change in iodide ion concentration since even at pI 3 it is too small to have an appreciable effect and, moreover, the iodide ion is a known structure breaker so that any effect would be in the opposite sense. A reasonable interpretation of these results is that silver iodide sol particles are surrounded by a layer of tetrahedral water structure which tends to break down at high surface potentials where water dipoles become orientated as around ions.

Supporting evidence for this view has been obtained from measurements of the rate of rapid flocculation of negative silver iodide sols in excess electrolyte. As shown by Smoluchowski[9], the bimolecular rate constant k_0 in the expression $-dN/dt = k_0N^2/2$, where N is the number of particles at any time t, should, in the absence of a force field, be given by $k_0 = 8\,kT/3\eta$, where k is the Boltzmann constant and η the viscosity of the dispersion medium. For particles of radius corresponding to the Rayleigh region k_0 can be measured turbidimetrically[10,11] by taking the initial slopes $(d\tau/dt)_{t\to 0}$ of plots of turbidity τ versus time, to give k_0 from:

$$\left(\frac{d\tau}{dt}\right)_{t\to 0} = \frac{AC_s^2k_0}{\rho^2} \qquad (1)$$

where C_s is the sol concentration (gm ml.$^{-1}$), ρ the particle density and A the Rayleigh constant. For these experiments sols of concentration 5×10^{-4} M were prepared by direct mixing of silver nitrate and potassium iodide solutions. The mean particle radius was found to be 70–100 Å by electron microscopy. Flocculation experiments using aged sols of appreciably larger particle radius gave, within the limits of experimental error, identical results to those obtained for the smaller particles.

Table 2. Bimolecular Rate Constants for Rapid Flocculation of Silver Iodide Sols

pI	k_0(obs.) ml. sec^{-1} × 10^{12}	k_0(obs.)/k_0(calc.)
3	8·7	0·70
4	7·3	0·59
5–13	4·7	0·38

Table 2 shows the results for the rapid flocculation of sols at various values of pI, and a comparison between the observed k_0 and that calculated from the Smoluchowski equation k_0(calc.). For pI values greater than 5 an appropriate amount of silver nitrate was included in the flocculating electrolyte and the combined solution added to a sol initially at pI 5. The results shown are average values for potassium, magnesium and lanthanum nitrates as flocculating electrolytes, differences between these electrolytes being insignificant compared with the estimated experimental error (~10 per cent).

Although the absolute values of k_0(obs.) may be somewhat in error because of either defects in the model used to derive equation (1) or uncertainties in the determination of the initial slopes of the curved τ versus t plots, the increase in rate from pI 5 to pI 3 seems significant. This increase corresponds with the increase in relaxation time towards that of pure water shown in Table 1 and could therefore be due to the dissolution of tetrahedral water structure which acts as a small energy barrier to flocculation at pI 5 and above. The asymmetry of the zero point of charge (pI 10·5) precludes investigation of a similar effect for positive sols.

Reversible Photochemical Bleaching in Frozen Aqueous Systems at 77° K

It is known that some colourless glasses containing certain impurity centres become coloured on exposure to visible light at room temperature and get colourless again in the dark, evidently due to some thermal back-reaction. We have found some systems which show a similar behaviour at temperatures of about 77° K. The systems referred to are transparent matrices of ice containing certain solutes such as sulphuric or phosphoric acid at concentrations of 1–10 mole per cent. If these glassy ice matrices are irradiated with ionizing radiations (γ-rays, X-rays, etc.) they become coloured, deep yellow in the case of sulphuric acid and pink in the case of phosphoric acid, respectively. If now these coloured glasses are exposed to a source of visible light for several minutes, for example, a 500-W tungsten lamp, this colour disappears. However, on annealing these glasses in the absence of light the colour is again restored, for example, at a temperature of about 120° K the original colour is very rapidly and completely restored in a very short time. These processes can be followed by both spectrophotometric as well as electron spin resonance techniques since the colour centres formed on irradiation as well as the species formed on optical bleaching of the colour centres show characteristic absorption and electron-spin resonance spectra. The results of these investigations, which will be published more fully elsewhere, have led to the following conclusions.

It is known that absorption of, for example, γ-radiation by the ice matrices leads, in the first instance, to the formation of positive and negative polarons in the ice designated by $(H_2O)^+$ and $(H_2O)^-$, respectively[1,2]. The negative polarons react with the protons in the acid matrix to give hydrogen atoms, whereas the positive

polarons react with, for example, the sulphate ions present according to:

$$HSO_4^- + (H_2O)^+ \rightarrow HSO_4.(H_2O) \rightarrow SO_4^-.(H_3O)^+ \quad (1a)$$

$$SO_4^{2-} + (H_2O)^+ \rightarrow SO_4^-.(H_2O) \quad (1b)$$

giving the radical ion SO_4^- which shows a characteristic electron spin resonance spectrum and absorbs light in the visible region with absorption maximum at 446 mμ. A corresponding process occurs in the phosphate matrices where it leads to the formation of the HPO_4^- radical ion, which shows maximum absorption at 525 mμ.

In the photochemical bleaching with light which is absorbed by these coloured radical ions an electron is transferred from the hydration shell to the radical ions, for example, according to:

$$SO_4^-.(H_2O) + h\nu \rightarrow SO_4^{2-}.(H_2O)^+ \quad (2)$$

leading to the formation of a positive hole trapped in the hydration shell of the respective ions. The presence of a positive hole can be inferred from an examination of the electron-spin resonance spectra. The latter were found to be identical after bleaching of both the γ-irradiated sulphate and phosphate ice matrices. If now these colourless matrices are warmed up to a temperature of about 120° K. the original colour is practically immediately restored. This procedure, that is, of photochemical bleaching and thermal restoration, corresponding to reaction (1*b*), can be repeated through many cycles with practically no change in the concentrations of the intermediate species involved in these processes.

Molecular Structure of π-allyl-palladium Acetate

The structures of π-allyl complexes of transition metal ions are of interest because the allyl ligand can be regarded as intermediate in behaviour between olefines and conjugated aromatic systems. π-Allyl palladium complexes have, in particular, assumed importance as catalytic agents in carbonylation and other reactions involving unsaturated organic halides[1,2]. The only structural analysis of an allyl complex so far reported is that of the dimeric π-allyl palladium chloride[3], the reaction of this complex with silver acetate yielding π-allyl palladium acetate[4]. A three-dimensional X-ray analysis of the structure of this molecule has now been completed, the molecular stereochemistry being shown in Fig. 1; estimated standard deviations of the observed bond lengths are 0·003 Å (Pd–Pd), 0·02 Å (Pd–O), 0·035 Å (Pd–C), 0·04 Å (O–C) and 0·05 Å (C–C) and correspond to a discrepancy index of 0·068 for 1,065 reflexions.

The π-allyl palladium residues are bridged by the two acetate groups, the overall arrangement showing considerable similarity to that of the binuclear cupric acetate dihydrate[5] in which a metal–metal bond is evidenced largely by magnetic and spectroscopic criteria (see, for example, ref. 6). The Cu–Cu bond-length of 2·64 Å is equivalent to that of 2·94 Å for the Pd–Pd distance in the present complex; the difference between the mean Cu–O (1·97 Å) and Pd–O (2·11 Å) bond-lengths can be taken as the difference between the metal radii so that judged by these data the Cu–Cu and Pd–Pd bond-lengths should differ by 0·28 Å (observed 0·30 Å). Formally, with the allyl anion acting as a four-electron donor, the present results offer a further example of the formation of a metal–metal bond between two d^8 ions, but the relation between the cupric acetate structure and the present one

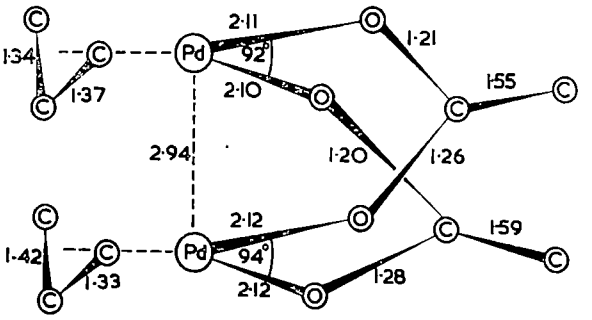

Fig. 1

is perhaps made clearer if we regard the palladium ion as interacting with the π-allylic radical since metal–metal bonds are then formed between d^9 ions in both examples. The Pd–Pd distance is 0·3–0·4 Å shorter than those reported for Pd (dimethylglyoxime)$_2$ (3·26 Å) (ref. 7), $[Pd(NH_3)_4].[PdCl_4]$ – 3·25 Å (ref. 8), $[Pd(NH_3)_4].[Pd(Br_4)]$ – 3·33 Å and $[Pd(NH_3)_4]$ $[Pd(SCN)_4]$ – 3·35 Å (ref. 9), in which complexes there is no ligand bridging of the d^8 palladium ions.

The palladium–allyl bonding is such that the planes of the allyl ligands make dihedral angles of 125° and 110° (± 5°) with those defined by the respective O–Pd–O groups. A re-examination of the structure of $(\pi\text{-}C_3H_5PdCl)_2$ (ref. 10) shows the allyl plane in this complex to be similarly oriented at an angle of 118° with respect to the plane of the Pd_2Cl_2 system with the Pd–C (allyl) bond-lengths varying from 2·15 ± 0·02 Å in the case of the terminal carbon atoms to 2·01 ± 0·04 Å for the central atom of the allyl group. An independent examination[11] of the structure of $(\pi\text{-}C_3H_5PdCl)_2$ at −140° C does not, however, confirm this difference, and indeed while the mean values for these bonds in the present structure are 2·08 Å and 2·05 Å, respectively, no significance can be attached to this result, or to the observed differences in the carbon–carbon bond distances in the allyl ligands.

The configuration of the allyl ligand with respect to the palladium ion differs from that which might have been anticipated on the basis of a molecular orbital description of the electron distribution in the free ligand. As such the same conditions may apply, *mutatis mutandis*, to those which have been discussed elsewhere for the bonding of cyclic ligands to transition metal ions[12–14].

We thank Dr. B. L. Shaw for providing us with a sample of the complex, and the Department of Scientific and Industrial Research for a studentship (M. R. C.).

Phosphate-mediated Dehydrogenation of Alcohol in the Photochemistry of Ferrocyanide in Aqueous Solution

In a series of investigations it was shown[1] that the excited states of negative ions in aqueous solution may dissociate thermally to yield a solvated electron. Thus in the case of the halide ions[1] (chloride, bromide and iodide), the hydroxyl ion[1], thiocyanate[2] and thiosulphate[3] the reactions of solvated electrons could be investigated. The application of flash photolysis techniques[2] permitted the detection of the absorption spectrum of the solvated electron in such systems, including solutions of ferrocyanide. In the case of organic solutes in aqueous solution (phenolate and β-naphtholate[4]), the formation of solvated electrons was shown to occur from an excited state resulting from an internal transition not involving charge transfer to the solvent, as was the case with other ions.

It was shown that solvated electrons photochemically produced could be converted to hydrogen atoms, for example, by hydrogen ions and also by a series of reagents acting as Bronsted acids. Of these the role of phosphate ions was of particular interest since they occurred in neutral solutions[5].

Solvated electrons act as reducing agents, but hydrogen atoms may act not only as reducing agents but also as oxidizing agents by virtue of the high bond energy of the H–H bond[6]. Accordingly, hydrogen atoms resulting from such conversion of solvated electrons may dehydrogenate, for example, alcohols and oxidize them by stages to aldehydes or ketones[1a]. The full sequence is then, for example:

$$X^- + h\nu \longrightarrow (X^-)^* \longrightarrow X\cdot + e^-_{aq} \quad (1)$$

$$e^-_{aq} + H_2PO_4^- \longrightarrow H\cdot + HPO_4^{=} \quad (2)$$

$$H^\circ + CH_3CH_2OH \longrightarrow H_2 + CH_3\dot{C}HOH \quad (3)$$

$$X + CH_3\dot{C}HOH \longrightarrow X^- + H^+ + CH_3CHO \quad (4)$$

This sequence is of particular interest for the photo and radiation chemistry of biological systems, since at near neutral *p*H the main primary product will be the solvated electron. However, if suitable converters, phosphate ions or others, are present in the biological system then even at the biological *p*H the reactions of H atoms may be decisive for the results observed. For example, phosphate-mediated oxidations may be obtained from processes which are initiated in general as electron transfer processes—not necessarily initiated always by light or radiation.

We have now investigated the absorption spectrum and the photochemistry of ferrocyanide ion in aqueous solution. Of interest was the correlation between the absorption spectrum, which exhibits bands due to internal ligand field transitions, and the photochemistry of this ion which is a model for some biologically important substances. Photochemical experiments were carried out at 214, 229, 254 and 265 mμ as well as above 300 mμ.

The effect of *p*H on the absorption spectrum was examined. Using the technique of environmental effects on the absorption spectrum[3,7] a charge transfer to solvent band was found centring around 260 mμ, obscured underneath two ligand field transitions. At neutral *p*H the quantum yield for the formation of solvated electrons reaches a maximum of unity when irradiations are carried out in the charge transfer band at 254 mμ and is lower at quantum energies higher than that. Illumination in the absorption band above 300 mμ does not result in the formation of solvated electrons. The maximum quantum yields, φ, shown in Table 1 were determined using N_2O as the electron scavenger[8], which was shown to react rapidly with solvated electrons produced photochemically[1]. Experiments were carried out in the presence of added ethanol to capture O^- and OH radicals formed according to:

$$e^-_{aq} + N_2O \longrightarrow N_2 + O^- \xrightarrow{+H^+} \cdot OH \quad (5)$$

$$\cdot OH + C_2H_5OH \longrightarrow H_2O + \cdot C_2H_4OH \quad (6)$$

followed by

$$Fe(CN)_6^{3-} + \cdot C_2H_4OH \longrightarrow Fe(CN)_5^{4-} + C_2H_4O \quad (7)$$

Thus aldehyde is formed, but ferricyanide does not accumulate.

When using phosphate ions instead of N_2O as the electron scavenger and measuring the hydrogen evolved due to the dehydrogenation of the alcohol by the hydrogen atoms formed according to reaction 4, the results shown in Fig. 1 were obtained. When ferrocyanide is irradiated in the presence of alcohol but without phosphate being present, there is no hydrogen evolution at all. In the presence of phosphate dehydrogenation, thus oxidation, of the alcohol occurs and the kinetics represented by the half-power plot in Fig. 1 correspond formally to that expected[1] when phosphate competes with the recombination of the solvated electron with its parent ferricyanide ion. Using phosphate, the peak limiting quantum yields obtained with N_2O as the electron scavenger could not be reached. With increasing concentration phosphate became a limiting factor. Similar observations were obtained[9] in studies of the oxidizing action of H atoms produced from hydrogen gas[10]. The results there showed that phosphate ions may form complexes with atomic hydrogen, competing with other acceptors.

Table 1. Dependence of the Photochemical Parameters on the Wavelength of the Exciting Light

λ mμ	φ(N_2), from experiments with N_2O	α, arbitrary units
214	0·88	1·5
229	0·89	1·2
254	1·00	0·96
265	0·40	1·1
> 300	0·0	—

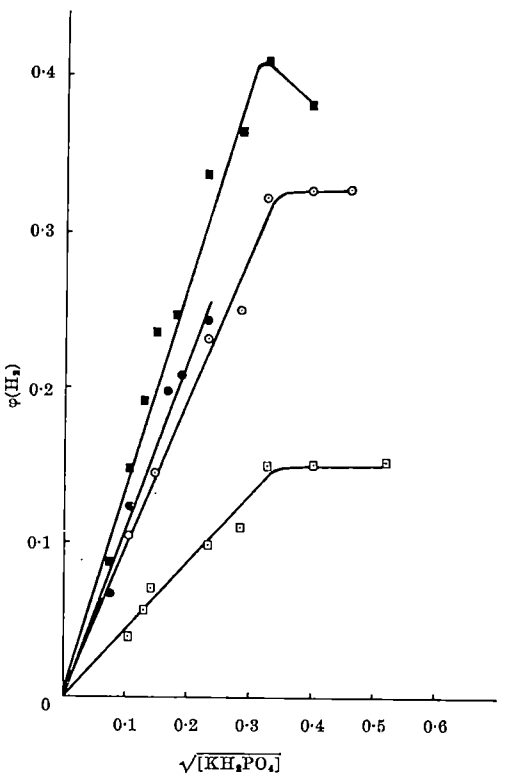

Fig. 1. Dependence of the quantum yield of hydrogen evolution on the square root of the concentration of phosphate. Solutions illuminated with light at ■ 214, ● 229, ○ 254 and □ 265 mμ. Concentration of ethanol = 1·0 M, of ferrocyanide 1 × 10⁻³ M. Note that at 214 mμ some of the incident light is absorbed by phosphate itself at high concentrations

The formal treatment of the photochemical scavenger kinetics results in the dependence of the quantum yield, φ, on scavenger concentration $[S]$, over a range of concentrations according to:

$$\varphi = \varphi_r + a\Phi \sqrt{[S]} \quad (8)$$

where, as shown in Fig. 1, in the present case the residual quantum yield in the absence of scavenger, φ_r, equals zero. a is a parameter representing the probability of recombination between the solvated electron and its parent ion. Increasing a points to an increased probability for the solvated electron to escape and react with the scavenger. The slopes of the straight lines in Fig. 1, obtained from experiments with phosphate, together with the values of the maximum quantum yield, Φ, obtained from experiments with N_2O, show that at 254 mμ in the charge transfer band the maximum quantum yield reaches its highest value; but at the same time the probability of recombination between the solvated electron thus formed and the parent ion is also at its highest. At higher quantum energies the maximum quantum yield for solvated electron formation decreases somewhat, but the probability that the solvated electron once formed escapes recombination with its geminate partner increases somewhat. These results point to the possibility of investigating the characteristics of the photochemical 'cage'.

It is to be emphasized that in the sequence of reactions 1–4 the absorbing species, ferrocyanide in the present case, is not consumed and serves as a catalytic mediator for the light-induced dehydrogenation of the alcohol.

BIOCHEMISTRY

Heat-yellowing of Wool and Silk

Previous work on the heat-yellowing of wool has been summarized by Howitt[1]. Neither the amino-acids responsible for the phenomenon, nor the reactions involved, have been elucidated, and an attempt has, therefore, been made to solve these problems by studying the action of heat on untreated and chemically modified wools. The general principle was to modify different side-chains and cross-linkages in turn, and then to compare the extent of yellowing of the untreated and chemically modified wools after heating for 24 h in a slow stream of dry air or nitrogen at 150° C, the yellowness indices of the samples being determined by a procedure similar to that of Norton and Nicholls[2]. Using iodinated wool and wool methylated with diazomethane it was shown that the tyrosine side-chains of wool play little part in heat-yellowing under the foregoing conditions; but no satisfactory way of discovering the part played by the hydroxylic side-chains of serine and threonine could be devised. As silk is rich in these amino-acids, and as methylation with dimethyl sulphate and alkali is permissible with this material[3], the action of heat on untreated and methylated silk was examined. The results are given in Table 1.

Table 1

Sample	Yellow index: Before heating	After heating in: Air	After heating in: Nitrogen
Untreated	1	44	11
Methylated	12	18	17

It is clear that the hydroxylic side-chains of either serine or threonine, or both, play an important part in the heat-yellowing of silk, and, presumably, wool. Recent work by Norton and Nicholls[4] suggests that threonine plays little part in heat-yellowing, but the importance of serine is confirmed by the fact that it promotes the N → O peptidyl shift, which appears to be crucial in the only method of acetylation[5], among the many we have examined, that is capable of minimizing the heat-discoloration of wool.

We thank the International Wool Secretariat for grants in aid of this investigation.

Scopoletin, Scopolin and Chlorogenic Acid in Tumours of Interspecific *Nicotiana* Hybrids

Phenol and certain substituted phenolic compounds were reported recently to be co-carcinogenic in animal tissue[1]. The investigation of phenolic compounds in tumorous plant tissue of *Nicotiana* hybrids is of great academic interest in that much is known of the genetic background[2,3], cytology[4], chemical composition[5] and the effects of radiation[6] and of certain anti-tumour chemicals[7] on the tumorous plant. Some of these compounds are known to take part in alkaloid metabolism[8].

Certain interspecific combinations of *Nicotiana* are known to produce tumours spontaneously[2]. Materials used in the work recorded here were *N. glauca* Grah., *N. langsdorffii* Weinm., *N. suaveolens* Lehm., *2n* and *4n* (*N. glauca* × *N. langsdorffii*) and *4n* (*N. suaveolens* × *N. langsdorffii*). New tumours were green or white in colour, and when older they gradually turned brown or grey.

Composite material from the same group of test plants was used for analysis. Tumours were separated by the location of their growth, and by their age. Extractions were made immediately after gathering in a Waring blender at room temperature (22 ± 2) Each 30 g of fresh material was extracted twice with 120 ml. of 70 per cent ethanol, allowing 7 min for each extraction. Additional ethanol was used for washing. Combined ethanol fractions were diluted with an equal volume of water and extracted with ethyl ether to remove pigments.

The ethanol fraction was filtered, concentrated *in vacuo*, and then made up to a 30 per cent methanol solution. This solution was fractionated with a polyamide resin 'Ultramidpulver' column. Three main zones were detected with ultra-violet light (3660 Å) and were eluted separately: fraction 1, a blue-fluorescing front zone containing scopolin; fraction 2, a non-fluorescing zone; and fraction 3, an intense blue-fluorescing zone containing scopoletin.

Identification of scopoletin. The scopoletin (6-methoxy-7-hydroxycoumarin) fraction was first concentrated *in vacuo* to dryness at room temperature, using a rotary evaporator, by azeotroping the water with isopropyl

alcohol. The solid was then sublimed, and the sublimed scopoletin was re-crystallized from methanol (m.p. 207°–209° uncorr.; authentic scopoletin[9], m.p. 208°–209°). The ultra-violet absorption spectrum of the isolated scopoletin was identical with that of synthetic scopoletin (max. 344, 297, 252 and 228 mμ, min. 306, 270 and 248 mμ). R_F values of the crystalline scopoletin agreed with those of the synthetic scopoletin from four different solvent systems by paper chromatography. Results are shown in Table 1.

Table 1. R_F VALUES OF SCOPOLETIN, SCOPOLIN, CHLOROGENIC ACID AND RELATED COMPOUNDS

Compound	R_F values in solvent systems*					
	1	2	3	4	5	6
Scopoletin, synthetic	0·92	0·47	0·48	0·42	—	—
Scopoletin, isolated	0·91	0·47	0·48	0·42	—	—
Scopolin, synthetic	0·56	0·73	—	0·44	0·74	—
Scopolin, isolated	0·57	0·74	—	0·44	0·72	—
Isolated and authentic chlorogenic acid	0·68	0·60 0·80	—	—	0·48	0·75 0·82
Caffeic acid	—	0·35	0·10	—	—	—
Quinic acid	0·30	—	—	—	0·09	0·51

* Solvent systems used are: (1) *n*-butyl alcohol–acetic acid–water (6 : 1 : 2, v/v/v); (2) isopropyl alcohol–acetic acid–water (5 : 0·1 : 95, v/v/v); (3) benzene–acetic acid–water (6 : 7 : 3, v/v/v, upper layer); (4) *n*-butyl alcohol saturated with 2 N ammonium; (5) *n*-butyl alcohol–benzene–pyridine–water (5 : 1 : 3 : 3, v/v/v/v, upper phase); (6) 15 per cent aqueous acetic acid.

Identification of scopolin. The scopolin (7-glucoside of scopoletin) containing fraction 1 obtained from the 'Ultramidpulver' column was purified through a cellulose column. The charged column was then washed with benzene saturated with water until the eluate no longer fluoresced red. The eluting solvent was then changed to water-saturated ethyl acetate to which additional ethyl acetate was added in the amount of 33 per cent of the solution volume. Three zones were visible under ultra-violet light. The third zone fluoresced blue and contained scopolin. The eluate was then concentrated to dryness by evaporating an azeotropic mixture of water and isopropyl alcohol. The solid residue was recrystallized from methanol and proved to be scopolin (m.p. 214°–215° uncorrected; synthetic scopolin 215°–216°). The ultra-violet absorption spectra for the isolated and synthetic scopolin were identical (max. 286 and 337 mμ, min. at 264 and 304 mμ). Paper chromatographic R_F values of the isolated and synthetic scopolin were in good agreement in the four solvent systems, as shown in Table 1.

Isolated scopolin was hydrolysed with hydrochloric acid. The hydrolysate was extracted with ethyl acetate. The aglucone present was identical with reference scopoletin. The sugar in the water layer of the hydrolysate was found to be glucose.

Quantitative determination of scopolin and scopoletin. The procedure of Dieterman *et al.*[10] was used to determine the scopolin and scopoletin in tumour tissue. The results obtained are presented in Table 2. Each value represents an average of three determinations.

Table 2. SCOPOLIN AND SCOPOLETIN IN VARIOUS *Nicotiana* TUMOURS

Samples	μg Scopolin/g fresh wt.	μg Scopoletin/g fresh wt.
2*n* (*N. glauca* × *N. langsdorffii*)		
Old tumours from root and stem	125	1,143
New tumours from root and stem	142	8·8
4*n* (*N. glauca* × *N. langsdorffii*)		
Old floral tumours	1,433	285
New floral tumours	433	12·5
Old tumours from root and stem	533	20·5
New tumours from root and stem	1,150	87
4*n* (*N. suaveolens* × *N. langsdorffii*)		
Mixed tumours	70	0·9

It appears that there is no consistent relationship between the amount of scopoletin and the amount of scopolin. In tumours from (*N. glauca* × *N. langsdorffii*) a higher level of scopolin and scopoletin was found than in those of (*N. suaveolens* × *N. langsdorffii*).

Identification of chlorogenic acid. A portion of the original ethanol extract was fractionated on a Magnesol column to examine chlorogenic acid (3-caffeoylquinic acid) content. The eluate containing the first major yellow band was concentrated *in vacuo* at 35°. This aliquot was then streaked on 3 *MM* Whatman paper, and developed in the *n*-butyl alcohol–acetic acid–water system. The blue fluorescing zone, with R_F of 0·63, was eluted with methanol. The eluate was concentrated and proved to be chlorogenic acid by using several solvent systems with paper chromatography and also by hydrolysis. The R_F value of the isolated chlorogenic acid was identical with that of the authentic chlorogenic acid. The R_F value of the caffeic and quinic acids obtained from 1 N sodium hydroxide hydrolysate was identical with the authentic caffeic and quinic acids[11] (Table 1).

To examine the chemical and genetical background, the relative amount of scopolin, scopoletin and chlorogenic acid present was estimated in the parental tissue of these tumour-producing *Nicotiana* hybrids. This was done by visual comparison of samples with standards of various known quantity on paper chromatograms (ethyl acetate : pyridine : water, 2 : 1 : 2). As shown in Table 3, scopoletin is not detectable in all three parent species. Scopolin is almost absent in *N. suaveolens*, very low in *N. langsdorffii*, and present only in about one-third to one-fifth in *N. glauca* in comparison with its tumorous hybrid. Chlorogenic acid levels, however, are similar in the parents or the hybrid. Quantitative results, however, were not obtained for chlorogenic acid in tumorous tissue.

Table 3. RELATIVE AMOUNT OF SCOPOLIN, SCOPOLETIN AND CHLOROGENIC ACID IN *N. glauca*, *N. langsdorffii* AND *N. suaveolens*

Plant tissue	μg Scopolin/g fresh wt.	μg Scopoletin/g fresh wt.	μg Chlorogenic acid/g fresh wt.
2*n* (*N. glauca* × *N. langsdorffii*)	125	1,143	100
N. glauca			
Leaves and stems	44	0	113
Floral tissue	23	0	35
N. langsdorffii			
Leaves and stems	5	0	112
Floral tissue	0	0	175
N. suaveolens			
Leaves and stems	1	0	245
Floral tissue	0	0	70

In a separate investigation, using a variety (one sucker) from *Nicotiana tabacum*, scopoletin was also not detected in healthy plants, but a very minute quantity of scopolin was found in leaves and stems. In the roots, however, a considerable amount (118 μg/g) of scopolin was found.

This communication provides results on the sharp increase of scopolin and the new formation of scopoletin in the tumorous tissue of *Nicotiana* hybrids as compared with parental material. These compounds appear to be related to the formation of tumours in the F_1 hybrid.

Utilization of Saccharose and Maltose by Yeasts

WORK on the utilization of saccharose by *Saccharomyces oleaginosus*[1], and other species, has been continued on other yeasts lacking invertase. The results with *S. rouxii* were: (*a*) negative assimilation in yeast nitrogen base Wickerham (YNB) with 0·5 per cent saccharose, and positive assimilation in the same medium with a 2 per cent sugar concentration; in the latter case, the assimilation is appreciably quicker in Erlenmeyer flasks; (*b*) slow fermentation in a 2 per cent concentration in yeast infusion (YI), and slightly more active fermentation in yeast autolysate (YA). With *S. italicus VB* 20 the assimilation of saccharose in YNB was also negative with 0·5 per cent saccharose, and positive with 2 per cent; the fermentation was extremely weak in YI and YA.

Further, a series of yeasts was chosen capable of assimilating saccharose, but not raffinose, and it was proved that they lacked beta-fructosidase; their behaviour in the presence of saccharose varied from extremely active fermentation (*C. tropicalis*) to very weak (*H. angusta Ac* 455, *C. lusitanae Ac* 475) to a negative fermentation (*C. pulcherrima, T. ernobii, H. californica*, and the majority of the *C. lusitanae* strains).

A similar behaviour with maltose was found only in the yeasts lacking invertase, *S. rouxii Me* 3, that fermented maltose (slowly in YI and more rapidly in YA) and did not assimilate it in YNB with 0·5 per cent sugar; in the same manner, two invertase-positive yeasts (*C. utilis Ac* 551 and *S. kluyveri Ac* 316) fermented maltose in YA, but not in YI.

Considering the general problem of utilizing saccharose and maltose, we note that the following points stand out, at least in the group of yeasts treated: (*a*) Whenever a yeast ferments maltose, it ferments saccharose, even though this fermentation be weak or may need special media. (*b*) A yeast may ferment saccharose in the absence of invertase, but can neither assimilate nor ferment maltose (*S. wickerhamii*), or can only assimilate it (*H. angusta Ac* 455). (*c*) There are yeasts that ferment glucose and assimilate maltose and/or saccharose, but are incapable of fermenting them. (*d*) Within one species, there may be appreciable variation between different strains with regard to the assimilation or fermentation of maltose and/or saccharose (*S. rouxii, S. kluyveri, S. italicus, C. lusitanae, C. utilis*).

From the quantitative point of view, for example the amount of sugar utilized, there are differences between cultures. For example, with *S. oleaginosus, S. hienipiensis, S. italicus, C. tropicalis*, some strains of *C. lusitanae*, and others, the maltose utilized in 10 days in YNB represents practically 100 per cent of the initial amount (2 per cent), while *S. rouxii, S. lactis, C. utilis* var. *major*, other strains of *C. lusitanae*, and others, the corresponding figure after 20 days is only 10 to 20 per cent. The culture medium used has a profound influence on the rate of sugar utilization. The same happens with saccharose: *C. tropicalis Ac* 433 utilizes 100 per cent of the initial amount (4 per cent) in 48 h, while *C. lusitanae Ac* 19 utilizes 17 per cent, *T. ernobii* 8 per cent, and *H. californica* 10 per cent. The addition of various peptones to the growth medium has no influence on the results. In the case of saccharose, YA may not be substituted by YNB plus vitamin-free acid hydrolysed casein, using *S. oleaginosus, S. italicus VB* 20, *S. hienipiensis, S. rouxii, H. angusta*. On the other hand, *S. rouxii Me* 3, which does not assimilate maltose in YNB, will do so if it is complemented by 'Bacto' vitamin-free casamino-acids. In small inoculations, adaptation to maltose or saccharose has no influence on utilization of the saccharose by *S. oleaginosus, S. hienipiensis, S. italicus VB* 20, *S. rouxii*, or by maltose by *S. rouxii Me* 3, unlike that which occurs with other inducible enzymes.

We see, therefore, that with regard to the utilization of saccharose and/or maltose by yeasts lacking invertase, it is possible to use them in simple media (YNB) or more complicated ones (YA) which may be fermentative or merely assimilative. We also observe that if there is invertase, the saccharose is fermented, and equally, if there is melibiase, the melibiose is fermented; on the other hand, maltose and saccharose, in the absence of invertase, may be assimilated and not fermented: a similar case occurs with beta-galactosidase in *S. marxianus*. This seems to coincide with the fact that beta-fructosidase (invertase) and alpha-galactosidase (melibiase) involve external hydrolysis.

From these results we may deduce that: (i) it is probable that utilization of saccharose by yeasts lacking invertase may be due, at least in some cases, to a different enzymatic system from that used in the utilization of maltose; (ii) in the utilization of saccharose and maltose diverse factors (such as medium, concentration of sugar, aerobiosis, strain of yeast) have such a decisive influence that the sugar utilization pattern is unstable; this must be taken into account from the taxonomic point of view; (iii) the utilization of saccharose in the absence of invertase without external hydrolysis having been confirmed, it seems logical to admit the existence of a similar system to that of maltozimase[2], but the fact that yeasts that ferment glucose are only capable of assimilating maltose[3] or saccharose remains unexplained.

Action of Phospholipase C on Influenza Virus

INFLUENZA virus is known to contain large amounts of phospholipid. By treating the virus with phospholipase *C*, considerable amounts of acid-soluble phosphoric compounds are released, and the virus becomes sensitive to the action of proteinase from *Streptomyces griseus* (proteinase SG, ref. 1) with reduction of its infectivity.

The 'A2/Kumamoto Y/5/57' strain[2] of influenza virus (non-avid) was used for this experiment. Virus was labelled with ^{32}P by the method of Liu *et al.*[3], and was purified by three cycles of adsorption-elution from chicken red cells, followed by high- and low-speed centrifugation. The final product was suspended in veronal buffered saline, *p*H 7·8, and tested for contamination with non-viral ^{32}P by determining the Geiger count before and after adsorption with red cells. The preparations had an average hæmagglutinin titre of 10,240 and an average Geiger count of 5,480 c.p.m./ml. Of this radioactivity more than 98·5 per cent was carried by the virus particles, and was adsorbable on the red cells. Attempts were made to determine the relative distribution of the isotope in the virus phospholipid. Labelled virus was fractionated by a modification of the Schmidt–Thannhauser technique[4]. The cold trichloroacetic acid (TCA), hot alcohol–ether, hot TCA-soluble fractions, and the residue, were assayed for radioactivity. On average, 15, 50, 24 and 11 per cent of the label were found respectively in cold TCA, hot alcohol–ether, hot TCA fractions and residue. Phospholipase *C*, kindly supplied to us by Dr. H. Ikezawa of this Institute, had been purified from *Cl. perfringens* type *A* α-toxin by the ammonium sulphate and alcohol precipitation procedure[5]. *Streptomyces griseus* proteinase, which is known to have extremely broad substrate specificity, was obtained from the Institute of Physical and Chemical Research, Tokyo.

Aliquots of labelled virus were treated with (1) phospholipase *C*, varying the concentration of enzyme and

the incubation time; (2) phospholipase *C* followed by RNase; (3) phospholipase *C* followed by proteinase SG; (4) phospholipase *C* followed by proteinase SG and RNase; (5) proteinase SG; (6) proteinase SG followed by RNase; and (7) RNase. After treatment, they were chilled and added to cold TCA (final concentration 5 per cent), and centrifuged. The supernatants (acid-soluble fraction) and the precipitates were separated and counted, and the relative radioactivity of each acid-soluble fraction was calculated. The experimental conditions and typical observations, including virus infectivity, as titrated in the allantoic cavity of chick embryos after the enzymatic treatments, are shown in Table 1. A remarkable increase in relative radioactivity of the acid-soluble fraction was observed by the treatment of labelled virus with phospholipase *C*. When the virus was treated for 8 h with this enzyme, the increase reached to 27 per cent of the original label. As 50 per cent of the original label is considered to be due to the virus phospholipid, this value means that about 54 per cent of the virus phospholipid is released into the acid-soluble state. Infectivity after the treatment, as titrated in the allantoic cavity of chick embryos, was 6·5 ($\log_{10}$), whereas that of the control was 7·0. The additional treatment with RNase did not result in further increase of acid-soluble radioactivity. This suggests that virus ribonucleic acid is not yet exposed by the treatment with phospholipase *C* alone. Neither a significant increase of acid-soluble radioactivity nor a reduction of virus infectivity was observed by treatment with RNase alone, proteinase SG alone, and proteinase SG followed by RNase. On the other hand, treatment of the virus with phospholipase *C* followed by proteinase SG reduced its infectivity significantly, and subsequent additional treatment with RNase resulted in a further slight increase of acid-soluble radioactivity. A preliminary experiment using the picrylation method[1] showed that proteinase SG liberated significantly more amino-acid from the phospholipase *C*-treated virus than from this intact virus.

Table 1. Relative Radioactivity of Acid-soluble Fraction and Infectivity after the Successive Treatment of Influenza Virus with Phospholipase *C*; Proteinase SG; and RNase

Treatment			Relative radioactivity of acid-soluble fraction (%)	Infectivity (Log_{10})
Control (incubated without enzyme)			15	7·0
L	2 mg	1 h	37	—
L	2 mg	3 h	38	—
L	10 mg	8 h	42	6·5
LP		0 h	—	6·0
LP		3 h	42	4·5
LPR			49	4·3
LR			43	6·3
P			17	7·3
PR			17	7·3
R			15	7·0

Notes: L, phospholipase *C*; P, proteinase SG, 150 γ for 3 h; R, RNase, 50 γ for 2 h; LP, phospholipase *C* 10 mg for 8 h followed by proteinase SG 150 γ for 0 h or 3 h; LPR, phospholipase *C* 10 mg for 8 h followed by proteinase SG 150 γ for 3 h and RNase 50 γ for 2 h; LR, phospholipase C 10 mg for 8 h followed by RNase 50 γ for 2 h; PR, proteinase SG 150 γ for 3 h followed by RNase 50 γ for 2 h.
Diluent: 0·001 M $CaCl_2$ containing veronal buffered saline. After treatment, enzymes were inhibited by addition of anti-α toxin (for phospholipase *C*) and one-tenth volume of 0·1 M EDTA (for proteinase SG).

The simplest explanation of the observed results would be that virus phospholipid protects, enzymatically or constitutionally, a part of the virus protein which is essential for virus infection. The statement by Hoyle and Frisch–Niggemeyer[6] that, on entry into a host cell, influenza virus phospholipid is destroyed, seems to agree with this hypothesis. Anderson and Ada[7] reported that phospholipase *A* purified from the venom of the black snake failed to inactivate influenza virus, and they considered two possibilities: (1) that intact phospholipid was not necessary for infectivity; or (2) the virus phospholipid was not accessible to the action of the enzyme. The present work shows that the virus phospholipid was accessible to the action of phospholipase *C*.

We thank Dr. Thomas Francis, jun., for advice, Dr. H. Ikezawa for the sample of phospholipase *C*, and Dr. T. Komai for isotopic measurements.

Fatty Acids of Beef Heart Sphingomyelin

A ceramide lactoside, synthesized to approximate to the structure of the tumour hapten cytolipin *H*[1], was reported[2] to have a melting point of 86° C, which appeared low for a cerebroside analogue. A 25-mg sample was absorbed on 7 g silicic acid : 'Celite' (5 : 2) in chloroform, and eluted with increasing methanol concentrations in chloroform. At 5 per cent methanol, about 2 mg of ceramide (m.p. 84°–86° C) was obtained, while the bulk of the material, recovered at 30 per cent methanol, had an infra-red spectrum identical to that of the original material, and a melting point of 167°–170° C (measured on a Kohfler micro-hot stage). Under the same conditions, authentic cytolipin *H* melted at 174°–183° C. At this point, it appeared that the original sample had contained about 10 per cent ceramide (by weight), a contaminant which could not be detected in the infra-red spectrum at that concentration. But the differences in the new melting points could be accounted for by differences in the fatty acids residues of both compounds. A preliminary attempt at the identification of the fatty acid residues of the ceramide lactoside indicated that lignoceric acid (C_{24}, tetracosanoic acid) made up only one-third of the total fatty acids residues, while another one-third was made up on some odd-number saturated fatty acid. It was, therefore, of interest to determine the components of the fatty acid mixture in the sphingomyelin from which the ceramide was prepared for the synthesis of ceramide lactoside.

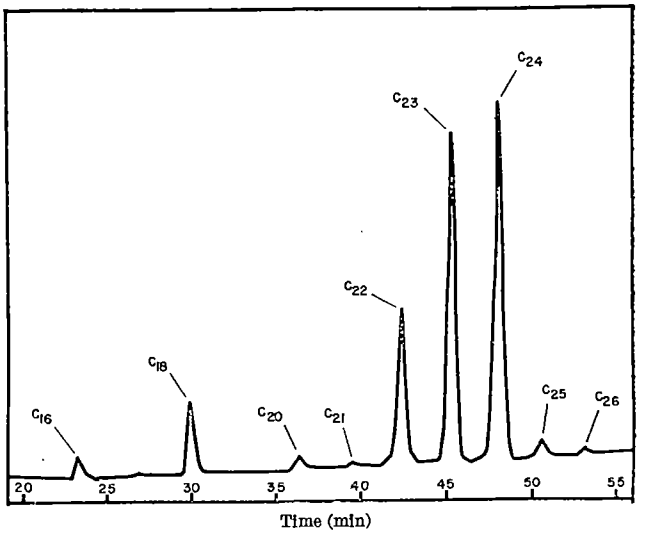

Fig. 1. Gas chromatogram of the methyl esters of sphingomyelin fatty acid residues. Detector: ^{90}Sr argon ionization. Column: 1 per cent *SE* on 'Chromosorb *W*' 80/100 mesh, 6 ft. × 1/8 in. internal diameter, glass. Column temperature; programmed from 125 to 300° C, at 3°/min. Cell temperature: 285° C. Flash heater: 295° C

Sphingomyelin was obtained by repeated recrystallizations in cyclohexane : acetone (1 : 1 v/v) of a beef heart lecithin-sphingomyelin sludge, until the infra-red spectrum showed the absence of absorption at 1,741 cm^{-1} (ester carbonyl from contaminating hydrolecithins). The melting point of sphingomyelins purified in this fashion was raised from 196° to 210°–211° C. A sample of purified sphingomyelin was refluxed for 3·5 h in 10 per cent sulphuric acid in methanol. The methanol was removed under reduced pressure, and water was added to the residue, which was then extracted with methylene chloride. The methylene chloride extracts were dried over anhydrous sodium sulphate, and evaporated to dryness. The waxy residue was recrystallized from methanol, and fractionated by gas chromatography, to give the pattern shown in Fig. 1. The individual peaks were identified by their retention time, and by cochromatography with pure methyl esters of fatty acids. Integration of the area under the peaks gave the relative proportions of the methyl esters in the sample, as recorded in Table 1.

Table 1. Composition of the Methyl Esters Mixture

Methyl ester of:	Per cent
Palmitic acid (C_{16})	1·7
Heptanoic acid (C_{17})	0·3
Stearic acid (C_{18})	7·7
Eicosanoic acid (C_{20})	1·5
Henneicosanoic acid (C_{21})	0·4
Docosanoic acid (C_{22})	16·8
Tricosanoic acid (C_{23})	33·6
Tetracosanoic acid (C_{24})	35·8
Pentacosanoic acid (C_{25})	1·7
Hexacosanoic acid (C_{26})	0·5

In the procedure outlined, the methyl esters of the lower fatty acids would be lost, should this sphingomyelin contain such residues. But there was no evidence of unsaturated, hydroxy, keto, or branched fatty acid methyl esters in the mixture. With the crude assumption that all the fatty acid residues of sphingomyelin were hydrolysed and esterified to the same extent, Table 1 represents an approximation of the ratio of the fatty acid residues in sphingomyelin. The presence of relatively large amounts of an odd-number fatty acid (tricosanoic acid, peak C_{23} in Fig. 1) was not unexpected, since normal even- and odd-number fatty acids from C_{18} to C_{28} occur in butter fat[3]. The chemical and physical properties of tricosanoic and tetracosanoic acids are so similar that it would be difficult to separate and identify them by classical methods. It is, therefore, not surprising that sphingomyelin has long been assumed to contain mostly docosanoic and tetracosanoic acids as fatty acid residues[4].

A similar sphingomyelin preparation had been used in the synthesis of the ceramide lactoside[1]. It appears now that the fatty acid residue of the ceramide lactoside is a mixture whose composition also approaches that shown in Table 1.

Pure fatty acids methyl esters were purchased from the Applied Science Laboratories, State College, Pennsylvania. The beef heart lecithin-sphingomyelin sludges were gifts of the Sylvana Chemical Co., Orange, New Jersey. The authentic sample of cytolipin *H* was donated by Dr. Rapport. This work was supported in part by a grant (*CA* 06991–01) from the U.S. Public Health Service.

Determination of Dipeptidase Activities

Investigations of intestinal mucosal dipeptidases have been hampered in the past by the lack of suitable assay methods. The methods in use at present[1] require relatively large amounts of substrate and are inadequate for the examination of dipeptidase activities in crude tissue extracts or partially purified preparations. The new assay method described here has a wide application and is simple and rapid. It is convenient even when a large number of determinations is required.

The method utilizes the difference in absorption between peptides and amino-acids in the low ultra-violet region[2], in contrast to most current methods which are based on either the release of amino groups[3] or carboxyl groups[4]. Many substances, including proteins, carboxylic acids and buffer ions, also have a strong absorption in the low ultra-violet region and can interfere with the absorption to be measured. These interfering substances are present in relatively high concentrations in crude tissue extracts, and special measures must be adopted to remove them. If this is not done, a method based on the disappearance of the absorption due to the peptide bond will not offer any substantial advantage over those based on the release of amino or carboxyl groups[5].

By using ethanol, with a negligible absorption down to 210 mμ, it is possible to remove the interfering substances by precipitation. This permits the full utilization of the strong absorption of the peptide bond in the low ultra-violet region, and increases the sensitivity many times compared with earlier methods. The precipitation procedure also permits readings with a narrow slit width in the spectrophotometer and therefore eliminates the

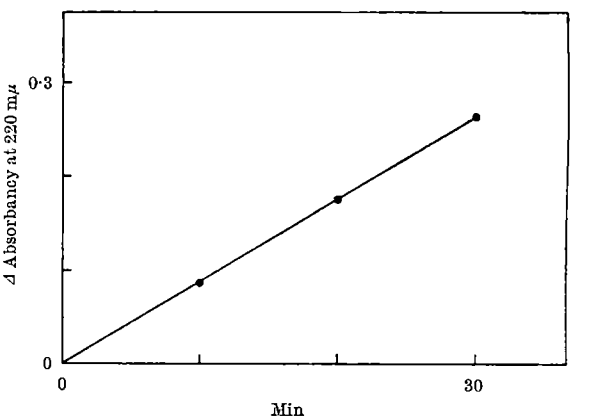

Fig. 1. Change of absorbancy at 220 mμ with hydrolysis of 3·75 μmoles of glycylglycine at 37° C and *p*H 8·0. The enzyme source was a mucosal homogenate from pig intestine, added in an amount containing 5·75 μg of nitrogen. No metal ions were added

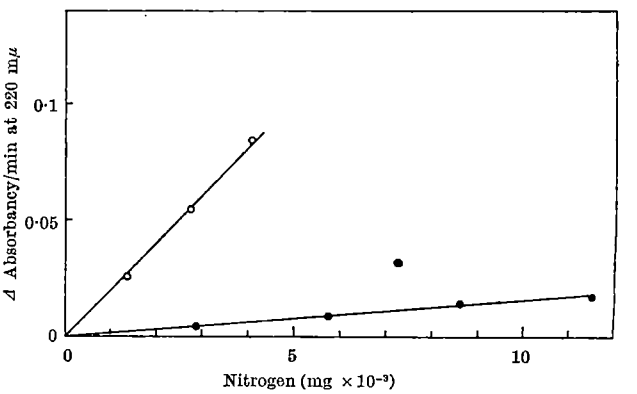

Fig. 2. Velocity of hydrolysis measured at 220 mμ, 37° C and *p*H 8·0 versus enzyme concentration. The enzyme source was a mucosal homogenate from pig intestine and was added in increasing amounts of nitrogen per sample. No metal ions were added. ○, 1·5 μmoles of glycyl-L-leucine. ●, 3·75 μmoles of glycylglycine

risk of interference from stray radiation occurring at these wave-lengths[6].

In general, the assay procedure is performed in the following manner. Fifty μl. of an aqueous dipeptide solution and 100 μl. of a 0·15 M sodium borate solution are mixed in centrifuge tubes. The tubes are kept in a water bath at 37° ± 0·05° C. Appropriate amounts of enzyme (for example, intestinal mucosal homogenate) are then added and thoroughly mixed with the substrate solution. After suitable time intervals, the reaction is interrupted when 1·3 ml. of ethanol is added and the resulting precipitate centrifuged off at 4,000 r.p.m. The clear supernatant is removed and read at 220 mμ in a Beckman spectrophotometer (Model DU) provided with 10 mm semi-micro cuvettes. Samples treated identically, but containing equivalent amounts of the corresponding amino-acids instead of dipeptide, serve as blanks. The concentrations of the substrate solutions were chosen to give an absorbancy for the supernatant from the zero time samples of about 0·9 at 220 mμ; for example, 0·03 M for glycyl-L-leucine and 0·075 M for glycylglycine. The *p*H of the buffer was adjusted to give an optimal *p*H-value for the enzymatic activity to be measured. Metal ions, when used for activation of the enzymes, were added to the digest mixture via the buffer solution.

The assay procedure gives straight-line relationship up to about 40 per cent hydrolysis. The results of a typical experiment are shown in Fig. 1. The velocity when measured by the outlined procedure is proportional to the enzyme concentration, as shown in Fig. 2. The assay method is accurate to within about ± 1 per cent, even when crude tissue extracts are used as the source of enzymes.

PHYSIOLOGY

Formation of Isorhodopsin in the Frog's Eye during Continuous Illumination

Both in solution and in the intact rods the rhodopsin of the frog, *Rana temporaria*, absorbs light maximally at the wave-length 502 mμ (λ_{max} 502 mμ)[1]. Like the other vertebrate rhodopsins it is composed of a colourless protein, opsin, combined with the 11-*cis* isomer of retinal (formerly retinene)[2]. Light isomerizes the 11-*cis* retinal (the chromophore) to the all-*trans* configuration, thereby converting rhodopsin into all-*trans* lumi- and meta-rhodopsin. In the dark or in weak illumination the meta-rhodopsin (λ_{max} at about 480 mμ) completely hydrolyses to free opsin and pale yellow all-*trans* retinal, which reduces to colourless retinol (formerly vitamin A) (ref. 3). But it has been demonstrated that in solutions a bright light can isomerize the all-*trans* chromophores of lumi- or meta-rhodopsin into mixtures of stereoisomeric chromophores, all still attached to opsin. The 11-*cis* fraction of this mixture is rhodopsin, the 9-*cis* fraction isorhodopsin (a thermally stable but photosensitive rhodopsin analogue, λ_m486 mμ (refs. 3–5)). It has been demonstrated that this back-isomerization of coloured intermediates also takes place during flash-irradiation in suspensions of rods[5] and in the living rat eye[6], but the yield of isorhodopsin is less in these experiments *in situ* (about 20 per cent of the thermally stable pigment) than in the corresponding experiments with solutions (about 50 per cent)[4].

The coloured intermediates are, however, so short-lived that they occur in large amounts only after bright flashes of light. During continuous illumination the amounts of intermediates are so slight in the mammalian eye that their isomerization into isorhodopsin and back into rhodopsin cannot be detected. The formation of rhodopsin during permanent illumination is thus not faster than in the dark, when rhodopsin is regenerated only from free 11-*cis* retinal and opsin[6–8]. But in the frog's eye the situation is apparently different. The orange intermediate (λ_{max} 470–480 mμ) observed *in situ* in the frog's rods is more stable than the metarhodopsin in solution[5,9], and my experiments suggest that an isomerization of this intermediate into rhodopsin and isorhodopsin plays an important part in excised and opened frog eyes during strong and continuous illumination at 13°–14° C.

I have investigated the regeneration of rhodopsin in opened eyes. These eyes are excised from strongly light-adapted (60 min) frogs, then opened in white light and further illuminated for 25 min at 13°–14° C, and after that left to dark-adapt in a dark chamber at 13°–14° C for different lengths of time. The course of the regeneration is the same as with intact frogs[10]. The careful preparation of the opened eyes, the extraction and the spectrophotometric measurements have been described earlier[11]. In the actual experiments the digitonin solution and the ice-cold acetate buffer (*p*H 4·6), into which the eyes are placed immediately after regeneration, contained 0·1 M hydroxylamine in order to prevent a synthesis of rhodopsin or isorhodopsin *in vitro* or during the washing of the retinas.

The content (more exactly the extinction) of the red photosensitive pigments in the central parts of the light-adapted retinæ is 5·1 ± 0·1 per cent of the rhodopsin content (extinction) in the central parts of fully dark-adapted retinæ and during the first 10 min in the dark an average of 0·5 per cent is regenerated per min. Since the bleaching and synthesis of the photosensitive pigments are in equilibrium in the light-adapted eyes, we can also estimate the rate of synthesis in light, if we know the bleaching rate. Since the bleaching effect of the lamp on the rhodopsin in a dark-adapted retina is known, and the screening effect of the pigment epithelium in the central parts of the light-adapted retinæ can be estimated[9], it seems possible to calculate the rate of bleaching. In this way I have found that 1·5–2·5 per cent (of the extinction of the dark-adapted rhodopsin content) is synthesized per minute in the central parts of the light-adapted retinæ. This leads to the unexpected conclusion that rhodopsin synthesis is faster in light than during the first minutes in the dark. The difference spectrum of the pigment extracted from eyes strongly light-adapted for a considerable time, however, helps us to explain the situation. I have put together all the difference spectra I have obtained from these light-adapted retinæ and the resulting curve (Fig. 1) shows that λ is maximal at 490–495 mμ and is in fair agreement with the difference spectrum of a photosensitive pigment, which Bridges[4,5] has obtained by flash-illumination of frog rhodopsin (λ_{max} 502 mμ). In Bridges's pigment, λ_{max} = 494 mμ; by partial bleaching analysis it was proved to be a nearly 50 : 50 mixture of rhodopsin and isorhodopsin (λ_{max}, 486 mμ). This suggests that a photoisomerization of intermediates has occurred and that a considerable amount of isorhodopsin is formed in the opened eyes during continuous illumination. This effect of a long illumination is in agreement with Hubbard and Kropf's[3] observation that the relative quantum efficiency for converting cattle metarhodopsin (in solution) to rhodopsin is 5 times larger than the quantum efficiency for converting metarhodopsin to isorhodopsin, but that

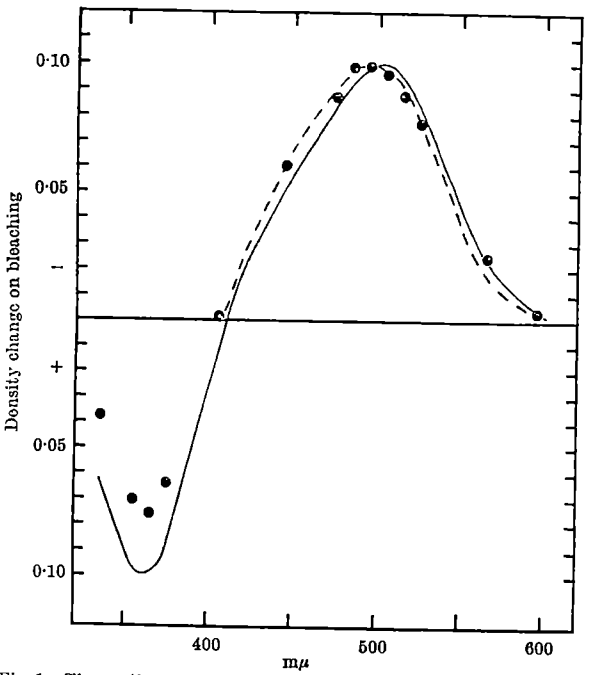

Fig. 1. The continuous line shows the difference spectrum of rhodopsin, extracted from fully dark-adapted frogs' retinæ. The broken line shows the difference spectrum of Bridges's (ref. 4) 50 : 50 mixture of rhodopsin and isorhodopsin, and the solid circles are measurements of the difference spectrum of a photosensitive pigment extracted from strongly light-adapted frogs' retinæ. All spectra refer to extracts which contain hydroxylamine

the rhodopsin bleaches about 3 times faster than isorhodopsin in a dim white light.

I have also investigated the photoisomerization *in vivo* by calibrating two lights, one blue (462 mμ) and one green (558 mμ), so that they had an equal bleaching effect on a rhodopsin solution, and by allowing the two dark-adapted eyes (opened in red light) from the same frog to bleach in these lights. Several such experiments were made, and the rhodopsin contents in both eyes were measured after different lengths of exposure to these coloured lights. After 1–20 min of bleaching the 'blue eyes' always contained significantly more rhodopsin than the 'green eyes'. After 10 min in the lights the blue and the green eye respectively contained 52 and 28 per cent of the rhodopsin content in an unbleached eye, but after that the differences became smaller. This difference between the blue and the green light suggests that the intermediate, which *in vivo* is isomerized back to rhodopsin, is Bridges's metarhodopsin-like orange intermediate[5] (λ_{max}, 470–480 mμ), and not a lumirhodopsin, because the absorption spectrum of the frog's lumirhodopsin is not displaced to shorter wavelengths from the spectrum of rhodopsin[12].

This investigation was supported by grants from the "Svenska Vetenskapliga Centrālradet", the "Leo och Regina Wainsteins Stiftelse" and the "Oskar Öflunds Stiftelse".

I thank Dr. K. O. Donner for many helpful suggestions.

Effect of *d*-Gamma-tocopherol on the Incidence of Teratogeny in Vitamin E-deficient Rats

IT has been found that administration of an adequate dose of *d*,l-α-tocopheryl acetate (*d*,l-ATA, 1 mg or more) to vitamin E-deficient rats, not later than the 8th day of gestation, prevented fœtal resorption and insured birth of the usual number of full-term normal young[1]. When female rats were given vitamin E at too late a stage of pregnancy (after the 12th day of gestation) their fœtuses were partially or wholly resorbed or were dwarfed and dead. Congenital abnormalities occurred when a single dose of 1 mg or more of vitamin E was given at a critical time during gestation, between the 8th and 12th days. Such abnormalities included exencephalus, cleft palate, facial fissures, arrested development of the parietal and occipital bones, nasal fossæ and sternebræ, ectocardia and gastroschisis.

The development of the abnormalities has been traced[2]. Arrested development could be seen in 11-day embryos. By the 13th day of gestation, exencephalus was apparent. Preliminary observations on changes in the glycogen content of developing embryos have been made[3]. Œstrogen or progesterone has been found to abolish or reduce the incidence of these congenital abnormalities[4].

Variations in the composition of the rations affected the yield of the abnormal as well as the normal young, the incidence of resorption and the average number of implantation sites[5]. It was also found by chemical assay that maternal serum and liver tocopherol-levels were lowest in the vitamin E-sufficient group, highest in the vitamin E-deficient group and intermediate in the marginally E-deficient groups with abnormal young[6]. The tocopherol-level of the maternal skeletal muscle, however, showed the opposite trend. Furthermore, the tocopherol-levels of the abnormal fœtal sera, liver and carcasses were slightly, though not significantly, lower than those of the normal ones from the corresponding groups.

Since there are many forms of vitamin E, it was deemed of interest to determine the effect of these on the incidence of teratogeny. However, many forms were not readily available. In this study *d*-γ-tocopherol (*d*-GT) was used and its effects were compared with those of *d*,*l*-ATA.

Weanling female rats of the Holtzman strain, weighing approximately 40 g, were fed a vitamin E-deficient ration consisting of 49 per cent dextrin, 22 per cent lard, 18 per cent vitamin-free casein, 5 per cent brewer's yeast, 4 per cent salt mixture (U.S.N. XIV) and 2 per cent cod liver oil[5]. When they reached a weight of about 175 g they were mated with males which were fed 'Purina' pellets. After mating, as evidenced by the presence of sperm in the vaginal smear, females were assigned to different groups. In one series of experiments 1, 2, 4 or 8 mg of *d*,*l*-ATA in 1 ml. of corn oil ('Mazola') was given to each rat by gavage on the 10th day of gestation. Also, positive controls which received 2 mg of *d*,*l*-ATA during the first five days of gestation and negative controls which did not receive any vitamin E supplementation were used. In the second series of experiments, 1, 2, 4 or 8 mg of *d*-GT was given on the 10th day of gestation. Positive controls which received 2 mg of *d*-GT daily during the first five days of gestation were also used. All rats were laparotomized on the 21st day of gestation and the fœtuses examined for gross congenital malformations.

The reproductive performance of the vitamin E-deficient rats given *d*-GT and *d*,*l*-ATA is presented in Table 1. Rats with *d*-GT supplementation did not gain as much weight as those of corresponding groups on *d*,*l*-ATA. This was especially striking in the positive control group which gained only half as much weight as those given *d*,*l*-ATA. Rats given 1 mg *d*-GT gained as little weight as the negative control. The average gain in weight of rats given 2, 4 or 8 mg *d*-GT was only slightly higher than that of the negative controls, but lower than that of rats given as little as 1 mg of *d*,*l*-ATA. However, for some unknown reason,

Table 1. Reproductive Performance of Vitamin E-deficient Rats given *d*-Gamma-Tocopherol (*d*-GT) and *d,l*-Alpha-Tocopherol Acetate (*d,l*-ATA) during Gestation

Vitamin E given	Dose/day mg	Given on day(s) of gestation	No. rats bred	Avg. wt. gain/rat during gestation g	Live fœtuses: Normal % †	Live fœtuses: Abnormal % †	Live fœtuses: Abnormal % ‡	Dead fœtuses: Not resorbed % †	Dead fœtuses: Resorbed % †	Implantation sites* Avg. No. ± *S.D.*

* Including those of live resorbed and non-resorbed dead fœtuses. † In terms of total number of implantation sites. ‡ In terms of total number of viable young. § $P < 0{\cdot}01$ relative to corresponding groups given *dl*-ATA. ¶ $P < 0{\cdot}05$ relative to corresponding groups given *dl*-ATA. ‖ $P < 0{\cdot}02$ relative to corresponding groups given *dl*-ATA.

the rats with 8 mg *d,l*-ATA did not gain more weight than those given 4 mg of the same vitamin although there was an increase in the incidence of normal young. At all four levels of *d*-GT supplementation there was a significant decrease in the percentage of normal and abnormal live young with a concomitant increase in the incidence of resorption when compared with rats that had received *d,l*-ATA. It is of interest to note that even in the positive control group the *d*-GT could only produce 16 per cent of live normal young whereas identical treatment with *d,l*-ATA yielded 100 per cent live normal offspring. However, the 10 mg of *d*-GT given to the positive control group in five separate doses did also prevent teratogeny altogether as in the case of *d,l*-ATA.

Recently, by the dialuric acid and hæmolysis assay test of vitamin E, Friedman *et al.* found that *d*-γ-tocopherol had about one-fifth the potency of the α form and that tocopherol esters were about as potent as free tocopherols[7]. In their work on the influence of various tocopherols on the incidence of encephalomalacia, Bunnell *et al.*[8] observed that *d*-α-tocopherol compared with *d*- or *d,l*-α-tocopheryl acetate gave higher incidence of encephalomalacia and lower blood tocopherol-levels. The intramuscular injection of 9 per cent 'Tween-80' emulsion of pure α-, δ- and γ-tocopherols showed γ-tocopherol to be nearly equivalent to α-tocopherol in preventing encephalomalacia, and δ-tocopherol to be ineffective. Scott *et al.*[9] noted that γ-tocopherol fed at a level of 20 mg/lb. of ration delayed onset of symptoms of exudative diathesis in some chickens, while *d*-α-tocopheryl acetate (5 mg/lb.) prevented all symptoms and promoted a good rate of growth. In examining the utilization of pure α-, γ- and δ-tocopherols by laying hens. Dju *et al.*[10] found that α-tocopherol induced the greatest deposition of the vitamin in the eggs while γ-tocopherol was one-fourth as effective as α-tocopherol. Selzer *et al.*[11] reported little or no protection against liver necrosis in rats when γ-tocopherol was fed on a molar basis equivalent to that at which α-tocopherol gave protection. In studying liver degeneration in rats on diets containing 30 per cent *Torula* yeast, Emerson and Dooley observed that *d*-γ-tocopherol afforded less than one-tenth the protection given by α-tocopherol[12]. Griffiths[3] showed a relative rate of 18·7 per cent for the liver storage of γ-tocopherol in the growing chick compared to 100 per cent for α-tocopherol. Our results indicated that *d*-γ-tocopherol was much less effective (84 per cent) than *d,l*-α-tocopheryl acetate in preventing fœtal death and resorption. This phenomenon was probably due to both the absence of the α form[14] and the absence of the ester which is 62 per cent more potent than the free form[15]. By virtue of its low biological potency[16], *d*-γ-tocopherol also eliminated or reduced the occurrence of congenital malformations. Furthermore, higher levels of supplementation of *d*-γ-tocopherol were no more beneficial than the lower ones since even at 8 mg it was still below the median fertility dose of 8·9 mg calculated out by Joffe and Harris[14]. This was contrary to the observed beneficial effect of corresponding higher levels of *d,l*-α-tocopheryl acetate as far as increase in the number of normal young and decrease in fœtal resorption were concerned.

It has been observed that an oral dose of γ-tocopherol is deposited in the ingested form in livers of rats[17]. Apparently no methylation to α-tocopherol occurs. This may, in part, explain the ineffectiveness of even higher levels of γ-tocopherol in improving the growth of the fœtuses and preventing fœtal death and resorption.

I thank Dr. P. L. Harris of Distillation Products Industries, Rochester, New York, for *d*-γ-tocopherol, and Dr. J. P. Kass of Pabst Laboratories, Milwaukee, Wisconsin, for the brewer's yeast.

Site of Cardiac Glycoside Inhibition of Cation Transport

The cardiac glycosides have been shown to be specific inhibitors of active cation transport in a wide variety of tissues[1–4]. The specificity of this inhibition was first demonstrated by Schatzmann, who found that these glycosides blocked sodium extrusion from cold-stored red cells without affecting either lactate production or oxygen consumption[4].

The isolated toad bladder has been extensively used as an *in vitro* analogue for the investigation of a variety of transport processes. In the present investigation, the cardiac glycoside strophanthin *K* has been shown to

produce a marked inhibition of sodium transport in this tissue, an inhibition which was specifically blocked by increasing the serosal potassium concentration.

Hemibladders from freshly pithed *Bufo marinus* were dissected free and mounted between the halves of a modified Ussing short-circuit apparatus[6]. Boyle–Conway medium (Na, 104; K, 2·5; Ca, 1·6; Mg, 1·2; Cl, 78; HCO_3, 2·5; PO_4, 3·0; SO_4, 1·9; and glucose, 5·5 m.moles/l.) independently bathed the two surfaces of the membrane[7]. Aeration and continuous stirring were provided by a mixture of O_2 and CO_2, 95 : 5; the final *p*H was 7·6. Net transmembrane sodium transport from the mucosal to the serosal surface of the tissue was measured as its electrical analogue, the short-circuit current (SCC) (ref. 6).

After a stable baseline current had been recorded with conventional Boyle–Conway medium (Na, 104; K, 2·5 m.moles/l.) on both sides of the membrane, a high potassium Boyle–Conway medium (Na, 5; K, 102 m.moles/l.) was substituted at the serosal surface of the preparation. When the SCC was stable, strophanthin *K** was added to the serosal medium in a final concentration of 2×10^{-4} moles/l. Inhibition of sodium transport was assessed as the decrease in SCC measured as a percentage of the predicted value obtained by extrapolation of the control curve 10 min after glycoside was added.

The solutions were then removed, and replaced by the original Boyle–Conway medium (Na, 104; K, 2·5 m.moles/l.). After a suitable control period, strophanthin *K* was again added to the serosal medium in a final concentration of 2×10^{-4} moles/l. and the inhibition of sodium transport assessed as previously described.

The mean SCC in the five experiments was 57 (range 20–90) μamp in the presence of 2·5 m.moles/l. potassium at both surfaces of the membrane. When strophanthin *K* was added to the serosal chamber the mean decrease in SCC was 55 ± 10 per cent ($P < 0{\cdot}001$) after 10 min. In four of these experiments, the SCC fell to zero within 30 min, indicating total cessation of active sodium transport.

The substitution of high-potassium medium at the serosal membrane reduced the SCC to a mean of 30 (range 10–60) μamp. When strophanthin *K* was added to the serosal compartment in the presence of this high-potassium medium, however, there was no further reduction in SCC (4 ± 2 per cent). At no time did the SCC approach zero, in marked contrast to the results with normal potassium buffer.

Strophanthin *K* was totally ineffective in suppressing the SCC when added to the mucosal medium under any circumstances.

Sodium transport by the isolated surviving toad bladder has been extensively investigated in recent years[8,9].

Sodium ions penetrate the cell through the mucosal (urinary) membrane, which is selectively permeable to sodium, along a favourably oriented electrochemical gradient. The extrusion of sodium through the serosal membrane occurs against the electrochemical gradient for sodium and is by definition an 'active' process accomplished by a 'pump' mechanism, located in the serosal membrane, and is dependent on the metabolic integrity of the tissue[10]. The rate of sodium transport is determined by both the 'passive' permeability of the mucosal membrane to sodium ion and the activity of the serosal pump.

Bricker, Biber and Ussing[10] and Frazier and Leaf[11] recently showed that active sodium transport persists in the isolated frog skin and the toad bladder, respectively, in the presence of inside (serosal) potassium concentrations of 120 m.moles/l. This property was employed in the studies reported here for the evaluation of cardiac glycoside inhibition of the serosal sodium pump, when it was exposed to medium approximating extracellular cation composition (Na, 104; K, 2·5 m.moles/l.), and independently to high potassium serosal medium (Na, 5; K, 102 m.moles/l.). Since the composition of the mucosal medium was not altered (Na,104; K, 2·5 m.moles/l.), the concentration driving force for sodium penetration into the cell at the mucosal surface remained constant, and the effect of the potassium concentration on the serosal sodium pump could be independently evaluated.

It is apparent that the cardiac glycoside, strophanthin *K*, did not significantly modify sodium transport when the serosal sodium pump was exposed to a high-potassium environment. In contrast, a marked inhibition of sodium transport was noted when conventional 2·5 m.mole-potassium serosal medium was employed.

Caldwell and Keynes have demonstrated that ouabain inhibited sodium transport in nerve fibres when applied externally but not when injected intracellularly[12]. This lack of intracellular glycoside effect could result from either a marked spatial specificity of carrier–inhibitor interaction or a competitive inhibition of the glycoside effect by the normally high intracellular potassium concentration. The experiments described here, in which the potassium concentration of the medium to which the serosal sodium pump is exposed can be increased while the sodium concentration necessary for mucosal sodium penetration is held constant, favour the latter explanation.

The therapeutic effects of cardiac glycosides are widely held to be exerted through a modification of cation transport processes[13], although this has not been substantiated in all studies[14]. Since the normally high intracellular potassium concentration appears to inhibit the action of intracellular glycosides on cation transport processes, it is concluded that these effects are a function of their concentration in the extracellular medium *per se*.

In summary, the isolated surviving toad bladder was employed to evaluate the effect of cardiac glycosides on active sodium transport. Strophanthin *K*, 2×10^{-4} moles/l., markedly depressed the short-circuit current when the serosal membrane was in contact with medium containing 2·5 m.moles/l. potassium but had no inhibitory effect when medium containing 102 m.moles/l. potassium was substituted at the serosal surface. These observations suggest that the lack of inhibition by intracellular glycoside of sodium transport previously described in squid axon is attributable to the intracellular potassium concentration. As a corollary, the therapeutic effects of cardiac glycosides *in vivo* appear to be a function of their extracellular concentration alone.

I thank Dr. Isidore S. Edelman and Dr. Peter H. Forsham for help and advice.

PHARMACOLOGY

'Viractin': a Prophylactic Agent against Upper Respiratory Infections

'Viractin' is the name we are proposing for the active principle in the mycelium of *Streptomyces griseus* cultures which produce actidione[1,2], and which we have found to prevent selectively upper respiratory infections in man. The activity of viractin was first noted in 1946 while one of us (B. E. L.) was isolating, crystallizing, and characterizing actidione. It was observed then that the people working with the actidione process were not susceptible to upper respiratory infections.

The preparation that has been used for *in vitro* investigations, tissue culture, animal, and also clinical studies was developed from residues of actidione mother liquors (generously supplied by the Upjohn Co., Kalamazoo, Michigan). The active principle was concentrated by distillation from this residue which has a characteristic mouldy odour. The crude distillate is the fraction collected between 60° and 200° C at 200μ. The viractin concentrate used in all investigations reported here was obtained by redistilling the crude distillate and collecting the fraction boiling at 105°–135° C at 200μ. Neither the crude distillate nor the redistilled preparation contains actidione. Gas–liquid chromatography shows that the active concentrate contains approximately 30 peaks. Only two compounds, 2,4-dimethyl*cyclo*hexanone and maltol, have been identified in this mixture. The cyclic ketones are apparently the major components, and it is postulated that one or more of these ketones is the active principle. Concentrated sulphuric acid produces a highly coloured product with the major peak at 292 mμ. This peak has been used to assay the product and to serve as a guide in dispensing the material for clinical testing.

Tissue culture investigations have shown that viractin has no significant *in vitro* viricidal activity against seven human respiratory viruses, measles and polio virus at a concentration of 0·5 mg/ml. When tested by the intranasal route in mice infected with the influenza virus, it showed only marginal activity at 100, 200 and 400 mg/kg. The LD_{50} of the preparation is 200 mg/kg intranasally, 300 mg/kg intravenously and more than 300 mg/kg subcutaneously. Inhalation toxicity of the vapours of viractin has been determined in rats confined to a chamber of 80 l. capacity into which air was introduced at a rate of approximately 250 ml./min after being directed forcefully against the surface of the viractin distillate contained in a 25 ml. vial. Three of the ten male rats comprising the treated group were killed after exposure for five days to 2·5 gm of the volatilized concentrate, and the remainder after an additional four days of exposure to another 2·5 gm of the volatilized product. No gross detrimental effects were observed. In fact, the treated animals had gained slightly more weight than the controls. Gross and histopathological investigations were made of their respiratory tract and other organs. Microscopic examinations of the lungs, trachea, spleen, kidney, adrenals and heart showed no essential differences between exposed and control animals. In concentrations used clinically, viractin has shown no toxic symptoms in animals or man. The lack of an *in vivo* or *in vitro* assay method to demonstrate antiviral activity has seriously delayed this investigation.

Since there is no reliable assay method in animals (except for toxicity investigations) for antiviral preparations which are not viricidal, such as viractin, observations on the human being were undertaken cautiously. The concentrated distillate has a vapour pressure which makes it possible to administer viractin as an inhalant over prolonged periods at extremely low concentrations. It was first tested for its effectiveness in reducing the incidence of upper respiratory infection prophylactically, using the family as a unit. After collecting these preliminary results, it was realized that they would not be scientifically acceptable for a number of reasons, including the lack of adequate controls. Also, the criteria of what constitutes an upper respiratory infection are debatable among clinicians. It was decided to carry out a preliminary study in a hospital of the chronically ill (neurological and psychiatric patients) since the turnover of patients would be very low. The viractin was evaporated from cotton balls at room temperature in two wards of approximately 80 patients each for a period of five months. The cotton balls were replenished with viractin concentrate at bi-monthly intervals. The results were striking in that the patients in these two wards escaped the Asian influenza epidemic which went through the hospital while the test was under-way. The two wards used to control this investigation had 47 patients with acute attacks of influenza among the 112 patients. It was also effective in preventing the occurrence of the common upper respiratory infections, for only 8 patients out of the 160 in the test wards had upper respiratory infections during that 5-month period of observation. Viractin was again tested the following winter with equally good results.

Table 1. Effect of Treatment with Viractin on Upper Respiratory Infection in Man

No. of days the upper respiratory infection persisted	Experimental group. 310 patients for a period of 77 days. No. of patients with upper respiratory infection	Placebo group. 320 patients for a period of 77 days. No. of patients with upper respiratory infection
2	2	17
3	4	11
4	3	5
5 or more	0	11

From these preliminary clinical tests it was postulated that viractin acts prophylactically to prevent upper respiratory infections by combining competitively with the sites where the virus attaches itself to the host cells. This is not a novel idea without experimental evidence, because it has been shown by Davies *et al.*[3] that amantadine hydrochloride shows antiviral activity by interfering with the penetration of the virus into the host cell.

A double blind clinical study was then conducted in a hospital for the chronically ill during March 1–May 16, 1964, to determine the effectiveness of this agent. The product was dispensed on cotton gauze squares in four wards with an average population of 310 patients (neurological and psychiatric). We use the average population because the patient population is relatively constant at this hospital, never exceeding more than 10 patients admitted or discharged for any given week in the four experimental wards. The amount placed on each gauze square for evaporation at room temperature was 79,000 optical density units (optical density observed times dilution factor) calculated as the sulphuric acid chromogen at 292 mμ. This amount was allowed for 1,000 ft.^{3} of air space. These gauze squares were strategically placed only in the sleeping wards, and each square was replaced every 14 days. In this way, the active principle would be at a low and slowly decreasing concentration in the air for inhalation during each 14-day period. The placebo selected to control the investigation was a mixture of ethanol and amyl acetate in the same proportions in which they occurred in the test material, to which was added small amounts of kitchen bouquet for colouring and methyl salicylate for odour. This gave it a detectable but not easily recognizable odour. It was placed in four wards of the same hospital with an average population of 320 patients. The turnover of patients was the same as given for the experimental wards.

Since this was a double blind study, the physicians, nurses, and attendants were instructed to record all upper respiratory infections. Patients showing any symptoms of upper respiratory infections were recorded by the nurses and checked by the ward physician. Severity of symptoms was also recorded by a number code:

1, first mild symptom of upper respiratory infection; 2, moderate symptoms; 3, fever; 4, patients confined to the infirmary. Because the nurses and physicians had no way of positively diagnosing a true upper respiratory infection from an allergic response, psychosomatic upset, etc., they recorded all symptoms. We consider a true upper respiratory infection as one which persists for five or more days.

Table 1 gives the number of patients who had upper respiratory infection of 2, 3, 4 and 5 or more days duration for the entire investigation, control and experimental. The results indicate a lower incidence of upper respiratory infection in experimental wards for the 77-day observation period than in the wards with the placebo for the same time period. If we consider an upper respiratory infection of 5 or more days duration to be the ones representing a true upper respiratory infection in man, then viractin reduced the incidence to 0 in the experimental wards while the placebo wards had 11 patients with upper respiratory infection.

The cumulative evidence has shown that viractin holds promise as an effective prophylactic agent for upper respiratory infections. Additional evidence from several hundred other individuals and families over the past seventeen years is also worthy of note.

Solubility Relations of Fluorine Compounds and Inert Gas Narcosis

Two main physicochemical theories of inert gas narcosis have been put forward. The Meyer–Overton[1] theory postulates that the intensity of narcotic action varies as the concentration of narcotic in the lipids. More recently, Pauling[2] and Miller[3] have suggested that the aqueous phases play a dominant part and relate narcotic activity to the tendency to form hydrates or more generally to induce structure ('icebergs') in water.

For most simple narcotics the predictions of both theories are in substantial agreement as the narcotic effects of simple molecules are broadly in keeping with many of their thermodynamic properties, boiling points, ideal solubilities or polarizabilities[4,5]. However, in the case of fluorinated compounds these general relations break down and provide a means of discrimination between the theories. Such substances deviate very markedly from ideality in solution. Certain fully fluorinated gaseous compounds have the lowest recorded solubilities in water although their solubilities in organic solvents are less exceptional.

Though the dissociation pressures of hydrates at 0° C have been used to estimate the degree of structure a solute induces in water another indication is provided by the entropies of solution[6]. The entropy of solution of SF_6 has been estimated as -22 e.u. at 25° C using measurements of its solubility in water over a range of temperatures[7]. The results are in good agreement with those of Friedman[8], though both sets differ by a factor of five from another determination[9]. Such a high entropy of solution would suggest a narcotic activity much higher than that observed (as would the dissociation pressure of its hydrate). Table 1 summarizes the data for a typical series of gases[10] and illustrates that solubility in the lipids (as represented by olive oil) is the best indication of narcotic activity, other factors showing little correlation when fluorinated compounds are considered. In the case of CF_4 for which no anæsthetic data are available the predictions of the two theories are very different. The hydrate theory would suggest an anæsthetic pressure of ~0·5 atm., a degree of narcotic activity unlikely to have gone unnoticed during the search for fluorocarbon anæsthetics, whereas the lipid solubility theory would indicate about 5 atm*.

Table 1

Gas	Anæsthetic pressure (atm.)	Diss. pressure hydrate 0° C (atm.)	$-\Delta S$ soln (25°C) (cal. deg^{-1} mole^{-1})	Bunsen coeff. olive oil (37° C)
He	~200	—	3	0·015
N_2	29	160	7	0·067
A	20	95·0	9	0·14
Kr	2·9	14·5	13	0·43
CH_4	4·6	26·0	11	0·28
SF_6	3·0	1·0	22	0·25
Xe	0·85	1·2	16	1·70

We thank Prof. W. D. M. Paton for his advice.

**Note added in proof.* Preliminary experiments have shown that CF_4, at a partial pressure of 3 atm., does not produce anæsthesia in mice.

Effects of Insecticide Synergists on Duration of Sleep induced in Mice by Barbiturates

A number of otherwise pharmacologically inactive compounds are known to prolong sleep induced by barbiturates in mammals[1]. The most widely investigated of these is '*SKF 525A*' (2-diethylaminoethyl 2,2-diphenylpentanoate), which prolongs the action of barbiturates and other drugs by inhibiting liver microsomal enzymes which degrade a wide variety of drugs[1]. When applied to insects, '*SKF 525A*' synergizes pyrethroid insecticides and antagonizes the toxicity of the organophosphorus poison, malathion[2]. In these respects, '*SKF 525A*' mimics the action of commonly used insecticide synergists such as piperonyl butoxide[2]. Although piperonyl butoxide and other chemically related synergists have been included in insecticide formulations for many years, their effects on drug activity in mammals have not been examined. In this communication the effects of two insecticide synergists on the hypnotic action of barbiturates are described.

The synergists (Fig. 1) examined were: (1) technical piperonyl butoxide containing 80 per cent 3,4-methylenedioxy-6-propylbenzyl butyldiethylene glycol ether and 20 per cent related compounds; (2) 96–98 per cent pure sesoxane (2-(2-ethoxy ethoxy)-ethyl 3,4-methylenedioxyphenyl acetal of acetaldehyde). The synergists were administered by intraperitoneal injection to 15–20 g female mice. Initially it was established that the synergists themselves (emulsified with 'Tween 20' in physiological saline) injected at dosages as high as 75 mg/kg did

	R	R_1
Piperonyl butoxide	$CH_2CH_2CH_3$	$CH_2(OCH_2CH_2)_2OC_4H_9$
Sesoxane	$O—CCH_3(OCH_2CH_2)_2C_2H_5$ (OH)	H

Fig. 1. Structure of piperonyl butoxide and sesoxane

not induce sleep or cause any visible harmful effects in mice observed for 24 h. Synergists were then given at 50 mg/kg to batches of 10 mice, and 30 min later the mice received 100 mg/kg hexobarbital sodium in saline. At the same time a control group of 10 mice were injected with 20 mg/kg of the emulsifying agent 'Tween 20' 30 min before receiving 100 mg/kg of the hexobarbital. A few minutes after being injected with hexobarbital, the mice in all three groups lost their 'righting reflex' and the time taken to regain this reflex was regarded as the sleeping time.

The results of this experiment are given in Table 1. They demonstrate that the synergists prolong sleep which is induced by the hexobarbital. Essentially the same results were obtained when either synergist was injected simultaneously with the barbiturate. Piperonyl butoxide was also found to extend the sleeping time of another barbiturate, pentobarbital sodium. Piperonyl butoxide (75 mg/kg), given simultaneously with 50 mg/kg pentobarbital ('Nembutal'), caused a batch of 17 mice to sleep an average of 220 ± 77 min compared with 33 ± 16 min for a control group of 18 mice (P = 0·00025–0·0005). (Two of the 19 mice originally injected with the pentobarbital and the synergist failed to recover from their sleep.) Piperonyl butoxide loses its ability to extend sleeping time within 24 h. Thus 19 mice treated with 75 mg/kg piperonyl butoxide 24 h before receiving 100 mg/kg hexobarbital slept an average of 17 ± 4 min compared with 24 ± 8 min for a control group of 18 mice (P = 0·1–0·05).

Table 1. Effect of Piperonyl Butoxide and Sesoxane on the Duration of Hexobarbital Sodium (100 mg/kg) Sleeping Time

Sleeping time ± S.D. (min)		
Control	Mice treated with 50 mg/kg piperonyl butoxide	Mice treated with 50 mg/kg sesoxane
25 ± 9	102* ± 29	143* ± 27

* Means significantly different from control; $P < 0·0005$ (Student's t test).

The means by which piperonyl butoxide and sesoxane prolong barbiturate action is not known. They do not appear to act by increasing the sensitivity of the site of action of the drugs, as mice receiving either synergist immediately following recovery from hexobarbital hypnosis did not return to sleep. Piperonyl butoxide and sesoxane and some related methylenedioxy phenyl synergists are known to block detoxication mechanisms in insects[3,4] and rats[5]. It would seem likely, therefore, that like '*SKF 525A*' the synergists also prolong the effects of barbiturates on mice by inhibiting drug detoxication.

Methylenedioxy phenyl synergists such as piperonyl butoxide are often included in pyrethrin insecticide formulations. In ordinary usage it is unlikely that mixtures of this kind would offer any risk to individuals taking barbiturates. Barbiturates are, however, recommended for supportive therapy in cases of accidental poisoning with synergized and non-synergized insecticides[6]. The findings obtained here suggest that this practice could bear re-examination, especially as some chlorinated and organophosphorus insecticides which are not usually combined with synergists are also known to lengthen the duration of action of barbiturate in mice[7].

The results presented in this communication raise three other interesting points. First, they indicate that insecticide synergists, of which a wide variety are known[3], could be useful tools in pharmacological research. Secondly, it is possible that the incorporation of moieties associated with synergistic activity (for example, methylenedioxy phenyl groups)[3] into suitable structured drug molecules could result in longer-lasting drug action. In this connexion, it is noteworthy that the methylenedioxy analogue of trimethoxyamphetamine is reported to be somewhat more potent to man than trimethoxyamphetamine or the closely alled compound, mescaline[8]. Finally, it has been shown that measures of pyrethrin-resistance are substantially reduced in the presence of methylenedioxy phenyl synergists[9]. These synergists might also have some practical application in overcoming drug-resistance in those bacteria and protozoa where resistance is determined by drug degradation mechanisms.

TPNH Oxidation by the Prepuberal Rat Testis

TPNH generation in immature and adult rat testis *in vivo* is under hormonal control[1,2]. Greenberg and Glick, working with ACTH injections in the adrenal cortex, also found increased TPN reduction[3]. There is biochemical evidence that reduced TPN is required for steroid synthesis *in vitro*. Lynn and Brown[4] showed that TPNH is essential for testosterone microsomic synthesis. Hall and Eik-Nes[5] demonstrated in the rabbit testis *in vitro* that TPNH accelerates the conversion of ^{14}C cholesterol to ^{14}C testosterone. The experiment related in this communication was performed with the aim of elucidating whether or not reduced TPN is oxidized by the immature rat testis, and if this function is under hormonal control. Immature animals were selected because in them the dilution factors that interfere with enzymatic assays in adult animals[2] are not significant.

Immature A × C inbred rats of our colony were used, weighing 20 g at the onset of the experiment. The experimental animals were injected with 5 units per day of chorionic gonadotrophin for five days. At the end of the experiment the animals were killed by sudden decapitation. The biological effect of the hormone was measured by testis, seminal vesicle and prostate weight. The testicular tissue, free from its capsule, was homogenized in 10 per cent 0·25 M sucrose in a motor-driven Potter–Elvehjem homogenizer at 2,000 r.p.m. Then the homogenate was centrifuged at 1,800 and 10,000 r.p.m. under refrigeration. The two fractions obtained in this way were called fraction 1 and fraction 2.

The following assays were performed in fraction 1: G-6-P dehydrogenase by the method of Horecker and Kornberg[6], isocitric dehydrogenase by the method of Ochoa[7], and TPNH oxidase by the method of Kaplan[8].

In fraction 2, TPNH diaphorase was assayed by the method of Ernster[9].

The following results were obtained:

	Control	Experimental	Increase (%)
G-6-P dehydrogenase	35·6 ± 3·6	78 ± 2·7	116
Isocitric ,,	74·5 ± 9·2	120 ± 3·1	61
TPNH oxidase	0	0	0
TPNH diaphorase	43·2 ± 3·5	76·4 ± 7·2	76
Testis weight	60 ± 5	74·5 ± 2·9	25
Prostate weight	6·7 ± 2·7	12·2 ± 1·2	82
Seminal vesicle weight	3·2 ± 0·98	11·9 ± 1·2	270

G-6-P and isocitric dehydrogenase activities are expressed as millimicromoles of reduced TPNH per mg of protein in 5 min, TPNH diaphorase as millimicromoles of reduced dichlorophenolindophenol. Organ weights are expressed in relation to 10 g body-weight.

These results confirm our previous findings showing that the specific activities of the enzymes that generate TPNH in the prepuberal testis of the rat are under hormonal control; they also show that TPN diaphorase is under hormonal control, while there is no TPNH oxidation in either the normal rats or the stimulated ones. Another series of experiments[10] demonstrated by manometric techniques that TPNH generating systems cannot be coupled to respiration unless an exogenous mediator, vitamin K, is supplied.

There is a striking discrepancy between the increased activity of TPNH diaphorase elicited by the hormone and the absence of TPNH oxidation. Since TPNH diaphorase is considered a component of the respiratory chain and it is not possible to stimulate respiration in testis by TPNH generating systems, it seems plausible that in this system the electron acceptor for soluble TPNH diaphorase is other than cytochrome *c*.

Steroid synthesis is a microsomal function which entails hydroxylation. In view of the results obtained in this work we can assume that testis TPNH diaphorase may have hydroxylating activity analogous to that of the hydroxylases already described in the literature[11]. Philips and Langdon[12], in a study done on liver microsomal TPNH cytochrome *c* reductase, have suggested that this enzyme could have a function analogous to that which we propose for TPNH diaphorase.

Alkaloid Content of Tobacco Seeds

There are many publications in various languages about the alkaloid content of tobacco leaves. The same cannot be said about tobacco seeds, and the few publications that exist do not all agree. G. Albo[1] accepted the probable presence of a solanin-like substance, but not nicotine. In his opinion this is a nutritive substance for the embryo, and therefore not to be expected in the developed plant. Scurti and Perciabosco[2] found neither solanin nor any alkaloid-like substance in tobacco seeds, but instead did find allantoin. According to G. Paris[3], the ripe seeds are free from nicotine. J. Chaze[4] investigated the existence and cytological formation of alkaloids in tobacco plants, and maintained that nicotine is not present in the seed. He showed that alkaloids do exist in the germinated seeds, in the vacuoles of cells of the growing seedling.

According to G. Klein[5], tobacco seeds contain trigonelline, but this was not confirmed by Abdoh and Taufel[6]. On the other hand, Abdoh and Taufel proved that trigonelline was not present in the tobacco seed, but found a compound with a pyridine ring, possibly nicotinamide or nicotinic acid. G. I. Vormann[7] examined the oil of tobacco seeds for alkaloids and found a very weak positive reaction with phosphotungstic acid. On the other hand, P. Radua[8] reported a lack of nicotine-positive reaction in the mature seeds of *N. tabacum*. The gradual degradation of nicotine in the presence of tobacco seeds was shown by Walter G. Frankenburg[9].

We have again re-examined the question of the occurrence of nicotine or other tobacco alkaloids in mature tobacco seeds.

Mature seeds, which were 1, 2, 3 or 4 years old from three species of Iranian tobacco plants—*Nicotiniana basmacerus*, *N. trabzant* and *N. tikolak*, acclimatized to the northern areas of Iran—were used in the present investigation.

20 g of seeds were ground in a porcelain pestle and mortar, then mixed with 150 ml. 30 per cent sodium hydroxide and finally extracted with 75 ml. of a mixture of benzene and chloroform in the ratio of 9 : 1 in a separating funnel. The procedure was repeated five times. The benzene and chloroform layers were separated and filtered. Ethanol and water (50 : 50) were added and the mixture acidulated with sulphuric acid (N/10). After shaking in a separating funnel the water layer, which contained alkaloids, was removed and concentrated to 5 ml. To this concentrate a solution of sodium hydroxide was added to bring the *p*H to 7·2. This concentrate was used in chromatography.

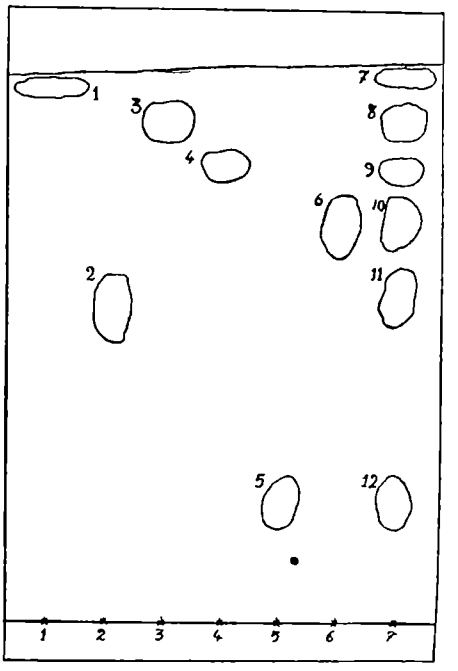

Fig. 1. Chromatogram of extract of fresh seeds. 1, Nicotyrine; 2, nornicotine; 3, nicotine; 4, nicotinamide; 5, nicotinic acid; 6, anabasine; 7, Nicotyrine; 8, Nicotine; 9, Nicotinamide; 10, anabasine; 11, nornicotine; 12, nicotinic acid. Solvent *n*-butanol/acetate buffer 0·1 M (*p*H 5·6), 50 : 50 v/v—upper layer is used

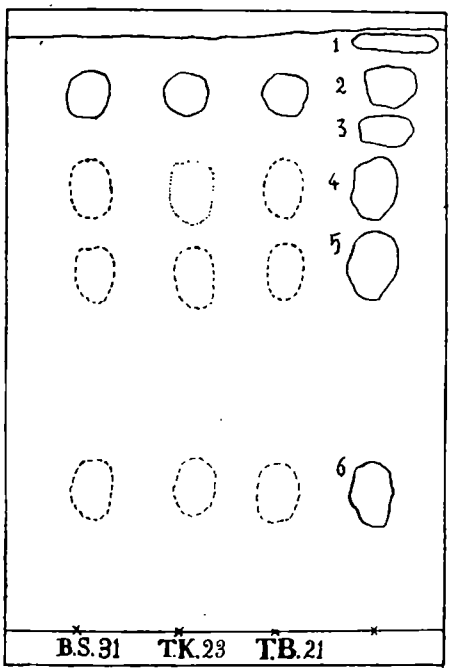

Fig. 2. Chromatogram of extract of 1-yr-old seeds. 1, Nicotyrine; 2, nicotine; 3, nicotinamide; 4, anabasine; 5, nornicotine; 6, nicotinic acid. Solvent *n*-butanol/acetate buffer 0·1 M (*p*H 5·6), 50 : 50 v/v—upper layer is used

Experiments with non-buffering and buffering papers revealed that the best system was achieved by spraying the paper with 0·1 M acetate-buffer (*p*H 5·6), and using the upper layer of normal butanol–acetate buffer 0·1 M (*p*H 5·6) in the ratio 50 : 50. We sprayed the Whatman No. 1 paper with acetate buffer and dried it in air. The samples were applied to this paper, and it was kept in a cylinder filled with the vapour of the lower layer of the above-mentioned mixture for 0·5 h to reach a state of equilibrium. It was then developed for 21 h at 23° C by the ascending method, in a closed glass cylinder, which was lined with paper saturated with the vapour of the lower phase of the mixture.

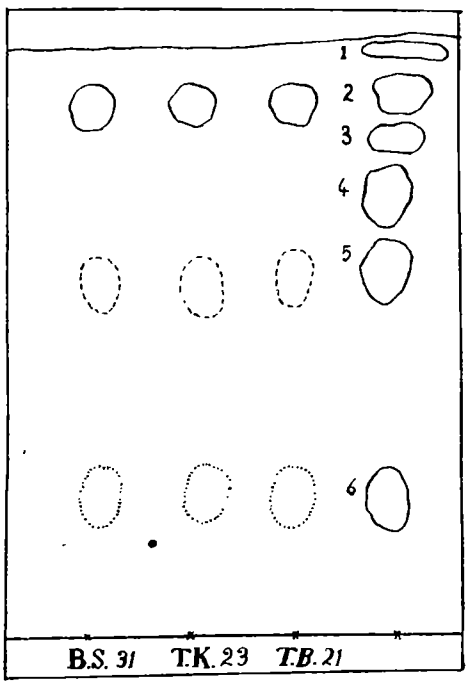

Fig. 3. Chromatogram of extract of old seeds. 1, Nicotyrine; 2, nicotine; 3, nicotinamide; 4, anabasine; 5, nornicotine; 6, nicotinic acid. Solvent *n*-butanol/acetate buffer 0·1 M (*p*H 5·6), 50 : 50 v/v—upper layer is used

The chromatograms were first examined with a 2 per cent alcoholic solution of 2,4-dinitrofluorobenzene and 5 per cent solution of sodium hydroxide. In the later experiments we used *p*-aminobenzoic acid and cyanogen-bromide fumes. Fig. 1 shows the chromatogram of six alkaloids and related compounds which were obtained from pure substances. In the experiments with one-year-old seeds, we first used the 2,4-dinitrofluorobenzene and sodium hydroxide solution. The results for all three species showed the appearance of nicotine spots.

To confirm the foregoing results we repeated the experiments with *p*-aminobenzoic acid and cyanogen-bromide fumes. The result showed the presence of four substances, nicotine, anabasine, nornicotine and nicotinic acid (Fig. 2). Of the two reagents, cyanogenbromide fumes were more effective.

Further experiments with the old seeds were carried out. The extract of old seeds (B.S.31, three years old; T.K.23, two years old; T.B.21, four years old) were examined with 2,4-dinitrofluorobenzene and sodium hydroxide, and nicotine spots were obtained from all three plant species. We repeated this experiment with the reagent P.A.B.A. and cyanogen-bromide fumes. We obtained nicotine, nicotinic acid and nornicotine spots in all three species, but found no anabasine (Fig. 3). Generally, the spots of anabasine, nornicotine and nicotinic acid were less pronounced than the nicotine spot; furthermore, the spots (especially of nicotinic acid) of the old seeds were clearer than those of the one-year-old seeds, and the spots of the T.K.23 species were weaker than those of the other two species.

We conclude, therefore, that the alkaloids nicotine, anabasine, nornicotine and nicotinic acid exist in mature seeds, and it appears that more alkaloids can be found in the fresh mature seeds than in the old seeds.

We thank Mr. Saphir Paulis for the supply of tobacco seeds and Messrs. E. Merk for the tobacco alkaloids.

HÆMATOLOGY

Xg^a Investigations of the Family of a Child with a Ring *X* Chromosome

Elsewhere in this issue of *Nature* (p. 804) Pfeiffer and Büchner report their observations on the morphology and DNA synthesis of a ring *X* chromosome in a child with Turner's syndrome. The investigators kindly gave us the opportunity to test the blood of the patient and her relatives for *Xg*^{a}. (The anti-*Xg*^{a} serum was kindly provided by Dr. A. Cahan, Knickerbocker Biological Inc., New York.)

The first observations of the *Xg*^{a} testing in this family were: mother, brother and sister of the patient positive, father and patient very weakly positive or negative. Repeating the tests with the red cell suspensions of father and patient resulted again in doubtful reactions, even when a double volume of antiserum was used. Therefore,

absorption tests were performed: one volume of anti-Xg^a-serum was incubated with one volume of packed red cells for 30 min at 37° C. After incubation with the father's and the patient's red cells the absorbed sera reacted negatively or almost negatively with a suspension of the mother's erythrocytes. It may be concluded from these findings that some weak Xg^a activity is present on the father's and the patient's red cells.

A few possibilities are suggested as an explanation for these results: (1) the mother is homozygous Xg^aXg^a or heterozygous Xg^aXg^b; the patient received an Xg^a carrying chromosome which lacks its Xg^a locus by deletion. (2) The mother is heterozygous Xg^aXg^b and the child received the Xg^b carrying chromosome, which may have lost its Xg locus or not. In both cases the intact X chromosome in the patient must be the paternal one, carrying the very weak Xg^a factor. (3) The ring chromosome carries the mother's 'normal' Xg^a factor, the patient's very weak Xg^a reaction being due to the mixed occurrence of cells with the ring chromosome and XO cells. This seems improbable, however, since the patient's red cells reacted at least as weakly with anti-Xg^a as those of the father. In the presence of a normal X with weak Xg^a in a mosaic, with a normal Xg^a factor, a stronger reaction would be expected. (4) Another possibility is that both father and patient possess normal Xg^a factors, and that modifying genes are responsible for their weak manifestations, a hypothesis impossible to assess from available data.

As the mother has two normal Xg^a positive children, the probability of her genotype being Xg^aXg^a is about 80 per cent. The chance that she would transmit an Xg^b gene to a third child is therefore 10 per cent: the most probable interpretation of the observed facts is that the child received a maternal X chromosome from which the Xg locus had been deleted. This would indicate that the Xg locus is situated at the short arm, or far from the centromere at the long arm, of the X chromosome.

Separation of White Blood Cells

A convenient way of obtaining white cells from whole blood is simply to allow EDTA-blood to settle in siliconized glasses and then pipette off the leucocyte-rich supernatant after 1·5 h or more. A more rapid separation occurs when agents which aggregate erythrocytes are added to the blood[1]. The effect of these agents may be utilized even without mixing them with the blood. From physical chemistry it is known that a reaction between two compounds may be increased manifold if it occurs at an interface[2]. Similarly, the clumping of the erythrocytes may be accelerated when the process occurs at an interface.

Methylcellulose ('Methocel', Dow Chemical Co., Michigan), ethylhydroxyethylcellulose, methylhydroxypropylcellulose and hydroxyethylcellulose have been found to clump erythrocytes quite efficiently. Methylcellulose (MC) is mixed with 'Natrii' *N*-methyl-3,5-diacetamido-, 2,4,6,-trijodbenzoas ('Isopaque', Nyco Ltd., Oslo, Norway), which is an X-ray contrast for intravenous use. 'Isopaque' (Is) is suitable for many purposes in this field, because of its low viscosity at high concentrations, and its rather low osmotic activity.

A stock solution of Is with specific gravity of 1·20 (33⅓ per cent) has been mixed with solutions of MC of 0·8, 1·2, 1·6 and 2 per cent, to form final solutions with specific gravities of 1·08, 1·09, 1·10, 1·11 and 1·12. One ml. EDTA blood (EDTA 10 per cent, 1 : 50) is then applied on the top

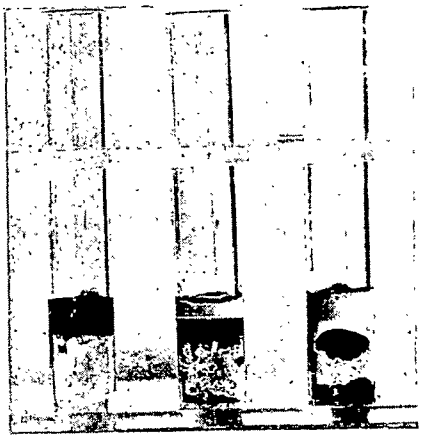

Fig. 1. Cell separation with a mixture of 'Isopaque' (33⅓ per cent) and methylcellulose (1·2 per cent). Specific gravity 1·09. The figure shows the situation after 1, 15 and 30 min

of these mixed solutions in siliconized centrifuge glasses with inner diameter of 13 mm. The blood column is about 7 mm high. The red cells are now clumped by MC at the interface, and fall down to the bottom of the glass (Fig. 1).

When the sedimentation of red cells is completed, the white cells follow them slowly downwards. Therefore, the supernatant should be pipetted off when there is a clear zone of 2–3 mm between the layers. The time for separation to occur will vary between 15–65 min in this system. The separation time is lengthened as the specific gravity or viscosity increases.

The supernatant contains platelets and 30–50 per cent of the white cells in the original blood volume. As to the contamination of red cells in the supernatant, the following points can be noted.

(1) When the specific gravity is kept constant, the number of red cells in the supernatant is reduced as the concentration of MC increases.

(2) If the concentration of MC is constant, the removal of red cells is more efficient as the specific gravity increases.

(3) The best separation is obtained with a rather high specific gravity and a low MC concentration.

Table 1 gives the result at five different levels. Each value represents the average of 10 samples, taken from different persons: 0·5 ml. (about five-sixths) of the supernatant was pipetted off from each glass. The mean white cell count in peripheral blood was 6,138/mm³.

Table 1. Separation of Blood Cells in the Methylcellulose 'Isopaque' System

Stock solutions (%)	Sp. gr.	MC conc. (%)	Leucocyte count in supernatant /mm³	Erythrocyte count in supernatant /mm³	Separation time (min)
Is. 33⅓ MC 2·0	1·08	1·25	4,451	3,309	18·0
Is. 33⅓ MC 2·0	1·09	1·11	4,430	2,512	24·5
Is. 33⅓ MC 1·6	1·10	0·80	4,303	1,999	35·0
Is. 33⅓ MC 1·2	1·11	0·54	4,313	1,636	44·5
Is. 33⅓ MC 1·2	1·12	0·48	3,700	925	58·0

The 'Isopaque'/methylcellulose system has served as a model system for other combinations of compounds, where the reaction principles are the same, for example, red cell removal. Some of these will be briefly described.

'Isopaque'/dextran. A 6 per cent solution of dextran ('Dextran 500', Pharmacia, Uppsala, Sweden) is mixed with Is (33⅓ per cent) to form solutions with specific gravities of 1·07–1·11. Separation time will be 10–60 min. The white cell yield is 30–50 per cent. The red cell number in the supernatant may be below 500/mm³. This system provides a very stable interface, since, when separation has occurred, plasma and white cells will remain at the top for hours.

'Isopaque'/'Ficoll'. Is (33⅓) is mixed with 'Ficoll' (Pharmacia, Uppsala, Sweden). Solutions with 10–15 per cent of 'Ficoll' and specific gravities of 1·09 are suitable.

Leucocyte yield is 40–60 per cent. Erythrocyte number in the supernatant is usually somewhat greater than in the two former systems.

'Ficoll'/EDTA. A 50 per cent solution of 'Ficoll' is mixed with 4–5 per cent EDTA to form a solution with specific gravity of 1·09. Separation time is about 40 min. White cell yield is 50–60 per cent. 1,000–2,000 red cells/mm³ are found in the supernatant.

EDTA/dextran. A 28 per cent solution of EDTA is mixed with 10–20 per cent solutions of 'Dextran 500' to form solutions with specific gravities of 1·11–1·14. Separation time will vary between 20 and 60 min. The white cell yield is 60–80 per cent. The red cell number in the supernatant will be somewhat higher than in the other systems. A 28 per cent EDTA solution is made in the following way: 35 ml. of distilled water is added to 28 g of EDTA and *p*H is then adjusted to 7·3 with a 30 per cent sodium hydroxide solution. Distilled water is then added to a final volume of 100 ml.

In some cases some small red clumps will be left exactly at the interfacial level. Therefore, to obtain a low red cell contamination, only the upper five-sixths of the supernatant should be pipetted off. The white cell yield is increased by using a greater volume of blood. With heparin as anticoagulant, 2·5 I.U. per ml. blood is suitable.

IMMUNOLOGY

Cell-bound and Cell-binding Antibody in the Peripheral Blood of Immunized Rabbits

In a previous communication we reported on the production of antibody by peripheral blood leucocytes of rabbits[1]. The following work was undertaken to examine the relationship between cell-bound and cell-binding antibody in blood. The term 'cell-bound antibody' is used here to describe substances which at the time of testing were associated with blood leucocytes and enabled these cells to react specifically with the homologous antigen. The expressions 'cell-binding antibody' and 'cytophilic antibody' will connote globulin components of immune serum which become attached *in vitro* to cells in such a way that these cells are afterwards capable of specifically absorbing antigen[2,3].

A study of cell-bound and cytophilic antibodies appears to be of special interest in view of the continued need for a simple and sensitive direct *in vitro* test for reagins. The present model, although not dealing with reagins, was thought to give some indication as to the feasibility of such tests for cell-bound and cell-binding antibody.

Rabbits were immunized by eight intravenous injections of 1 ml. human serum. After 12 weeks of rest they were boosted with 1 ml. human serum intravenously. Five days later the animals were bled from the femoralis. 25 ml. of blood were immediately mixed with 5,000 units of heparin/0·5 ml. saline and 2·5 ml. Dextran solution ('Macrodex', Pharmacia, Uppsala, Sweden). After standing for 1 h at room temperature at an angle of 45°, the supernatant fluid with the leucocytes was withdrawn and centrifuged at 400 g for 7 min. Further lots of leucocytes were obtained by two more centrifugations of the remaining blood. The combined leucocytes were removed after washing with 10 ml. of a solution containing 50 ml. 5 per cent rabbit serum in Gey's solution and 2·5 ml. of 20,000 units heparin.

For evaluating the level of cell-bound antibody about $30–50 \times 10^6$ leucocytes, which still contained up to 50×10^6 microgram ^{131}I–human serum albumin (HSA), and (*b*) first pretreated with methanol for 5 min at room temperature, washed three times with Gey's solution and then incubated with labelled antigen as under (*a*). Blood leucocytes and red cells from normal rabbits served as controls. The results are summarized in Table 1.

Table 1. Cell-bound Antibody in Rabbit Blood

Cells	Animal No.	Antigen (^{131}I–HSA) adsorbed on to cells	No methanol (c.p.m.)	Methanol pre-treatment (c.p.m.)
Leucocytes from immunized rabbits	66	(*a*)	164	(*a*) 1,441

Normal erythrocytes		(*a-c*)	1	(*a-c*) 3

Applied antigen in experiment (*a*) 0·5 μg ^{131}I–HSA = 2,751 c.p.m.
Applied antigen in experiment (*b*) 0·5 μg ^{131}I–HSA = 4,643 c.p.m.
Applied antigen in experiment (*c*) 0·5 μg ^{131}I–HSA = 11,103 c.p.m.

The blood leucocytes from immunized rabbits carried large amounts of cell-bound antibody. It is evident from the controls that this fixation of antigen is not due to red cells present in the leucocyte preparations, since in nearly all the rabbits even 5×10^8 red cells had no appreciable antigen-binding capacity. The effect of methanol was somewhat variable. In four out of six blood leucocyte preparations methanol increased the fixation of antigen. This observation would tend to suggest that some of the antibody responsible for antigen-binding was present intracellularly and made available by methanol pretreatment of cells, an interpretation compatible with our previous findings that blood leucocytes can produce antibodies[1].

Our findings[3] of the existence of cytophilic antibodies in antisera to various antigens suggested that part of the antigen-fixing capacity of blood leucocytes from immune rabbits may have been caused by fixation of humoral cytophilic antibody on to the leucocytes.

The sera of the immunized rabbits were therefore tested in our 'standard technique' for the titration of cytophilic antibody using blood leucocytes and spleen cells from normal rabbits[4,5]. Table 2 gives the results. Cytophilic antibody levels in the immunized animals, when tested with $1·5 \times 10^8$ normal nucleated spleen cells, showed the expected levels. In contrast, only low cytophilic titres could be measured with the same sera when 4×10^7 normal blood leucocytes were used. As is shown in Table 1, a similar cell number from immunized rabbits had a much higher affinity for the antigen. These results suggest that the antigen-binding capacity of blood leucocytes from immunized rabbits was probably due only to a small extent to passive adsorption of

Table 2. Cytophilic Antibody Levels in Immunized Rabbits

Type of rabbit cells used for antibody fixation	Sera Animal No.	Antigen (^{131}I–HSA) adsorbed on to cells (c.p.m.)
Normal leucocytes	66	69
	78	17
	85	7

circulating antibody on such cells. The main contribution to antigen fixation must therefore have been made by antibody-producing cells in blood, as demonstrated earlier.

In summary, the results suggest the possibility of measuring the levels of cell-bound and cell-binding antibody in blood. Whether this method can be applied to the measurement of circulating and blood cell-bound reagins, or factors associated with the delayed-type hypersensitivity, remains to be investigated.

7 S Globulin, Immunologically Identical to 19 S Gamma-1 (beta-2)-M-globulin, a New Protein of Horse Serum

KLAUSNER[1] described, at the beginning of the century, a precipitation produced by distilled water in syphilitic sera. This reaction was afterwards found in kala-azar (especially by Brahmahari and later by Sia; also called the Sia test), in malaria, in Waldenstroem's macroglobulinæmia, in the syndrome called African splenomegalia and in sleeping sickness. Chorine[2] showed that it consists in fact in an extension of the normal euglobulin precipitation to the alkaline area. The same extension was found by Felton[3] in the serum of horse immunized by pneumococci. Later it was demonstrated that this is the case for all horses immunized intravenously with bacteria. We show here that in equine serum the fraction responsible for this alkaline precipitation is composed mainly of a 7 *S* globulin, immunologically identical to 19 *S* γ-1 (β-2)-M-globulin.

Our work was performed with the sera of horses immunized intravenously with pneumococci, with meningococci, or with plague bacilli. The serum, diluted to 1/15 with 0·01 M phosphate buffer, was brought to *p*H 8. Indeed at this *p*H all the γ-group globulins are already anionic and therefore the heteropolar interactions which cause euglobulin precipitation[4] cease. The precipitate was washed 3–4 times with diluted phosphate buffer at *p*H 8 and lyophilized. Here we will call this precipitate 'Sia factor'. The quantity of Sia factor, lower than 0·1 per cent in normal horse serum, is 1–2 per cent in antibacterial horse sera[5]. Free electrophoresis shows the diffuse band of γ-globulins. The results of analytical ultracentrifugation depend largely on the value of the ionic strength. In the presence of concentrations lower than 2 per cent anhydrous sodium sulphate and lower than 5·5 per cent sodium chloride three components are present: a 7 *S* globulin, an atypical macroglobulin (9–12 *S*), and a typical macroglobulin (18–19 *S*). With higher salt concentrations, two components only are present: a 7 *S* and a 19 *S* globulin. The proportion of the latter does not change notably with the ionic strength; therefore it is the atypical macroglobulin that yields 7 *S* globulin when the ionic strength increases (Table 1). The 18–19 *S* component predominates in the case of normal equine serum (about 70 per cent); the atypical macroglobulin-yielding 7 *S* component predominates in the Sia factor of immune horse sera (75–95 per cent). The Sia factor is immunologically homogeneous in the case of immune sera. It has, on the immuno-electrophoretogram, the mobility of γ-1-globulin, and its long precipitation line presents the double curvature usually noticed with γ-1 (β-2)-*M*-globulin (Fig. 1). Two antigenic components are present in the Sia factor of normal horse serum; one has the immuno-electrophoretic appearance of 7 *S* γ-globulin and the other, that of the γ-1 (β-2)-*M*-globulin. A relation of partial immunological identity exists between the 7 *S* γ-globulin of normal horse serum and the Sia factor of immune horse sera (Fig. 2).

Table 1. RESULTS OF ANALYTICAL ULTRACENTRIFUGATION
Sia factor of horse anti-plague serum

Na_2SO_4 (%)	$(s_1)^w_{20}$ Proportion (%)	S	$(s_2)^w_{20}$ Proportion (%)	S	$(s_3)^w_{20}$ Proportion (%)	S

Sia factor was fractionated on DEAE-cellulose column. Three bands are obtained under comparable conditions either with the preparation from normal or from immune sera. The first band is eluted by 0·02 M phosphate buffer of *p*H 8; the second by 0·04 M phosphate buffer of *p*H 8; and the third by 0·2 M sodium monophosphate. In the case of normal horse serum, the first band is practically pure 7 *S* γ-globulin; the second and third bands give an

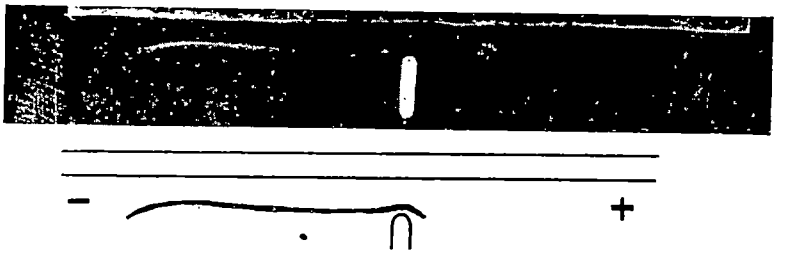

Fig. 1. Immuno-electrophoretogram of crude Sia factor obtained from anti-meningococcal horse serum. Rabbit anti-horse serum in the antibody trough

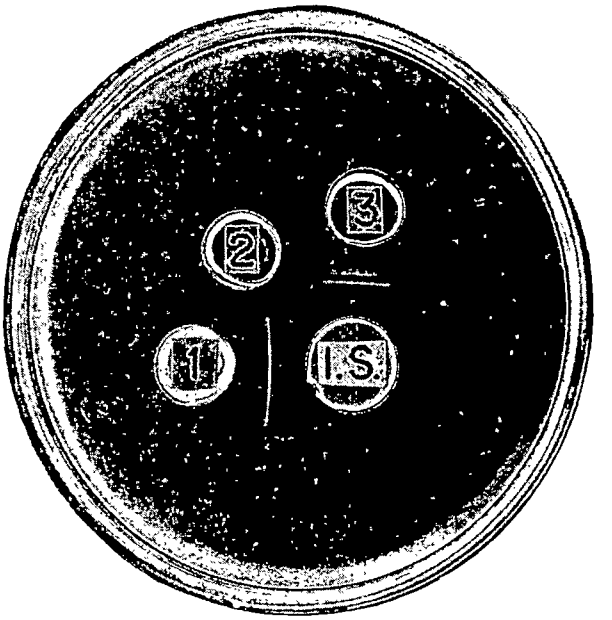

Fig. 2. Ouchterlony test comparing Sia factor to 7 *S* γ-globulin. Well 1, crude Sia factor of anti-meningococcal horse serum; well 2, 7 *S* γ-globulin of normal horse serum; well 3, normal horse serum; *I.S.*, crude anti-Sia factor serum of rabbit

immunological identity reaction with the Sia factor of immune horse sera, but the second band consists almost exclusively of the atypical macroglobulin yielding 7 *S* globulin in salt solutions of high ionic strength, where the third is composed for about 90 per cent of 18–19 *S* globulin. The first and second chromatographic bands seem to be identical in the case of immune sera. They are practically pure atypical macroglobulin yielding 7 *S* globulin in salt solutions of high ionic strength. All the 18–19 *S* globulin is found in the third band in a proportion varying between 20 and 70 per cent. The remainder is the atypical macroglobulin (Table 2). The molecular weights evaluated by light scattering in Brice's apparatus, in the presence of variable ionic strength, are presented in Fig. 3. The constant value of 170·000 in salt solutions of high ionic strength seems to become infinite when the ionic strength tends towards zero, suggesting a variably

Well 1, 7 *S* γ-globulin of normal horse serum; well 2, macroglobulins of normal horse serum; well 3, chromatographic band I; well 4, chromatographic band III; well 5, 7 *S* γ-globulin of normal horse serum; *I.S.*, rabbit anti-Sia factor serum saturated with 7 *S* γ-globulin of normal horse serum

Table 2. Sia Factor of Anti-plague Horse Serum

Analytical ultracentrifugation of the chromatographic bands

	Na_2SO_4 (%)	$(s_1)^w_{20}$ Proportion (%)	S	$(s_2)^w_{20}$ Proportion (%)	S	$(s_3)^w_{20}$ Proportion (%)	S
Band I							
0·19%	0·6			100·0	9·3		
Protein	1·2			100·0	8·2		
	2·5	91·0	6·9	9·0	?		
Band III							
0·16%	0·6			89·2	9·1	10·8	19·2
Protein	1·2			86·4	7·8+11·4	13·9	18·4
	2·5	76·5	6·6	4·4	10·0	19·2	18·4

aggregated precipitating system in weak ionic strength salt solutions. The three chromatographic bands are immunologically identical and they yield an identity reaction with a fraction of normal horse serum containing about 95 per cent 18–19 *S* globulins when examined by Ouchterlony test in the presence of anti-Sia factor rabbit serum (Fig. 4). The macroglobulin fraction of normal horse serum was obtained by Filitti-Wurmser and Hartmann's[6] modification of the technique of Koenig *et al.*[7].

The first and second chromatographic band of the Sia factor of immune horse sera, representing in a pure state the native monomeric γ-1 (β-2)-M-globulin, contains 16·4 ± 0·1 per cent nitrogen and a little less than 1 per cent of hexoses. It therefore differs from the polymeric γ-1 (β-2)-*M*-globulin also by having practically lost its carbohydrate part. It is constituted largely, perhaps entirely, of antibodies. Its minimum solubility is at *p*H 8. Normal horse serum contains about 0·01 per cent of this entity and immune horse sera 0·8–2 per cent.

Human serum differs in many respects from horse serum. Nothing precipitates in the normal human serum at *p*H 8 in solutions of low ionic strength. The precipitate produced in pathological sera is constituted exclusively of 7 *S* γ-globulin and of typical 19 *S* γ-1 (β-2)-*M*-globulin; the latter predominates (about 90–95 per cent).

RADIOBIOLOGY

Tritium Labelling of Antibodies

A large number of alkylating agents react with proteins while forming relatively stable compounds. Ethyl methane sulphonate (EMS) reacts in proteins mainly with non-ionized amino groups and ionized sulphydryl- and carboxyl-groups[1]. Below *p*H 8, the carboxyl groups constitute the majority of the alkylated groups, and above this *p*H-level the amino groups are also alkylated. By varying the *p*H it is possible to vary the pattern of the groups which are alkylated[2], and this can be utilized to attach tritium-labelled groups to proteins. In the work recorded here we used tritium-labelled EMS, which was synthesized from commercially available tritiated ethanol (ethanol-2-*T*, Radiochemical Centre, Amersham) and methanesulphonic anhydride.

210 mg of EMS (0·518 c. per mole) in a 21-ml. solution of 1 per cent human globulin in 0·5 M $NaHCO_3$ were incubated at 37° C in a water bath. Samples of 3 ml. were withdrawn at certain intervals and dialysed at a temperature of 5° C against 0·9 per cent NaCl, the latter being changed frequently until a constant value of outer liquid

radioactivity was reached (about 24 h). One-ml. portions of the protein samples were evaporated in aluminium trays, weighed, and measured in a windowless gas flow proportional counter. The amount of protein was sufficient to reach infinite thickness for tritium β-particles. To convert counts per minute to ethyl groups per gram of protein, the labelled protein was compared to known amounts of the original EMS solution + protein in a liquid scintillation counter. Fig. 1 shows c.p.m. and the corresponding number of ethyl groups, in gram equivalents attached to 10^5 g of protein as a function of time.

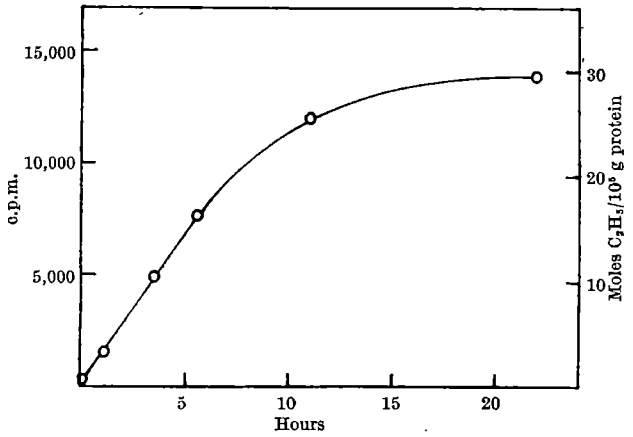

Fig. 1. Time study of the alkylation of the protein

Stability against hydrolysis. The stability of the alkylated protein against hydrolysis was investigated at five different *p*H levels. Samples of labelled globulin of known tritium content were dialysed at 37° C against phosphate buffer at *p*H 5·0, 6·3, 7·3, 7·7 and 8·9, and the release of tritiated ethanol was measured as a function of time. In Fig. 2, the remaining percentage of ethyl groups was plotted against time.

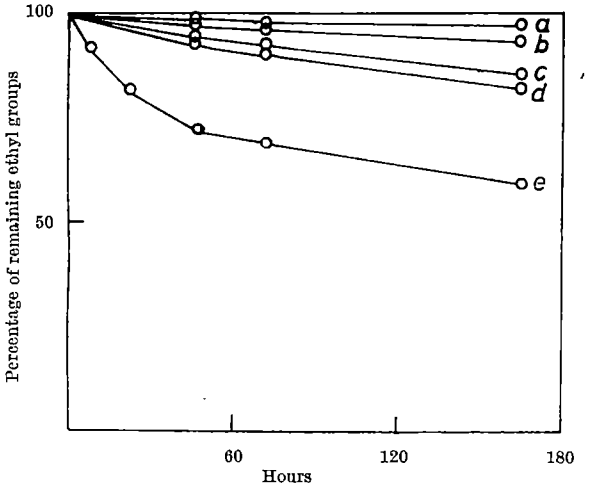

Fig. 2. Hydrolysis of ethyl protein as a function of time at *p*H: *a*, 5·0; *b*, 6·3; *c*, 7·3; *d*, 7·7; *e*, 8·9

Influence on immunological activity. To test its influence on the immunological activity of the globulin, the labelled protein was titrated against human erythrocytes. No serious damage in this respect was observed (Fig. 3).

Change in electrophoretic mobility. The mobility of the labelled globulin on paper electrophoresis in veronal buffer *p*H 8·6 was reduced to about 95 per cent of that of the untreated protein.

In this investigation we used EMS with a specific activity of only 0·518 c./mole. It is technically easy to increase this activity by a factor of 1,000; however, 10 mg of protein labelled with EMS of specific activity of

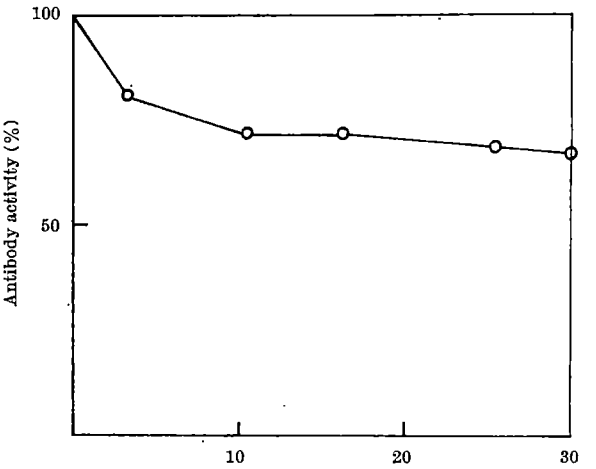

Fig. 3. Influence of the alkylation on the antibody titre

500 c./mole, gives approximately 35,000 ergs/h from tritium decay. This corresponds to 3·5 rads/h in a 100-ml. solution, which must be taken into account in *in vivo* experiments, but which is of minor importance with regard to protein destruction when working with *in vitro* systems.

Preliminary experiments with erythrocytes have shown that it is also possible to label whole cells in the manner described here. In this system, we found it convenient to measure the radioactivity by autoradiography or in a liquid scintillation counter after hydrolysis of ethyl ester bonds in alcoholic KOH and distillation of the alcohol.

The labelling process is strongly dependent on such factors as *p*H, temperature, and the concentrations of EMS and protein. The method described here might, therefore, be improved with respect to the utilization of the radioactive material and the stability of the labelled material.

BIOLOGY

Duration of Embryonic Hypersensitivity and its Relation to the Level of Differentiation of the Chick

The chick embryo is capable of developing hypersensitivity of the immediate type (anaphylaxis) to foreign proteins during most of its developmental life[1,2]. It has also been demonstrated that, from the 12th day of incubation, sensitization of the delayed type to transplantation antigens can be elicited by injection of whole blood[3]. Due to the fact that chick embryos also are susceptible to immunological suppression and are not capable of humoral antibody production[4,5], a new interpretation was needed to account for such distinctive immunological properties of the chick embryo. In proposing such a theory it was postulated that, during development of the embryo, tissue-bound antibodies can be elaborated by cells derived from inactive mesenchymal precursor cells. Such tissue-bound antibodies, in common with classical antibodies, have anaphylactogenic properties[1]. It was assumed that chicks, sensitized as embryos, would be capable of manifesting hypersensitive reactions for only a short time after

hatching. This was based on a common observation that chick embryos and young animals injected with antigen do not manifest anaphylaxis when tested one month or more after the initial injection[4,6]. The term hapto-antibody was suggested for these tissue-bound embryonic antibodies which manifest this anaphylactic property.

In order to determine if the tissue-bound hapto-antibodies possessed this anaphylactogenic property transiently or permanently, the following experiments were carried out.

Embryonic chicks were injected intravenously with 4 mg of human γ-globulin. One group was injected with antigen on the 12th day of incubation, at a time when the chick embryo is not susceptible to immunological suppression. The other group of chick embryos was injected on the 15th day of incubation when immunological suppression had been established[4]. From such experiments it could be ascertained if hypersensitivity, established in the embryo, might be of different duration in animals which are likely to manifest immunological suppression at 45 days post-hatching than chicks which do not exhibit immunological suppression. About 60 per cent of both groups of chicks hatched. These hatched chicks were given a second (shocking) injection of 40 mg of human γ-globulin with 4 mg of dried whole guinea-pig serum (Difco, Detroit, Michigan), 1, 2 or 3 weeks after hatching. The control groups of chick embryos were not given the sensitizing injection, however; they were given the shocking injection of human γ-globulin and guinea-pig serum.

Table 1. Effect of age on the anaphylactic response of chickens which as embryos had been given a sensitizing intravenous injection of 4 mg human γ-globulin (HGG) on either the twelfth or fifteenth day of incubation

Group	Sensitizing antigen	Second (shocking) injection of antigen into the heart at various times post-hatching: Age (Weeks)	Antigen	Amount (mg)	No. of chicks exhibiting an anaphylactic response: Sensitized at 12 days: None	Mild	Severe	Sensitized at 15 days: None	Mild	Severe
A	None	1	HGG	40	9	1	0	8	0	0
B	HGG	1	HGG	40	2	6	1	1	8	1
C	None	2	HGG	40	8	1	0	8	0	0
D	HGG	2	HGG	40	2	8	0	3	7	0
E	None	3	HGG	40	17	0	0	9	0	0
F	HGG	3	HGG	40	18	0	0	9	0	0

The anaphylactic responses following the shocking injection were either mild, lasting about 5 min, or severe, lasting about 15 min. Such gradations of responses have been described previously[1]. In these experiments no fatal anaphylactic response was observed. This is in agreement with the observation that the 3-week-old pullet showed a less severe anaphylactic reaction with histamine than the adult cock[7]. The results summarized in Table 1, group *B*, clearly demonstrate that both mild and severe responses were elicited when sensitized chicks were given a shocking injection 1 week post-hatching. Somewhat similar results were obtained in the group *D* chicks which were challenged 2 weeks after hatching. The two positive responses which were observed in control groups can be explained as previously stated[1]. In contrast, however, by the third week following hatching no anaphylaxis could be elicited when the shocking injection was given (group *F*). It was also observed that the anaphylactic response exhibited in chicks 1 week of age is not as severe as when the challenge was given on the third day after hatching[1].

These results support the thesis that hapto-antibodies are characterized by a transient state of involvement in anaphylactic responses. This is in keeping with the idea that, during differentiation of the immunological system, antigens are able to induce various types of immunological responses depending on the level of differentiation of the cellular population at the time antigen is administered. Thus, one will be able to observe embryonic hypersensitivity, immunological suppression or humoral antibody depending on the time when the antigen is injected[1].

These experiments verify one of the assumptions of Van Alten and Schechtman[1] that the embryonic anaphylactic state is relatively short-lived in contrast to the durable anaphylactic states of mature animals.

This investigation was supported by U.S. National Science Foundation grant *GB*-1685.

Effect of Time of Year on the Roughage Intake of Housed Sheep

The nutritional requirements of animals are said to vary with the amount of activity performed and with the environmental temperature. It is also said that darkness reduces activity and the maintenance of an air temperature above critical level leads to better food utilization.

As changes in nutritional requirements may be reflected by differences in the level of voluntary food intake, voluntary hay intake results were routinely obtained from sheep kept permanently indoors in individual pens measuring approximately 4 ft. 6 in. × 3 ft. 0 in. They were daily offered a small amount of mixed concentrates, always of the same composition and quality and always entirely consumed. In addition each received up to a maximum of 1·0 kg chopped hay a day. It was noticed that this voluntary hay intake varied with the season of the year and for this reason some continuous data which were available were examined. The results relate to the intakes of two young Shetland wethers and two mature Scottish Blackface ewes over a period of 23 months and are summarized in Table 1.

These animals were healthy and thriving throughout and had a good appetite. The two Shetland wethers (7 and 9) were completely normal. Each Blackface ewe (4 and 441) was fitted with a permanent ebonite rumen cannula and 441 had also had the right cervical vagus nerve severed and the left cervical vagus nerve exteriorized in a skin loop. There was no reason for assuming that these animals were adversely affected in any way.

There are small gaps in the data due to animals having been used for other purposes for short periods. Food intake was measured daily during the week and over two days at the week-end, as a routine laboratory procedure. The monthly mean air temperature was calculated

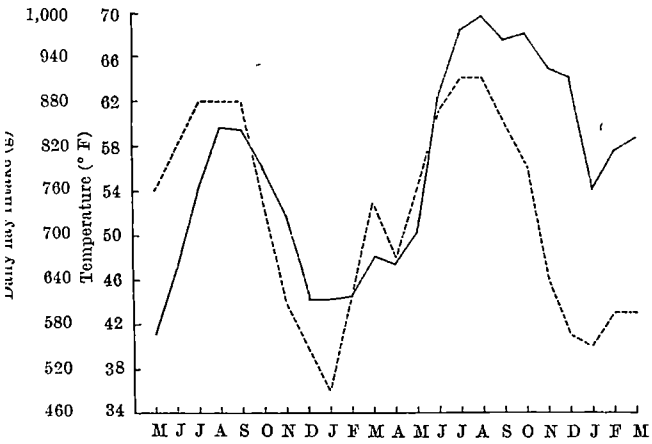

Fig. 1. Relationship between environmental temperature and hay intake. ——, intake; - - - -, temperature

from the maximum and minimum temperatures for each day, also routinely recorded. The results are further summarized in Fig. 1.

It is evident that all four sheep ate more hay a day during summer than in winter. The same hay was not used throughout. Housed sheep show preferences for different qualities and parts of hay and for no apparent reason one lot of hay may be less acceptable to some or all sheep than is another similar lot. However, it is unlikely that this is the reason for the variation in intake noted here. It is also most unlikely that the quality of hay offered was in any way responsible.

It is known that appetite is depressed by high environmental temperatures in the case of cattle[1], goats[2] and sheep[3] and in non-ruminants. In the outdoors sheep shearing has been found to lead to an increase in food intake[3]. In the rat, Brobeck[4] showed that food intake is a mechanism of temperature regulation and is not necessarily determined by total energy expenditure.

It might be argued that the foregoing result was due to seasonal changes in the activity of the animals. There is evidence that darkness reduces activity, for example, grazing sheep spend more time resting and less time grazing by night than by day[5,6] and do not travel between 22.00 and 03.00 h in summer[6]. Pastured dairy cattle also graze little at night and in addition they ruminate mainly at night[7], which is also true of housed sheep[8], and this tendency is not necessarily related to feeding times[9] but is related to the times of light and darkness[10]. With both sheep[11] and goats[2] the lowering of environmental temperature may lead to an increase in activity which would therefore operate against any decrease in activity due to darkness. It is therefore unlikely that activity is the all-important factor.

It is possible that the increase in intake of food is a direct relationship with length of daylight, but this appears unlikely since the rise in intake during June–August follows the rise in temperature and is in opposition to the decreasing hours of daylight, whereas if hours of light are concerned the relationship argued would require to be a positive one. However, the curves for intake and temperature do not always follow one another exactly since there is sometimes a lag of one or two months and this may also be true where the hours of daylight are concerned.

Douglas[12] has stated that, other things being equal, ventilation is more important for milk yield in dairy cattle than is temperature. The development of the winter coat and the reduction of activity in winter darkness may offset the effects of a lowered environmental temperature so that there may be no change in metabolic needs. For example, Doney[13] has found that the fleece of Blackface sheep apparently has some effect in reducing weight loss under adverse climatic conditions. The Eskimo is said to carry his environment around with him in his loose fur clothing and is thus virtually independent of low climatic temperature[14], and recently Cresswell[15] stated that "for all intents and purposes the sheep carries its own environment around with it in the form of its fleece". On the other hand, Hunter[16] found that hill ewes, presumably in full fleece, are sensitive to exposure, particularly in spring. With these housed sheep it is unlikely that length of coat was the only factor, since during June, when the animals were shorn, food intake did not reach its maximum, and since the period January–May is one of full coat one might expect a steady intake or even a fall in response to rising air temperature, instead of which there was a steep rise following the steep air temperature rise. Thus length of coat does not appear to offer an adequate explanation.

Mehrotra and Mullick[17] noted that sheep in Egypt showed a summer preference for leaves, but less concentrates were eaten so that the total dry-matter intake fell. This may be the answer in the present case, that is, appetite for hay increased with temperature, but since the intake of concentrates was always well below potential voluntary intake it was not possible to have a rise in winter concentrates intake and a fall in summer. However, this in itself is not an entirely satisfactory explanation since sheep at range do not normally receive concentrates. Food is scarce and of poorer quality during winter grazing under 'natural' conditions; it is therefore possible that some mechanism for improving the efficiency of food utilization may have been developed in the sheep.

Destruction of Homologous Cells in Tissue Culture by Nuclei of Immune Lymphocytes

THE mechanism of action of immune lymphocytes in transplantation immunity and other delayed-type immune responses is still obscure. It is almost generally assumed that these cells carry on the surface of their cytoplasm protein anti-determinant groups, that is to say, they behave as cells with fixed antibodies. We have suggested[1] that the effect of immune lymphocytes is a particular case of their morphogenetic action and is not connected with the antibody-like structures of their cytoplasm.

This suggestion has been experimentally checked in the work recorded here.

The experiments were carried out in the system described by Rosenau and Moon[2], namely, a culture of Earl's *L* cells and lymphoid cells of *BALB/c* mice immunized with *L* cells. Immune lymphoid cells (designated here as lymphocytes) and their nuclei were obtained from *BALB/c* mice on the fourth day after the last (intrasplenic) immunization with *L* cells. For this purpose, the spleens were aseptically isolated and minced by scissors. One-third of the mass was used for isolation of intact lymphocytes and two-thirds for isolation of their nuclei.

Lymphocytes were obtained by means of 2–3 gentle strikes in a Potter glass homogenizer in Medium 199 and filtration of the cell suspension through two layers of gauze; the cell suspension (about 95 per cent nucleated cells were lymphocytes) was brought by Medium 199 to a final concentration of 2,000,000 lymphocytes per ml. The nuclei were isolated by means of the combined Schneider and Petermann[3] and Allfrey[4] methods. Fragments of spleens were homogenized in a Potter homogenizer in a 30 per cent sucrose solution with 0·02 per cent calcium chloride; 6 per cent citric acid was used to bring the final sucrose concentration in the homogenate to about 1 per cent (not more), according to Dounce's[5] recommendations. Homogenization was carried out until disappearance of visible particles in transparent light.

The homogenate was diluted three times with a 30 per cent sucrose solution with 0·02 per cent calcium chloride and filtered afterwards through two and four layers of gauze and then through two and four layers of cambric. The nuclei were sedimented in the centrifuge at 2,000 r.p.m. and then twice washed in 8·5 per cent sucrose solution with 0·2 per cent potassium chloride for 10 min at 1,200, 1,000 and 800 r.p.m. respectively. To eliminate any traces of citric acid, nuclei were washed twice with large volumes of a lactalbumin-hydrolysate solution, and afterwards re-suspended in Medium 199 to a final concentration of 2,000,000/ml. and 4,000,000/ml. Stained smears were carefully examined under the microscope to check the morphology of nuclei and absence of any cytoplasmic contaminations. Control lymphocytes and nuclei from non-immune *BALB/c* mice were treated in the same way.

Trypsinized *L* cells were cultivated 24 h in test tubes in 90 per cent Medium 199 plus 10 per cent of bovine serum. Thereupon the medium was eliminated, the tubes with the culture rinsed with pure Medium 199, and 1 ml. of a suspension of normal or immune lymphocytes or nuclei in Medium 199 with no serum added to each tube.

Five groups of tubes with *L* cells were used in every experiment with the following additions: first, with normal lymphocytes; secondly, with normal nuclei; thirdly, with immune lymphocytes; fourthly, with immune nuclei; fifthly, without any addition.

Four to seven tubes were used in each group. After addition of lymphocytes or of their nuclei the tubes were incubated for 48–60 h at 37°.

The destructive action of lymphocytes or of their nuclei was determined by counting *L* cells in every tube.

Our experiments conclusively confirm the data of Rosenau and Moon[2] as to the destructive action of immune lymphocytes on homologous cells.

Our evidence shows that nuclei of immune lymphocytes behave in a similar way. These immune nuclei surround *L* cells and stick to their surface. This picture enhanced up to a maximum after incubation for 18–48 h. *L* cells lost their processes, rounded up, and a considerable part of them degenerated.

In each field of vision one could see such pictures and cell-free spaces. The nuclei of normal non-immune lymphocytes showed less tendency to attach to *L* cells; they did not cause any destruction, nor did the density of the cell layer diminish. The effect of nuclei of immune lymphocytes was quite similar to that of intact immune lymphocytes. Some tendency of both normal and immune nuclei to agglutination was noted.

In all tubes incubated with nuclei of immune lymphocytes a statistically significant decrease in the number of *L* cells was noted. Immune nuclei caused quite distinct destruction of *L* cells whereas normal nuclei exhibited no such action (Tables 1 and 2).

Similar results have been obtained in three more experiments. The number of *L* cells in tubes with no lymphocytes or nuclei was similar to that in tubes with normal lymphocytes and their nuclei, so that tubes containing only *L* cells are not presented in Tables 1 and

Table 1. Destruction of *L* Cells by Immune Lymphocytes and their Nuclei

Table 2. Destruction of *L* Cells by Immune Lymphocytes and their Nuclei

(Exp. No. 16/2)

No. of tubes in every group	Quantity of *L* cell per 1 ml. after 48-h incubation with: Immune lymphocytes	Normal lymphocytes	Immune nuclei	Normal nuclei
1	110,000	318,000	60,000	140,000
2	157,000	332,000	40,000	118,000
3	90,000	300,000	64,000	190,000
4	92,000	276,000	90,000	180,000
	$M = 112{,}000$	306,500	63,500	157,000
	$\sigma \pm 26{,}600$	$\sigma \pm 20{,}940$	$\sigma \pm 17{,}800$	$\sigma \mp 29{,}300$
	$m \pm 13{,}300$	$m \pm 10{,}470$	$m \pm 8{,}900$	$m \pm 14{,}600$

2. Complete elimination of cytoplasm is directly confirmed by constant examination under the microscope and indirectly by experiments in which lymphocytes and nuclei were suspended in Medium 199 supplemented with 10 per cent bovine serum inactivated at 56°.

Under these conditions, the effect of immune lymphocytes was retained, whereas that of immune nuclei was completely eliminated, probably by serum nucleases.

The very fact of the destructive action of immune nuclei refutes the role of hypothetic lymphocyte-bound antibodies or antibody-like rearrangements of their cytoplasm.

The question arises: How do immune lymphocytes destroy homologous cell-antigens?

The following possibilities may be considered. (1) Lymphocyte-bound antibodies are contained in both cytoplasm and nuclei or some nuclear structures have antibody-like properties. (2) The nucleus of the immune lymphocyte does not act through the agency of protein anti-determinants, but transmits to homologous cells some information which determines the synthesis of such anti-determinants as we considered in (1); this can be realized through: (*a*) transmission of DNA or of its individual informative moieties, or (*b*) the complex immune lymphocyte nucleus-homologous cell functions as an integrated system in which transmission of common messenger-RNA occurs from the immune nucleus, or (*c*) while active ribosome-like nuclear structures are transmitted from the immune nucleus to the homologous cell.

The first alternative, namely, the action of nuclear protein anti-determinants, seems highly improbable for the mere reason, at least, that the pattern of cell disintegration in transplantation immunity differs from that caused by antibodies in the presence of the complement.

The second alternative seems more convincing. The mechanism of lymphocyte-induced destruction of homologous cells is similar to the primary cytopathic effect in virus diseases.

If the role of the immune lymphocyte is not linked with the anti-determinants of its cytoplasm doubt is necessarily cast on the widespread concept as to the role of these hypothetical cytoplasmic antibody-like structures in the 'recognition' by immune lymphocytes of homologous

cell-antigens. In fact, there does not apparently exist any such 'recognition' at all; instead the effect of lymphocytes in the delayed type responses, especially in transplantation immunity is a particular case of their normal morphogenetic function[1].

The major function of lymphocytes consists in maintaining a constant level of differentiation of cells in various tissue systems by means of continued transmission of morphogenetic information.

In a similar way they transmit such information to a homograft. But in homotransplantation immunity there occur immune lymphocytes although the question is still open whether or not these cells result from instructive transformation or from clone selection.

Immune lymphocytes carry 'anti-information' to antigens of the grafts, that is, a system controlling complete or partial synthesis of protein anti-determinants to the graft antigens. Realization of this synthesis is unnecessary. Immune lymphocytes transmit this anti-information in the ordinary way both to normal tissues of the organism and to cells of the homograft. For normal body cells it is immaterial whether or not individual parts of the template received from lymphocytes can secure synthesis of a protein with anti-determinants to cell antigens of another strain of mice. As to the graft which consists of cells of this other strain of mice, incorporation of such anti-information is fatal.

Purification of Algal Cultures with Caffeine

Ducker and Willoughby[1] have suggested a method for eliminating bacteria from algal cultures. If a technique could be devised for selectively killing fungi and non-photosynthetic protozoa, the selection of pure strains of algae would be considerably simplified.

I have observed that when algae are raised on salt media they are remarkably resistant to caffeine. Concentrations of 0·01–0·03 M kill the fungi and non-photosynthetic protozoa and, if anything, stimulate the algae. In reconstitution experiments and wild isolates I have succeeded in eliminating from cultures of *Euglena* and *Chlamydomonas* contaminants including species of *Aspergillus*, *Penicillium*, *Saccharomyces* and *Paramecium*. This worked in various media including pond water, pea infusion, modified Cramer-Myers salt medium[2] and Beijerinck's mineral medium with acetate[3]. The fungi were not killed in '*Euglena* medium'[4] or the enriched medium of Gibor and Granick[5], possibly because of the adenine content.

This method is not invariably successful; *Scenedesmus*, for example, is considerably more sensitive than *Euglena*. It should, however, be included among techniques to be tried in case of necessity.

Oxygen Diffusion from the Roots of Some British Bog Plants

SEVERAL workers have shown that the roots of various plants are able to oxidize an anaerobic medium. With rice, van Raalte[1] was able to demonstrate that one oxidizing agent responsible was probably oxygen itself. Coult and Vallance[2] also showed that oxygen diffused from the sub-aerial parts of *Menyanthes trifoliata* L. into an anaerobic solution.

More recently, and concurrently with the work given in this communication, van Raalte *et al.*[3], using a 'polarographic' technique, have shown that oxygen diffuses from the roots of barley grown in anaerobic solutions.

The results presented here were also produced 'polarographically' using platinum versus saturated calomel electrode, the oxygen diffusion being measured in μamp. The platinum electrode is in the form of a small cylinder coated on the outside with 'Araldite', the reactive surface being on the inside.

The roots of the experimental plant are inserted with the electrodes into a deoxygenated solution, which is then 'sealed' with paraffin oil. At this stage a root can be inserted into the cylinder electrode, and a manual 'polarograph' taken, a 60-sec equilibration period being allowed for each reading. (Note that the plateau current is directly proportional to the oxygen diffusion.)

If the aerial parts are placed in an atmosphere of nitrogen, or cut and sealed with 'Vaseline', the oxygen diffusion from the root drops immediately. The minimum diffusion eventually recorded corresponds to the residual current[4] (Fig. 1). Further, if after a prolonged period the nitrogen is replaced by air or oxygen, or the aerial parts re-cut below the 'Vaseline' (zero time, Fig. 2), within 2 min oxygen again diffuses from the root. This latter observation is in agreement with the work of Barber *et al.*[5], who found that $^{15}O_2$ travelled down from the aerial parts of rice to the root tip in a similar time.

It has been found with *Eriophorum angustifolium* Honck. that, if air or nitrogen is replaced by oxygen, the diffusion rate from the root increases to five times that produced with the aerial parts in air (Fig. 1).

Moving the electrode farther up the root has shown which regions of the root are concerned in the release of

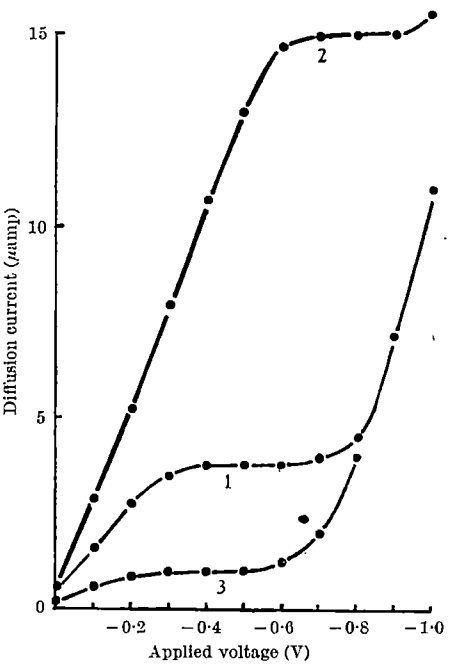

Fig. 1. *Eriophorum angustifolium*. (1) Oxygen diffusion round the root tip; aerial parts in air; (2) oxygen diffusion round the root tip: aerial parts in 100 per cent oxygen; (3) oxygen diffusion round the root tip ≡ residual current: aerial parts in 100 per cent nitrogen

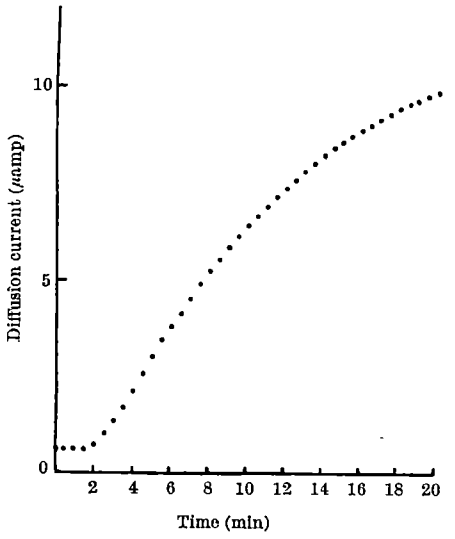

Fig. 2. *Menyanthes trifoliata.* Oxygen diffusion from the root plotted at −0·6 V. The aerial parts were in an atmosphere of nitrogen for 1·5 h before re-exposure to air at zero time

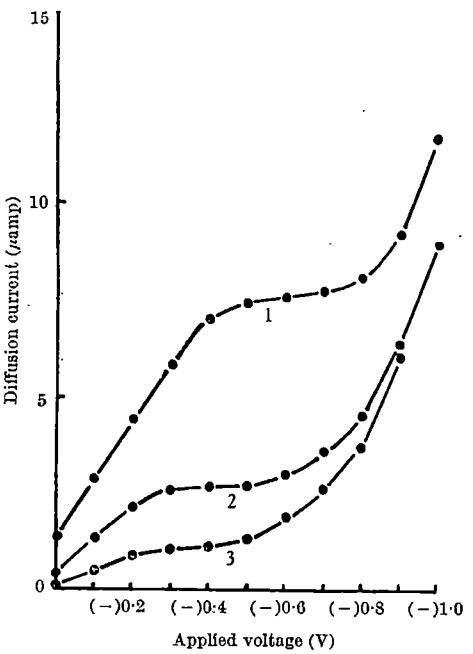

Fig. 3. *Eriophorum angustifolium.* (1) Oxygen diffusion round the root tip 0–1 cm; (2) oxygen diffusion round the root tip 0·5–1·5 cm; (3) oxygen diffusion round the root 1–2 cm

oxygen to the surrounding solution (Fig. 3). With *Eriophorum angustifolium* and *Molinea coerulea* (L) Moench. usually only the first centimetre of root tip is involved. With *Menyanthes trifoliata*, although the first 4 cm may be involved, the greatest oxygen diffusion value is found from the first centimetre of root tip.

Rates of diffusion which have been worked out for these species are as follows: *Menyanthes trifoliata*, 16 × 10^{-8} g O_2 cm^{-2} root surface min^{-1}; *E. angustifolium*, 13 × 10^{-8} g O_2 cm^{-2} root surface min^{-1}; *Molinea coerulea*, 1 × 10^{-8} g O_2 root surface min^{-1}.

These results suggest that there may be a similarly graded tolerance to reducing conditions by these species. Thus, as the rate of oxygen diffusion from *Menyanthes* roots is greater than the rate from the roots of *Eriophorum*, it might be expected that *Menyanthes* will withstand stronger reducing conditions than *Eriophorum*, and, similarly, *Eriophorum* than *Molinea*.

This is in accordance with measurements of redox potentials made at certain sites occupied by these species.

I thank Dr. D. J. Boatman for his advice.

MICROBIOLOGY

Fatty Acid Composition of Lipids extracted from Three Spherical Bacteria

Abel[1] suggested that taxonomic importance be attached to fatty acid components of bacterial lipid and proposed a simple and rapid scheme for the isolation and characterization of the lipid. Previous workers have shown slight similarities or differences in fatty acid contents of *Lactobacilli*[2], group '*N*' *Streptococci*[3], mesophilic and psychrophilic yeasts[4] and *Sarcina* species[5]. In several micro-organisms Bloch[6] showed that vaccinic acid is the principal acid in anaerobes whereas oleic acid predominates in aerobes. We have compared the fatty acid spectra of three spherical bacteria which are strikingly different in cellular arrangement, Gram staining, and habitat.

The micro-organisms were: (1) a marine isolate tolerant to 15 per cent sodium chloride tentatively assigned to genus *Gaffkya*; (2) *Micrococcus cryophilus*, A.T.C.C. 12226, a psychrophile; (3) *Veillonella alcalescens* A.T.C.C. 12641, an obligate anaerobe. Cells of micro-organisms listed were grown under appropriate conditions at optimum temperature in 20-l. lots of lipid-free trypticase soy broth (BBL) and harvested at the maximum stationary phase by centrifugation, and were washed twice with distilled water. Aqueous suspensions of cells were treated for 1 h in a 10 *KC* Raytheon magnetostrictor sonic oscillator (Raytheon Corp., Waltham, Mass.). Sonicated cells were dried *in vacuo* at 45° C over P_2O_5. Lipids were extracted from the dehydrated flaky material with chloroform–methanol 2 : 1 (v/v), according to the procedure of Folch[7]. Extracted lipids were weighed and recorded as percentages of cellular dry weights, and 20–40-mg aliquots were transesterified with 8 ml. of dry methanol and six drops of concentrated sulphuric acid. The resulting methyl esters, extracted and purified by the method of Luddy[8], were subjected to gas liquid chromatographic analysis on stainless steel columns employing the aerograph *A90C* (Wilkens Instrument and Research, Inc., Walnut Creek, California) 'Apiezon *L*' and diethylene glycol succinate polyester (DEGS) as the liquid phases. The methyl esters were identified by comparing 'carbon numbers'[9] with those of authentic esters. The lipid content for *Gaffkya* sp. was 7·1 per cent; *M. cryophilus* was 6·1 per cent and *V. alcalescens* was 10·1 per cent.

The data are presented in Table 1, where all fatty acids present in the concentration of 5 per cent or more are considered as major components, and dashes represent those present in less than 1 per cent. *Gaffkya* sp. has six major fatty acids; *M. cryophilus* three; and *V. alcalescens* six. Abel[1] detected essentially the same number of major fatty acids in *Gaffkya tetragena* as in our halo-tolerant *Gaffkya*, but differences are seen: (1) in the relatively high proportion of C_{20} acid present in the former; (2) the principal unsaturated C_{15} acid which was absent in the halo-tolerant *Gaffkya*.

Table 1. Fatty composition as g/100 g of methyl esters of unfractionated lipid extracted from *Gaffkya* sp., *Micrococcus cryophilus* and *Veillonella alcalescens*. Averages of duplicate runs

* First digit denotes number of carbon atoms; second, number of double bonds; *cy* indicates the cyclopropane ring of lactobacillic acid and *br*, a branched-chain acid.

M. cryophilus shows a relatively high proportion of unsaturated fatty acid and the absence of fatty acids with fewer than 16 carbons. The spectrum is markedly different from that of the mesophilic *Micrococcus ureae*, although similar results have been reported in psychrophilic yeasts. Our findings seem to corroborate the lipid distribution of plants and animals[10] living in a temperate or cold region, producing highly unsaturated lipids at low environmental temperatures. Prill[11], using *Aspergillus fischeri*, and Singh[12], employing *A. nidulans*, however, found the opposite correlation. Factors other than temperature may be involved in the regulation of degree of unsaturation.

V. alcalescens showed as the major component a 17 : 1 or 18 : 0 acid, so that additional investigations will establish whether its fatty acid spectrum exhibits a high proportion of unsaturated fatty acids and hence differs from that of the anaerobe *Clostridium*[13].

If the cultures are representative of the genera *Gaffkya* and *Veillonella*, these can be distinguished by the predominant fatty acid present, and in psychrophiles, *M. cryophilus* may represent fatty acid components characteristic of the low-temperature group. Investigations of additional members of these genera may corroborate the taxonomic or phylogenetic significance in lipid composition.

Use of a Fluorescent Brightener for tracing the Passage of *Salmonella* in Eggs

During investigations concerning the contamination of eggs by *Salmonella*, cultural methods for detecting the passage of the organisms through the shell into and beyond the membranes provided little evidence concerning possible sites of entry and subsequent translocation. The work of Darken[1,2] on the uses and properties of fluorescent brighteners suggested a suitable means of tracing these bacteria.

The most suitable material available for this purpose was 'Calcofluor White *M2R*, New', a water-soluble diamino-stilbene-disulphonic acid brightener, which differed from the compound used by Darken[2] in that it contained two diethylamino substituents on the triazine rings. A concentration of 0·05 per cent (w/v) of this compound in nutrient agar (Difco) plates supported the growth of various species of *Salmonella* without any apparent inhibition or mutagenesis[3]. The brightener was readily absorbed by the cells, which were collected after an incubation of 24 h at 37° C, washed and suspended in isotonic saline.

The bacteria were brightly fluorescent and the suspending fluid non-fluorescent when observed under ultra-violet radiation. Fluorescence microscopy confirmed that the individual cells were fluorescent. This effect did not alter in the saline suspension after an incubation of 21 days at 37° C.

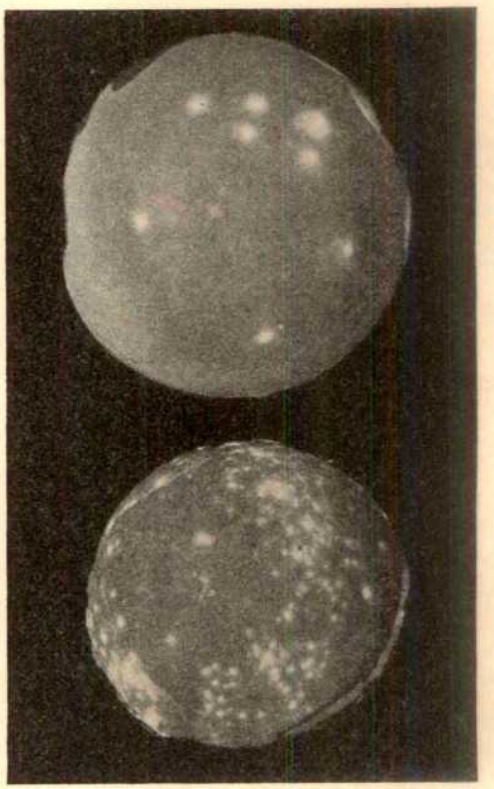

Fig. 1. Colonies of *S. anatum* treated with a fluorescent brightener, developing on the interior surfaces of moderately and heavily contaminated eggs. Photographed under ultra-violet light. (× 1)

Fresh hens' eggs held at 37° C for 3 h were immersed for 30 min in an iced saline suspension of treated *Salmonella anatum* (approximately 10^4 organisms per ml.). Thereafter the eggs were incubated for 5–7 days at 37° C. On breaking and examining the interiors of the shells under ultra-violet light, fluorescent spots were readily observed (Fig. 1). These spots were composed of micro-organisms identical by cultural and serological criteria with the *Salmonella* of the original suspension. Despite considerable multiplication the individual cells comprising the spots were still fluorescent. Untreated *Salmonella* suspensions provided no such fluorescent spots and their presence inside the egg shells could only be ascertained by cultural methods.

The visualization of the sites of entry and the degree of contamination by *Salmonella* in eggs could be used to determine the efficiency of control measures.

This work was supported in part by funds provided by the Western Utilization Research and Development Division of the U.S. Department of Agriculture. The 'Calcofluor White *M2R*, New' was provided by the American Cyanamid Co., Chicago.

Carbon Dioxide-dependent Morphogenesis in *Arthrobotrys conoides*

Carbon dioxide has been shown to influence morphogenesis in micro-organisms, higher plants and animals. Among the processes affected by carbon dioxide (or bicarbonate) concentration are sporangial differentiation in *Blastocladiella emersonii*[1], mould-yeast dimorphism[2,3], spherulation in *Coccidioides immitis*[4], sporulation by bacteria[5] and fungi[6,7], root development by pea[8], and sexual differentiation in *Hydra*[9]. This list can now be extended to include morphogenesis in *Arthrobotrys conoides*. *A. conoides* is a nematode-trapping fungus which captures prey in adhesive networks of hyphal loops. Usually, these organelles of capture are not formed spontaneously by the fungus but develop in response to the presence of prey. Morphogenesis is induced by a metabolic product of nematodes which has been partially purified[10–12] and designated nemin[13]. The tests described here provide evidence that nemin-induced morphogenesis in *A. conoides* is dependent on carbon dioxide.

Petri plates containing maize-meal extract agar were inoculated with *A. conoides* and stored in air at 28° C until the fungus developed as a single colony which covered approximately one-third of the agar surface in each plate. Some of these colonies were treated with nemin (added as an aqueous extract of ascarids) to induce morphological differentiation and then incubated, with untreated controls, for three days at 28° C in desiccators containing the following concentrations of carbon dioxide in air: (*a*) 0·00 per cent (1·0 N KOH placed in bottom of desiccator); (*b*) 0·03 per cent (air); (*c*) 10 per cent (air adjusted by introducing into the desiccator manometrically measured amount of carbon dioxide from a tank). A quantity of 1·0 N H_2SO_4 was placed in desiccators (*b*) and (*c*) to approximate the dehydrating effect of the KOH in desiccator (*a*). The influence of concentration of carbon dioxide on growth was measured as the change in diameter of colonies during storage in the desiccators, and cultures were examined microscopically for morphological change. The results of independent tests performed in our separate laboratories using two strains of *A. conoides* are summarized in Table 1.

A. conoides grew but formed no traps in the absence of carbon dioxide. Growth in air (0·03 per cent carbon dioxide) exceeded that in an atmosphere devoid of carbon dioxide, and, in air, the fungus formed traps in response to treatment with nemin. In no case did traps develop in controls that were not treated with nemin. Although nemin-induced morphogenesis was carbon dioxide-dependent, the influence of concentration of the gas on growth and trap formation varied with the strain of *A. conoides* tested. Growth and the response of strain *NB* to nemin were both greatest in air, and reduced by an absence or an abundance of carbon dioxide. Strain *C* developed best in air, but the morphogenic response of the fungus to nemin was maximum in an atmosphere containing 10 per cent carbon dioxide. Optimum levels have not been established; but growth and nemin-induced morphogenesis in *A. conoides* appear to be independent functions of carbon dioxide concentration.

Table 1. Influence of Concentration of Carbon Dioxide on Growth and Trap Formation by Two Strains of *A. conoides* treated with Nemin

CYTOLOGY

Absence of Late Replication of a Human X-Ring Chromosome

As autoradiographic examination of human and other mammalian chromosomes after incorporation of tritiated thymidine has revealed a characteristic pattern of replication during the late *S* phase for the heteropycnotic *X* chromosome and some autosomes, the lymphocyte culture technique associated with a simplified autoradiographic method may be used for diagnosis and investigations of the sex chromosomes even in smaller laboratories.

In lymphocytes of an intelligent girl, twelve years of age, with typical features of Turner's syndrome and negative sex chromatin in leucocytes and mucosa nuclei—the patient being one of a series of 40 females with chromatin negative Ullrich–Turner syndrome—we found two cell lines with 45 and 46 chromosomes respectively in a ratio of about 40/60. Cells with 46 chromosomes were characterized by a little odd-shaped chromosome which in 41 out of 113 complete mitoses had a ring configuration. Its diameter did not exceed the length of a chromosome in group 21–22. Bipartite (Fig. 1) and quadripartite configurations were like those shown by Lucas[1] and Gropp[2] on ring chromosomes of No. 18.

Autoradiographic examination using Ilford *K*-2 nuclear emulsion instead of stripping film for the exposure of the fixed, spread and orcein stained chromosomes following incubation for 6 h of tritiated thymidine failed to show late labelling of the ring chromosome which has been considered as a deleted *X*. Grains in 113 mitoses have been counted and *X*/45 ratio[3] was determined for several degrees of labelling. In mitoses which contained a few grains, thus marking late *S* phase, we saw clearly labelled

autosomes of group *B*, *D* and *E* (16), whereas over the ring there were usually no, or only very few, grains. The *R*/45 ratio for mitoses with fewer than 50 grains was 0·027; for all 113 mitoses, 0·015. The regression line is given in Fig. 2.

Although our results cannot be compared with those given by Rowley *et al.*[4], who examined an *X*-ring chromosome by modified techniques (shorter time of incubation, stripping film exposure), we may conclude that our ring chromosome does not exhibit late replication as found by these authors. This finding does not fulfil the hypothesis that the abnormal *X* chromosome is always the late replicating one. Otherwise the result of an examination of the normal *X* chromosome in human females and of the isochromosome of the long arm of *X* of which the regression lines are shown in Fig. 2 fits well with the data given by Muldal *et al.*[3]. This abnormal behaviour of a deleted *X* chromosome may be explained by the observation that pericentric and terminal regions complete DNA-synthesis at an earlier state than interstitial parts of the late replicating *X* chromosome[5,6]. We have seen this phenomenon in three different normal *X* chromosomes and are led to the conclusion that these interstitial parts have been deficient in our ring chromosome. The remainder of the chromosome behaves, therefore, apparently as an earlier replicating isopycnotic chromosome.

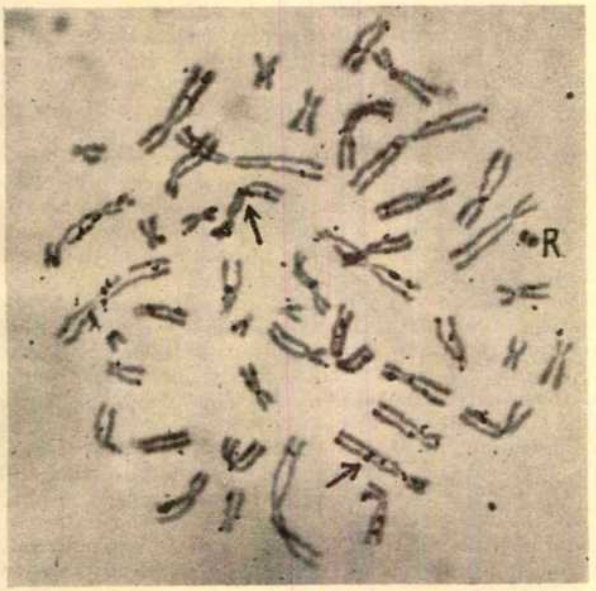

Fig. 1. Bipartite configurated ring chromosome which is not labelled in a mitosis with few grains thus marking late stage of the *S* phase. Two *B* chromosomes are labelled at identical regions (→)

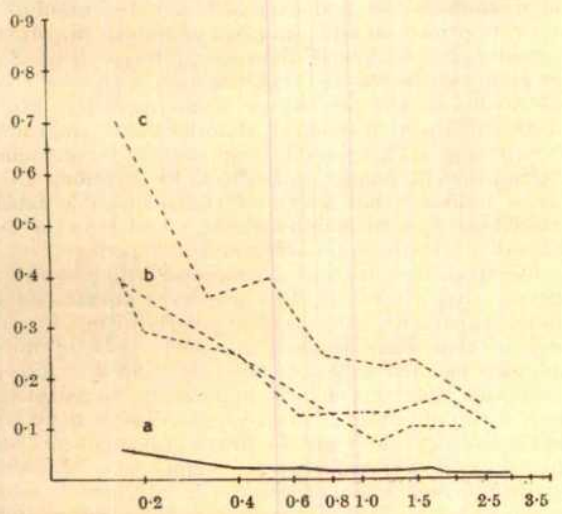

Fig. 2. *X*/45 (*R*/45) ratio plotted against mean counts of several degrees of labelling, mean labelling of total count being 1·0. *a*, Our ring chromosome; *b*, two normal female *X* chromosomes; *c*, isochromosome for the long arm of *X*

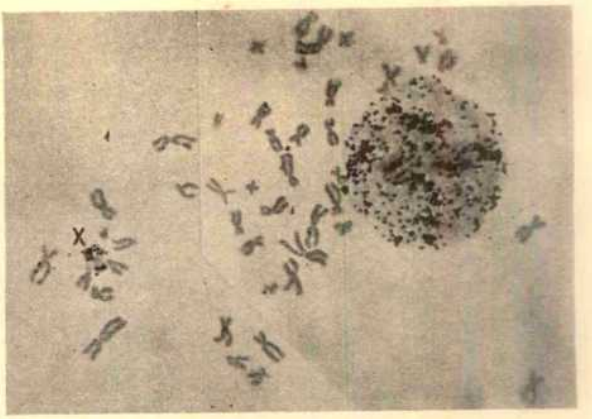

Fig. 3. Selective late labelling of interstitial areas on the long and short arm of a normal human *X* chromosome. DNA synthesis in the pericentric zone must have been completed before tritiated thymidine added

The appearance of our patient excludes the possibility that the ring chromosome is derived from an autosome, but we are unable to disprove that it represents a *Y* chromosome of which the *Y*/45 ratio equals that of *R*/45.

Percentage Incorporation of Leucine labelled with Carbon-14 into Isolated Mitotic Apparatus during Early Development of Sea Urchin Eggs

THERE is evidence that during division in sea urchin eggs a certain amount of protein specifically necessary for division is synthesized. Hultin[1] has shown that the division of these eggs is blocked at 'streak stage' by puromycin. Gross and Cousineau[2] have found, in autoradiographs of *Arbacia punctulata* eggs, that most of the labelled amino-acid incorporated in earliest cleavage is found in the region of the mitotic apparatus; the localization of label is particularly pronounced when supernumerary asters (cytasters) are induced in developing eggs by treatment with heavy water. On this basis, these authors suggest that the protein synthesized in earliest cleavage plays a structural or catalytic part in the operation of the mitotic apparatus. The suggestion is substantiated by the finding of Stafford and Iverson[3] that labelled amino-acid incorporated by fertilized eggs may be found in the isolated mitotic apparatus.

The experiments recorded here give the degree of localization in the isolated mitotic apparatus of amino-acid incorporated in earliest cleavage. The material used was *Paracentrotus lividus*.

Eggs and sperm were obtained by injection of sea urchins with 0·5 M potassium chloride. After washing

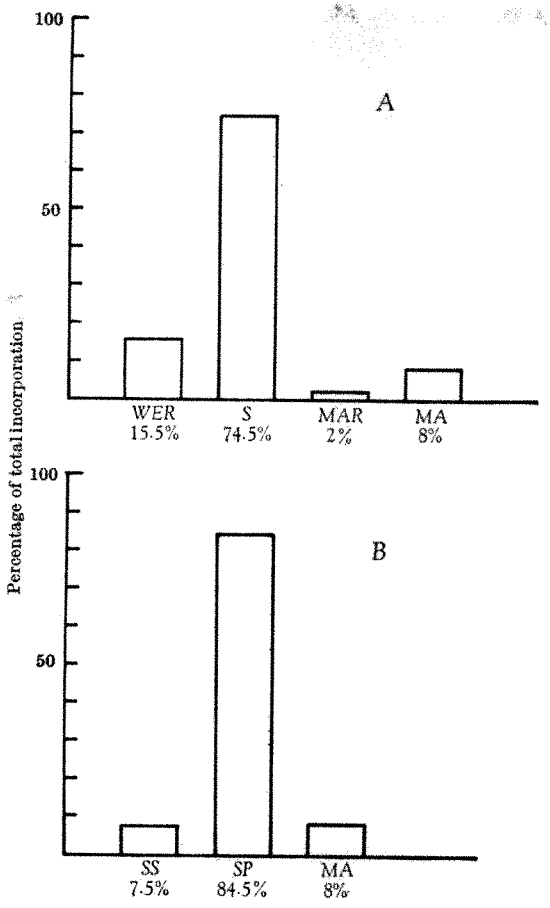

Fig. 1. *WER*, whole egg rinse; *S*, supernatant; *MAR*, mitotic apparatus rinse; *MA*, mitotic apparatus; *SS*, soluble supernatant; *SP*, pellet

several times with sea-water, the eggs were fertilized, and the fertilization membranes and gelatinous coats were removed by passing the eggs repeatedly through bolting silk, followed by several washes in sea-water. The embryos were then incubated until the time of mitotic apparatus isolation with 0·61 mμmole/ml. of leucine-^{14}C (160 mc./mmole), at 22° C. The mitotic apparatus was isolated using the procedure of Kane[4], either unmodified or with substitution of 0·01 M citrate buffer at *p*H 6·0 for the corresponding phthalate buffer. Results were substantially the same in the two cases. High yields of mitotic apparatus were obtained. A direct count, made during a typical isolation in a trial run (citrate buffer), showed a yield of 91 per cent.

During isolation, fractions were obtained and sampled for radioactivity according to the following schedule. After washes in isotonic sodium chloride–potassium chloride, 19 : 1, the eggs were suspended in isolation medium and centrifuged in a hand centrifuge to give a supernatant free of intact eggs—the whole egg rinse—and a pellet of swollen but undispersed eggs. The latter was resuspended in isolation medium, and the eggs were dispersed by agitation until the homogenate, which contained the mitotic apparatus, was free of intact eggs. The homogenate containing mitotic apparatus was then centrifuged sufficiently to give a supernatant free of mitotic apparatus and a pellet of unwashed mitotic apparatus. The latter was again resuspended in isolation medium, and recentrifuged to give a supernatant, the mitotic apparatus rinse, which was also free of mitotic apparatus and a pellet which constituted the mitotic apparatus fraction. A sample of non-mitotic apparatus fraction was also made up by pooling equal fractional parts of the whole egg rinse, supernatant and mitotic apparatus rinse fractions, and this was centrifuged for 90 min at 36,000 r.p.m. in a Spinco ultracentrifuge with a No. 40 rotor, to obtain a supernatant containing the fraction which was 'soluble' in the isolation medium used (molar hexanediol, *p*H 6·0), and a pellet of non-mitotic apparatus particulate material, presumably including ribosomes, mitochondria, and other particles sedimentable in more conventional homogenization media.

For determination of incorporated radioactivity, samples were fixed with an equal amount of 10 per cent trichloroacetic acid containing a 1,000-fold excess of leucine-^{12}C, the TCA-insoluble material was collected on 'Millipore' filters, and repeatedly washed with leucine-^{12}C in 5 per cent TCA, and the 'Millipore' filters were mounted in planchettes and counted in a thin end-window Geiger counter. From previous experience, we consider this radioactivity to be in protein.

Fig. 1 shows the percentage of total radioactivity that is found in the various fractions for an isolation of mitotic apparatus at first metaphase (88 per cent of the isolated mitotic apparatus at metaphase). In agreement with the results of Stafford and Iverson[3], some radioactivity is recovered in the mitotic apparatus fraction, but incorporation into mitotic apparatus was never in excess of 10 per cent, although the experiment was repeated several times.

In view of the autoradiographic findings of Gross and Cousineau[2], we had expected a much larger percentage of incorporation into the isolated mitotic apparatus. However (unless we are dealing with a species difference), we find that a considerable portion of earliest incorporation of amino-acid, which is localized in the mitotic apparatus region of eggs fixed *in vivo*, is not retained in that region during isolation of mitotic apparatus.

We have to some extent further characterized this fraction of labelled material which is detachable from the mitotic apparatus region during isolation of mitotic apparatus. In the first place, most of it is particulate in the isolation medium used. This can be seen from Fig. 1*B*, which shows that by far the larger part of the non-mitotic apparatus label is in the particulate fraction. The material is therefore either particulate to start with, or it is precipitated by the isolation medium.

In the second place, it appears that the detachable material is most strongly localized in the mitotic apparatus region at metaphase, in fact moving cyclically into and out of the mitotic apparatus region as the latter grows and recedes. This is in fact the behaviour found by Gross and Cousineau[2] for the labelled material in autoradiographs, but for mitotic apparatus, isolated at prophase and metaphase, we find that although the absolute incorporation into an equal number of mitotic apparatuses is greater at metaphase than at prophase (Fig. 2), in fact giving an increase of incorporation with time that is close to linear, the percentage of incorporation into the mitotic apparatus fraction is almost exactly the same in the two cases. Therefore, it is apparently the detachable material that fluctuates cyclically in localization.

It is unlikely that much of the detachable labelled material consists of spindle fibres, astral rays, or other classically recognizable structural components of the mitotic apparatus, because microscopic evidence strongly suggests that these are well preserved in the isolated mitotic apparatus; this is particularly true of spindle fibres in that Kane's[5] electron micrographs of mitotic apparatus isolated by his method show an abundance of the 20-mμ filaments which apparently constitute the classical spindle fibres. Moreover, as discussed by Gross and Cousineau[2], there are a number of components other than the classical structural components of mitotic apparatus which are concentrated in the *in vivo* mitotic apparatus region (see, for example, the electron micrographs of Harris[6]). Some of these components may be concentrated passively by the exclusion from the growing mitotic apparatus region of the yolk and other large

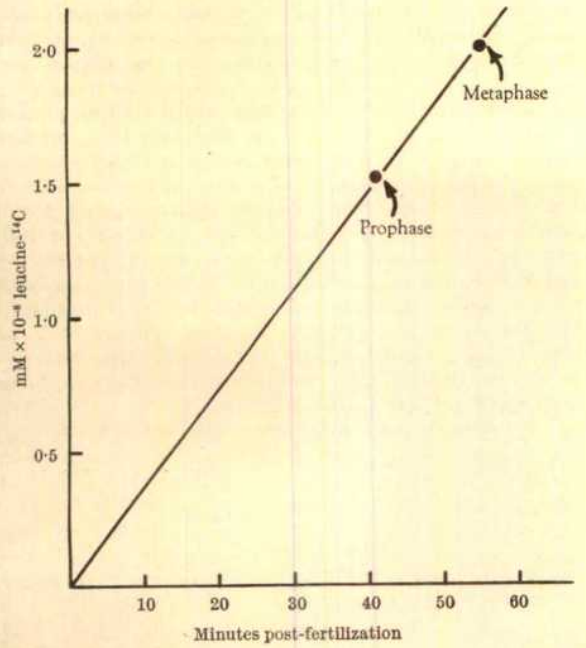

Fig. 2

particles which constitute a significant fraction of the cytoplasm of sea urchin eggs. These components include ribosomes, vesicular elements which Harris calls the 'matrix' of the mitotic apparatus[6], and possibly also soluble proteins. Furthermore, the amounts of both vesicular elements and ribosomes appear reduced in the electron micrographs of Kane[5], when fixation is in the isolation medium.

Our results do not bear directly on the broader question of whether the detachable material plays a part in the functioning of the mitotic apparatus. We have not, in fact, ruled out the possibility that the detachable material is bound *in vivo* to structural components of the mitotic apparatus and that the binding is in some way disrupted by the isolation medium. Whether or not it is so bound, the *in vivo* localization of the detachable material in the mitotic apparatus region is consistent with a functional role, for example, an enzymatic role as suggested by Gross and Cousineau[2].

If we cannot dismiss the possibility that the detachable material is bound under physiological conditions, neither can we dismiss the possibility that the bound material is, properly, detachable. Some label remains with the isolated mitotic apparatus and might in fact represent incorporation into the structural components mentioned above. However, in view of the small percentage of label which remains with the mitotic apparatus, and in view of the fact that the isolation of mitotic apparatus as a cohesive unit requires special stabilizing conditions, it also seems possible that the label which is isolated with mitotic apparatus represents a part of the detachable material which has 'coprecipitated' with mitotic apparatus in the course of its stabilization, perhaps irreversibly. The possibility of such a redistribution of label is illustrated by an experiment, done in collaboration with Dr. G. Giudice, which shows that when metaphase eggs, after exposure as above to leucine-^{14}C, are homogenized in a more conventional medium (0·44 M sucrose containing 0·005 M citrate and 0·01 M *tris*(hydroxymethyl)-aminomethane, at *p*H 7·8) considerably more of the incorporated radioactivity is found in the 'soluble' fraction, obtained by the same centrifugation procedure, than the 10 per cent reported above for conditions under which mitotic apparatus can be isolated; if the 'soluble' fraction is then made molar in hexanediol and titrated to *p*H 6·0, then an amount of label greater than that which is recoverable with isolated mitotic apparatus is precipitated from the soluble fraction, as judged from the fact that it appears in the pellet on recentrifugation.

Autoradiographic investigations of leucine incorporation in early development of *Paracentrotus* eggs are being carried out.

This investigation was supported by U.S. Public Health Service postdoctoral fellowships 1–*F2–CA*–6933–01 and 1–*F2–GM*15–45101. We are indebted to Dr. Paul R. Gross for helpful discussion of the manuscript.

VIROLOGY

Growth of Bovine Parainfluenza-3 Virus in Chick Tissues growing on Polythene

A BOVINE strain of myxovirus parainfluenza-3 was first isolated by Reisinger *et al.*[1] in cultures of embryonic bovine kidney cells. Recently, isolates have been made by intra-amniotic inoculation of 14-day-old chick embryos[2]; but evidence of a successful isolation was only obtained by titration of the amniotic fluids on embryonic bovine kidney cells.

Using the method of tissue culture on polythene described by Fulton[3], a bovine strain of parainfluenza-3 virus was found to multiply in tissues from 10- to 11-day-old chick embryos. The virus in freeze-dried monkey kidney culture fluid was passed twice in rhesus monkey kidney cultures growing in bottles and was collected by freezing and thawing. The supernatant had a hæmagglutinin titre of 1/128 when tested with 0·5 per cent guinea-pig erythrocytes at 4° C.

The virus was inoculated on chick lung, chick muscle, chick skin or chick intestine growing on disks of polythene. The disks were floated on Medium 199 and were

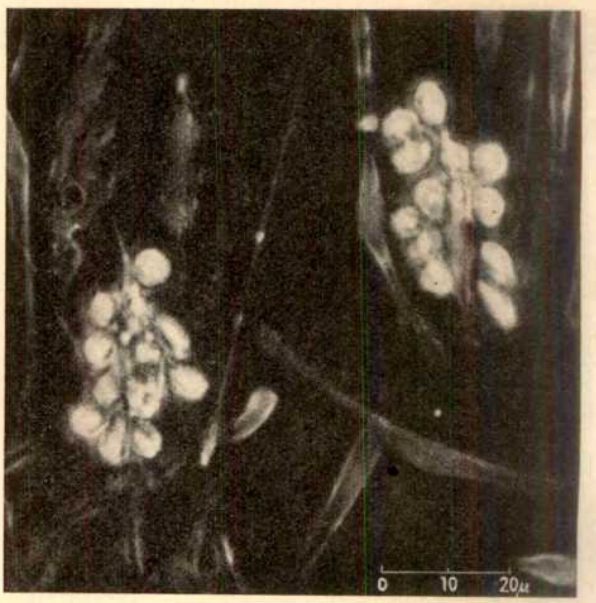

Fig. 1. Foci of hæmadsorption of guinea-pig erythrocytes after infection of chick lung with a bovine strain of myxovirus parainfluenza-3. Anoptral negative phase-contrast illumination. (*c.* × 875)

examined with phase-contrast illumination after 48 h. There was no apparent difference between the infected and the control disks; but if a 2 per cent suspension of guinea-pig erythrocytes was allowed to sediment on to the disks at 4° C, infected cells in all the tissues were labelled by the adsorption of erythrocytes. The foci of hæmadsorption were observed only on spindle-shaped cells (Fig. 1). The guinea-pig erythrocytes were hæmolysed within 15–20 min if the disks were stored at 4° C. When the disks were kept at room temperature, the erythrocytes were eluted from the cells very rapidly.

SOIL SCIENCE

Studies of Sensitivity and Electro-kinetic Potential in Leda Clay

In a previous communication[1], an anomalous difference was pointed out between two supposedly similar geological deposits from widely separated regions of the world. Whereas a relationship between sensitivity (the ratio of undisturbed shear strength to remoulded shear strength) and pore-water salt concentration has been reported for some Norwegian marine soils, this was not true for Leda clay from the Ottawa–Hull area in the St. Lawrence Lowland region of eastern Canada.

This has now been substantially confirmed at several new locations in the Ottawa–Hull area. Except for one location, the pore-water salt content is low and the sensitivity is not uniquely dependent on the amount of salt present. Fig. 1 shows that at specific conductivities of less than 4×10^{-3} ohm^{-1} cm^{-1} the sensitivity varied from 11 to 1,000+; as expected, at high specific conductivities the sensitivity remained relatively low.

What has been particularly puzzling, and for which no reason has been advanced, is the wide variation in sensitivity that is observed in this area for soils of low pore-water salt concentrations, which sometimes appear almost identical in other respects such as strength, water content, grain-size distribution, and clay mineral content.

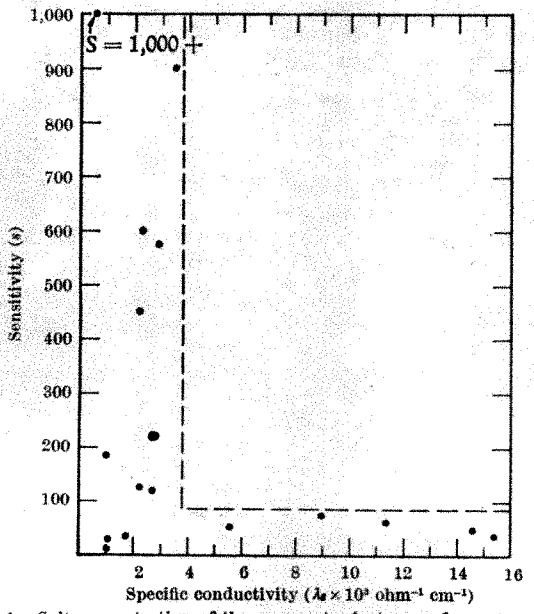

Fig. 1. Salt concentration of the pore water in terms of specific conductivity, as a function of sensitivity

Measurements of the electro-kinetic potential in undisturbed samples of this soil have shown that potential increases directly with increasing sensitivity. The electro-osmotic technique was selected because it has an important advantage for this type of investigation as it can be adapted to measure the electro-kinetic potential of undisturbed soil in its natural pore-water electrolyte environment. Because of the difficulties that are involved in electro-osmotic measurements and the uncertainties in using the appropriate values for dielectric constant and viscosity in calculating the potential, the numerical values recorded in this communication have a formal significance only, although they may be more confidently used for comparative purposes.

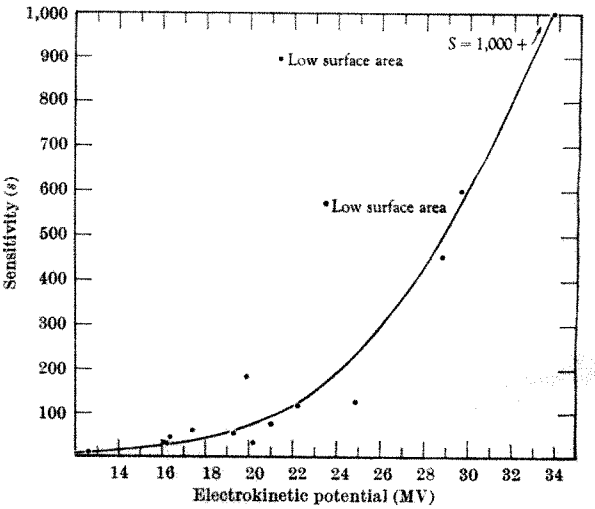

Fig. 2. Electrokinetic potentials of undisturbed Leda clay as a function of sensitivity

The results shown in Fig. 2 are for the same soils as in Fig. 1. Although there is scattering, the trend is thought to be sufficiently definite to be significant. The greatest deviations are for those soils that have a low surface area as compared with the average, although the clay-size content is essentially the same. One must assume from this that there are also purely physical factors which influence sensitivity.

The trend of the measured relationship between sensitivity and electro-kinetic potential—a first step in our investigations—simplifies the understanding of the wide variations in sensitivity, and such variations in potential need no longer be postulated to explain the phenomena. It follows that the higher the electro-kinetic potential, hence also the interparticle repulsion, the greater will be the loss in strength expressed in terms of sensitivity. The basic causes for the large variations in electro-kinetic potential at low pore-water salt content are not known in most instances, but in at least one case a change in the Na^+/Ca^{++} ratio in the pore water has been thought to be responsible.

In other investigations, measurements of the electro-kinetic potential at various stages of leaching (field pore-water salt concentration 10–15 gm/l.) gave an increase in potential as leaching proceeded. This supports Rosenqvist's theory of leaching to explain the formation of Norwegian quick clays. There is some doubt, however, based on recent geological evidence[2], about the marine origin of Leda clay; it is now thought that a large proportion of the Leda clay deposits in the Ottawa–Hull area consists of re-worked marine sediments that have been re-suspended and subsequently sedimented in an almost fresh-water environment as the salinity of the

Champlain Sea was decreasing. In one location near Ottawa a salty marine clay remnant appears to be flanked by such deposits. A similarity which is characteristic of all the deposits is the flocculated structure, but it is known that rather small concentrations of electrolyte during sedimentation are required to bring this about. If, in fact, these are essentially fresh-water deposits, the existing theory for sensitivity based on the salt-leaching is not satisfactory. Some progress is being made in exploring sensitivity on a new basis.

The main intent of the present communication is to show the trend in the measured relationship between electro-kinetic potential and sensitivity. Details of the apparatus and technique and more complete results are to be published shortly.

GENETICS

'Selfers' and High Mutation Rate during Meiosis in *Ascobolus immersus*

DEMEREC[1–3] applied the term 'selfers' to "auxotrophic mutants of bacteria in which transduction with homologous phage gives rise to significantly larger numbers of wild-type variants than occur by spontaneous reversion in uninfected control bacteria". Lissouba *et al.*[4] found that some mutants affecting ascospore pigmentation in *Ascobolus immersus* produce wild-type 'recombinants' in homo-allelic crosses, whereas numerous other whitespore mutants when selfed never give wild-type revertants. However, this phenomenon has not been investigated in detail. We have examined one such mutant, '186', more precisely, because it produced the 'recombinants' in relatively high frequency. Homo-allelic crosses of this mutant were carried out and tetrad analysis applied. It was characteristic that wild-type spores were found mainly in asci with 6 : 2 segregation, namely, 6 spores '186' and 2 wild. In the case of normal back mutation before meiosis, asci with 4 mutant and 4 wild spores should be obtained. Among 127,964 tetrads examined, 38 of the 6 : 2 and 3 of the 4 : 4 asci were found (frequencies 0·000297 and 0·000023, respectively). Asci with segregation 4 : 4 in homologous cross may represent the normal rate of spontaneous back-mutations that correspond to Demerec's control experiments, because only one set of genes is present during mitosis. In turn, the 6 : 2 tetrads can originate only during meiosis. In meiosis two sets of genes are present in the nucleus, so that the situation is analogous to the transduction experiments with 'homologous phage'. Assuming that the 4 : 4 asci result from back-mutations in mitosis and the 6 : 2 asci from back mutations in meiosis, it is obvious that the frequency of this phenomenon is about 10-fold higher in meiosis than in mitosis. Presumably this difference is even greater if we take into account the clonal effect which works only on back-mutations in mitosis, increasing the number of wild-type nuclei that could enter meiosis.

There are at least three possible explanations of the 'selfers' phenomenon: (*a*) unequal crossing-over; (*b*) copy-choice (non-reciprocal exchange) connected with illegitimate conjugation of similar components of structures involved in recombination; and (*c*) stimulation of mutability of the locus by its homologue. Demerec excluded the first and second possibility in his experiments. The third, however, gives actually no information of the mechanisms involved. We crossed all six white spores from one 6 : 2 ascus obtained in the cross '186' × '186' with the mutant '186' to see if there would be any difference in the frequency of the 6 : 2 asci in these crosses, because one could expect that two spores—the second product of unequal crossing-over—would behave differently from the other mutant spores. No difference was found between these crosses and the initial one as to the frequency of the 6 : 2 and 4 : 4 asci, which makes the hypothesis of unequal crossing-over rather improbable in this case. It is impossible to check the second hypothesis because we have no deletion mutant covering the site examined (as in Demerec's case).

In this situation we cannot distinguish between the second and the third hypotheses, which assume an increase of the mutation rate in meiosis. Whatever the mechanism of origin of the asci described, it is evident that in the site examined the mutation rate (if it is really mutation) in meiosis is higher than in mitosis. This is in agreement with the results obtained by Magni and von Borstel[5] with a number of genes in *Saccharomyces*. Magni[6] found later that there is no preferential mutation rate in either of the two chromosomes involved. We crossed double mutant '231' × '186' ('231' is located about 1·3 crossing-over units away from '186' and has the same phenotypic expression as '186') with the mutant '186'. In this situation we expected the frequency of the 6 : 2 asci to equal a half of that found in the cross '186' × '186', if the reversion occurs at random in all of the four strands. Among 95,972 asci examined, 15 of the 6 : 2 and 1 of the 4 : 4 tetrads were found (frequencies 0·00015 and 0·00001, respectively), which was in agreement with our assumption and also with Magni's results. On the other hand, Magni found that reversion was highly correlated with the exchange of the outside markers, suggesting that the phenomenon in question was due to the unequal crossing-over.

The analogy between our results and those obtained by Demerec and by Magni is striking. Possibly it may be a more general phenomenon that intimate contact of the two homologous fragments of genetic material can stimulate reversions. The molecular basis of this phenomenon is still unknown.

PSYCHOLOGY

Androgen-induced Reversal of Parental Behaviour in the Female Rabbit

DURING the course of recent experiments designed to investigate endocrine influence on the developing nervous system androgens have been given to pregnant guinea-pigs[1,2] and rats[3] without apparently disturbing parental behaviour at, or after, parturition. The effect of such treatment on the pregnant rabbit does not seem to have been previously reported. This has now been examined by injecting six rabbits during pregnancy with testosterone propionate in arachis oil. Three ('Chinchillas') received five injections of 5 mg beginning on the 10th day of pregnancy and on each 4th day afterwards; the other three animals ('New Zealand Whites') were all injected daily with 5 mg from the 17th until 21st day, 2·5 mg from the 22nd until 25th day and 1·0 mg from the 27th until

29th day. In other respects, such as caging, cleaning, lighting, temperature and diet, the animals were treated exactly as were non-injected pregnant rabbits. Litters were born within the gestation period found to be normal in this Department (31 ± 2 days).

None of the mothers exhibited normal parental behaviour. When given straw they made no attempt to build a nest and they did not pluck their fur before parturition. After the young were born the mothers showed no retrieval behaviour, but left the offspring lying about the cage for some hours, discouraging attempts at suckling, before chewing them. All members of each litter were eaten or fatally mutilated within 24 h from birth. Although such cannibalism sometimes occurs with normal rabbits[4] it has been rare in this laboratory. Since the behaviour of the male rabbit is characterized by a comparable initial indifference to offspring followed by cannibalism this phenomenon may perhaps be regarded as a reversal of parental behaviour.

It would be of interest to know why androgens during gestation cause behavioural reversal in some species but not others, and whether such effects are correlated with the presence (in the rat and guinea-pig) or absence (in the rabbit) of a mechanism for the cyclic release of gonadotrophins. The male rat does not exhibit spontaneous cyclic release of gonadotrophins and it has been shown[5] that intrahypothalamic injections of testosterone in this animal initiate female parental behaviour. However, another mechanism, unconnected with presence or absence of reproductive cycles, may be involved. Spayed rabbits, given daily injections of progesterone, build maternal nests of fur when the administration of the hormone is discontinued[6], and nest-building in this species has been attributed to the cessation at parturition of progesterone secretion by the corpora lutea[7]. It does not seem likely that this phenomenon is prevented by giving androgen during pregnancy. More probably, the action of testosterone in the pregnant rabbit is to render the hypothalamic regions involved in parental behaviour refractive to reduced blood levels of progesterone. It may tentatively be postulated that disturbances of maternal behaviour including the wish not to suckle in animals and, perhaps, humans may be associated with an abnormal release of androgens from the adrenal cortex occasioned by such factors as emotional stress.
